In the Average Flow Category, simulated annual average of daily temperatures and maximum temperatures under the Enhanced Coordination and Maximum Operational Flexibility Alternatives have a lower interquartile and overall range than the other alternatives. Under Dry and Critically Dry Flow Categories, simulated median annual average of daily temperatures and maximum temperatures and interquartile ranges increase across all alternatives, but the Enhanced Coordination Alternative has the lowest simulated median annual average of daily temperatures and maximum temperatures. CCS Comparative Baseline has the greatest annual maximum median temperature compared with the alternatives, which indicates that continuing current operations would have the potential to lead to the greatest maximum median temperature compared with all other alternatives.

The Enhanced Coordination Alternative has the greatest number of simulated futures that maintained cooler water temperatures at Lees Ferry and Pearce Ferry, which is beneficial for rainbow trout and limits smallmouth bass reproduction, but these temperatures also inhibit native fish growth and reproduction. See **TA 8.2.3**, in **TA 8**, Biological Resources – Fish and Other Aquatic Resources, and **TA 14.2.2**, in **TA 14**, Recreation, for more detailed information on changes in water temperature from Glen Canyon Dam downstream through the Grand Canyon to Pearce Ferry and impacts on rainbow trout and other sport fish, native Grand Canyon fishes, and nonnative predatory fish.

The CCS Comparative Baseline and the No Action, Basic Coordination, Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would pose an increased risk of cyanobacterial blooms due to the lower simulated Lake Powell elevations. These increased risks are more exaggerated under the Critically Dry Flow Category associated with lower reservoir elevations. The Enhanced Coordination Alternative had the greatest number of simulated futures in which the maximum annual change in water surface elevation was less than 31.45 feet in 4 years or more out of

10 years during the first decadal period (that is, 2027-2039). This could decrease the risk for cyanobacterial blooms associated with severe water level fluctuations under the Enhanced Coordination Alternative compared with the other alternatives.

Overall, the Enhanced Coordination and Maximum Operational Flexibility Alternatives have the best performance for dissolved oxygen under median 10-year average Lees Ferry annual flow and better relative maximum and average Colorado River temperature at Lees Ferry compared with the other alternatives. These alternatives also have slightly higher flows associated with hydrologic conditions associated with undesirable performance compared with the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches); however, undesirable performance for the Enhanced Coordination and Maximum Operational Flexibility Alternatives are still lower than 25 percent of hydrologic conditions that have already been observed.

TA 6.2.8 Statistical Summary Table

Table TA 6-2
Annual Flow-Weighted Average Salinity Concentrations Below Hoover Dam*

Alternative	Flow Category (maf)	Maximum** (mg/L)	90 percent*** (mg/L)
CCS Comparative Baseline	12.0-14.0 (Average Flow)	730	609
CCS Comparative Baseline	10.0-12.0 (Dry Flow)	763	643
CCS Comparative Baseline	4.46-10.0 (Critically Dry Flow)	956	696
No Action	12.0-14.0 (Average Flow)	809	607
No Action	10.0-12.0 (Dry Flow)	897	643
No Action	4.46-10.0 (Critically Dry Flow)	1295	698
Basic Coordination	12.0-14.0 (Average Flow)	761	611
Basic Coordination	10.0-12.0(Dry Flow)	858	640
Basic Coordination	4.46-10.0 (Critically Dry Flow)	1325	690
Enhanced Coordination	12.0-14.0 (Average Flow)	720	620
Enhanced Coordination	10.0-12.0 (Dry Flow)	810	659
Enhanced Coordination	4.46-10.0 (Critically Dry Flow)	1290	711
Maximum Operational Flexibility	12.0-14.0 (Average Flow)	708	611
Maximum Operational Flexibility	10.0-12.0 (Dry Flow)	763	644
Maximum Operational Flexibility	4.46-10.0 (Critically Dry Flow)	1111	697
Supply Driven (LB Priority approach)	12.0-14.0 (Average Flow)	722	608
Supply Driven (LB Priority approach)	10.0-12.0 (Dry Flow)	780	634
Supply Driven (LB Priority approach)	4.46-10.0 (Critically Dry Flow)	1014	667
Supply Driven (LB Pro Rata approach)	12.0-14.0 (Average Flow)	706	610
Supply Driven (LB Pro Rata approach)	10.0-12.0 (Dry Flow)	770	637
Supply Driven (LB Pro Rata approach)	4.46-10.0 (Critically Dry Flow)	989	668

*Concentrations that are shaded where simulated salinity exceeds the water quality standard below Hoover Dam (that is, 723 mg/L).
**Maximum refers to the simulated salinity concentration that is greatest under its corresponding alternative and flow category.
***90 percent refers to the simulated salinity concentration that is higher than 90 percent of the total outputs under its corresponding alternative and flow category. This means that 90 percent of the simulated salinity concentrations in this flow category and under this alternative are lower than this value.

TA 7. Air Quality

TA 7.1 Affected Environment

This section presents the existing conditions, regulatory framework and applicable laws, and available existing studies and resources pertaining to air quality. The geographic scope consists of Lake Powell to Southerly International Boundary (SIB), which includes the Arizona counties of Yuma, La Paz, Mohave, Coconino, Yavapai, and Navajo; the Utah counties of Washington, San Juan, and Kane; and Clark County, Nevada. These counties encompass the direct, indirect, and cumulative effects associated with air pollutant dispersal into the atmosphere. Carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and carbon dioxide equivalent (CO_2e) emissions and climate trends would be analyzed for the state, which would include every major hydropower facility along the Colorado River, from Lake Powell to the SIB. The geographic scope for analysis is referred to as the "analysis area" throughout this section.

TA 7.1.1 Criteria Pollutants

The Clean Air Act (CAA) was implemented to ensure acceptable and nonhazardous air quality for the people of the United States (U.S.) Subsequently, the U.S. Environmental Protection Agency (EPA) established the National Ambient Air Quality Standards (NAAQS) for pollutants considered harmful to public health and the environment, referred to as criteria pollutants (**Table TA 7-1**). Unlike the rest of the criteria pollutants, ground-level ozone is typically not directly emitted into the atmosphere from an emissions source. Instead, ozone is formed when emissions of nitrogen oxides (NO_x) and volatile organic compounds (VOCs) mix in the presence of sunlight. **Table TA 7-1** shows the current primary and secondary NAAQS and averaging period for each pollutant. Primary standards are set to protect the public health with a margin of safety, and secondary standards are meant to protect environmental concerns such as air quality related values, which are resources that may be adversely affected by a change in air quality (visibility, vegetation, water quality, soils, fish and wildlife, etc.). The applicable NAAQS have fully been adopted by Utah, Arizona, and Nevada (Clark County Division of Air Quality [DAQ] jurisdiction) and are provided in **Table TA 7-1**.

In addition, each state implements regulations that further govern fugitive dust. In Arizona, Arizona Administrative Code (Title 18, Chapter 2), enforced by the Arizona Department of Environmental Quality (ADEQ), applies to owners and operators of nonresidential construction sites in designated Dust Visibility Protection Areas and requires dust controls, vehicle speed limits and monitoring and recordings. Utah rules that address fugitive dust and particulate matter (PM) include Title R307 of the Utah Administrative Code, which applies to all new or existing sources of fugitive dust greater than one-fourth acres in size and are also in areas designated as nonattainment or maintenance for the federal PM_{10} and $PM_{2.5}$ standards. Title R307 also applies statewide outside nonattainment or maintenance areas and establishes minimum work practices and emission standards for fugitive dust. Fugitive dust controls for Nevada are outlined in Nevada Administrative Code 445B.22037. These

include best practical methods pertaining to fugitive dust and the requirement to obtain a surface disturbance operating permit for disturbance of 5 acres or more of land. These measures are generally adopted by permit conditions or compliance agreements with the Nevada Division of Environmental Protection (NDEP) and apply to regulated activities that can generate dust.

Table TA 7-1
National Ambient Air Quality Standards

Criteria Pollutant	Averaging Period	Primary NAAQS	Secondary NAAQS
Nitrogen Dioxide (NO_2)	1 hour	0.100 ppm*	N/A
	Annual	0.053 ppm†	0.053 ppm†
Sulfur Dioxide (SO_2)	1 hour	0.075 ppm‡	N/A

Note: N/A = not applicable; ppm = parts per million; ppb = parts per billion; µg/m^3 = micrograms per cubic meter/

* The standard is based on the 3-year average of the 98th percentile of the daily maximum 1-hour average.

† Annual mean value.

‡ The standard is based on the 3-year average of the 99th percentile of the daily maximum 1-hour average.

§ Not to be exceeded more than once per calendar year.

¶ Not to be exceeded.

Not to be exceeded more than once per calendar year on average over 3 years.

** The standard is based on the 3-year average of the 98th percentile of the 24-hour average.

†† The standard is based on the 3-year average of the weighted annual mean.

‡‡ The standard is 9 ppm for areas with an elevation less than 5,000 feet above mean sea level.

§§ The standard is based on the annual fourth-highest daily maximum 8-hour concentration averaged over 3 years.

¶¶ 30-day average.

For each criteria pollutant, the EPA classifies areas as in "attainment" if the area is in compliance with NAAQS or as "nonattainment," if one or more NAAQS is exceeded. Areas for which available data are not sufficient to make an attainment status designation are listed as unclassifiable. Air quality within the Arizona counties of La Paz, Mohave, Coconino, Yavapai, and Navajo is considered in "attainment" or "unclassifiable" for Carbon Monoxide (CO), lead, Nitrogen Dioxide

(NO_2), ozone (O_3), PM_{10}, $PM_{2.5}$, and Sulfur Dioxide (SO_2). Air quality within the Arizona county of Yuma has been designated as marginal nonattainment for the 2015 eight-hour O_3 standard, moderate nonattainment for PM_{10}, and considered in "attainment" or "unclassifiable" for all other pollutants. Air quality within the Utah counties of Washington, Kane, and San Juan is considered in "attainment" or "unclassifiable" for CO, lead, NO_2, O_3, PM_{10}, $PM_{2.5}$, and SO_2. Clark County, Nevada has been designated as serious nonattainment for the 2015 eight-hour O_3 standard and a maintenance area for CO and PM_{10}, and considered in "attainment" or "unclassifiable" for all other pollutants (EPA 2025b).

Therefore, the General Conformity Rule, which is designed to protect ambient air quality within nonattainment and maintenance areas against further degradation, would apply for O_3, CO, and PM_{10}. The general conformity de minimis thresholds for all pollutants pursuant to 40 CFR 93.153 (b)(1) are presented in **Table TA 7-2**.

Table TA 7-2
General Conformity De Minimis Levels

	Tons/Year	Nonattainment Area	Analysis Area Nonattainment
O_3 (VOCs or NO_x)	100	Other outside an ozone transport region	N/A
O_3 (VOCs or NO_x)	50	Serious	Clark County, NV
O_3 (VOCs or NO_x)	25	Severe	N/A
O_3 (VOCs or NO_x)	10	Extreme	N/A
SO_2 or NO_2	100	All	N/A
CO	100	All Maintenance Areas	Clark County, NV
PM_{10}	100	Moderate	Clark County, NV (maintenance)
PM_{10}	70	Serious	N/A
$PM_{2.5}$ (direct emissions, SO_2, VOCs, NO_x, ammonia)	100	Moderate	N/A
$PM_{2.5}$ (direct emissions, SO_2, VOCs, NO_x, ammonia)	70	Serious	N/A

Notes: VOC = volatile organic compound

TA 7.1.2 Hazardous Air Pollutants

CAA regulations also control the release of hazardous air pollutants (HAPs): chemicals that are known or suspected to cause cancer or other serious health effects, such as reproductive effects, birth defects, or adverse environmental effects. EPA currently lists 187 compounds as HAPs, including benzene, toluene, and formaldehyde, which may be emitted from oil and gas development operations but are generally minimal in solar development operations. NAAQS have not been set for HAPs; rather HAP emissions are controlled by source type– or industrial sector–specific regulations by developing standards for controlling emissions of air toxics known as maximum achievable control technology standards. There are no project-specific applicable maximum

achievable control technology requirements regarding HAPs, as these standards only apply to stationary sources within specific industrial groups.

TA 7.1.3 Existing Conditions

Air Quality Monitors and Design Values

Criteria pollutants are monitored throughout various parts of the country. Monitors measure concentrations of pollutant in the atmosphere, and the results are often presented in parts per million (ppm) or micrograms per cubic meter ($\mu g/m^3$). Pursuant to 40 CFR 58.14 (c)(1), the EPA and states periodically analyze and review monitor locations, discontinue monitoring at locations where pollutant concentrations have been well below the standards, and add monitors in areas where pollutant concentrations may be approaching air quality standards. Instantaneous on-demand monitored outdoor air quality data collected from state, local, and tribal monitoring agencies can be obtained from EPA's Air Data web page and interactive tool (EPA 2025d).

The EPA uses the criteria pollutant monitoring data to determine a "design value" for each pollutant and associated averaging time. A design value is a statistic representing the monitored concentration of a given pollutant in a given location, expressed in the manner of its standard, which can be compared to the NAAQS. Design values are updated annually and posted to the EPA's Air Quality Design Value website (EPA 2025d). The most recent available 2024 design values for the analysis area counties in Arizona, Nevada, and Utah are provided in **Table TA 7-3**, **Table TA 7-4**, and **Table TA 7-5**. Rural counties may not have existing monitors; therefore, no data are available, and it is assumed that pollutant concentrations meet ambient air quality standards. Other counties may have monitors that record only certain pollutants. With the exception of Kane and San Juan Counties, criteria pollutant monitoring data are available for at least one criteria air pollutant and available criteria pollutant monitoring data are reported. Design values are typically used to designate and classify nonattainment areas, as well as to assess progress toward meeting the NAAQS. The design value for O_3 for Clark County exceeds the NAAQS for O_3 (0.70 ppm), and the number of exceedances of the PM_{10} NAAQS exceed the standard for Clark County and Yuma County. None of the other design values listed in **Table TA 7-3**, **Table TA 7-4,** and **Table TA 7-5** exceed or approach proximity to the NAAQS (EPA 2025e).

National Emissions Inventory

Triennially, the EPA publishes a comprehensive summary of air emissions data, known as the National Emissions Inventory (NEI). The most recent NEI data available are from 2020. **Table TA 7-6** through **Table TA 7-10** provide the 2020 emissions for the six criteria air pollutants and HAPs for the U.S.; the State of Arizona; Nevada; and Utah; and all of counties in the analysis area. The EPA uses the NEI to develop and review regulations, conduct air quality modeling, and conduct risk assessments to understand how air pollution may affect the health in communities across the country. Therefore, the nonattainment status for some of the counties in the analysis area indicate the NEI data presented below are only a concern for those pollutants in nonattainment (EPA 2023).

Table TA 7-6
National Emissions Inventory 2020 Emissions Data for U.S., Nevada, Arizona, and Utah (tons)

Pollutant	U.S.	Nevada	Arizona	Utah
NO_x	8,814,608	80,106	147,990	110,291

Air Pollution Associated Diseases

Air pollution is associated with many respiratory diseases. These effects come from inhaling particulate matter, O_3, NO_X, SO_2, and other pollutants. For example, Valley Fever or coccidioidomycosis is a lung disease that is prevalent in the southwestern U.S. The fungus *Coccidioides immitis* causes Valley Fever, which grows in soils with low rainfall, high summer temperatures, and moderate winter temperatures. When the soil is disturbed by winds, construction, farming, or other activities, these fungal spores become airborne. Infection occurs when a spore is inhaled by a susceptible person or animal. Construction, agriculture, and archaeology workers are at a higher risk of exposure and disease because their jobs cause soil disturbance, which can lead to the presence of fungal spores. The analysis area counties are all areas that may harbor the fungus that causes the disease Valley Fever (CDC 2024). Depending on the level of exposure, breathing O_3 can also trigger a variety of health problems. Effects of O_3 inhalation can include coughing and sore or scratchy throat; difficulty breathing deeply and vigorously and pain when taking deep breaths; inflammation of and damage to the airways; increased susceptibility to lung infections; aggravation of lung diseases such as asthma, emphysema, and chronic bronchitis; and an increase in the frequency of asthma

attacks. Some of these effects have been found even in healthy people, but effects are more serious in people with lung diseases such as asthma. O_3 exposure may lead to increased school absences, medication use, visits to doctors and emergency rooms, and hospital admissions. Long-term exposure to O_3 is linked to aggravation of asthma and is likely to be one of many causes of asthma development. Studies in locations with elevated O_3 concentrations also report associations of O_3 with deaths from respiratory causes. Asthma often starts during childhood when the immune system is still developing. Multiple factors may work together to cause asthma. These factors include allergens in the environment that affect babies or young children, including cigarette smoke and certain germs; viral infections that affect breathing; and family history, such as a parent (in particular, a mother) who has asthma. Common triggers for asthma include indoor allergens, such as dust mites, mold, and pet dander or fur; outdoor allergens, such as pollens and mold; emotional stress; physical activity (although with treatment, most individuals can still be active); infections, such as colds, influenza (flu), or COVID-19; certain medicines, such as aspirin, which may cause serious breathing problems in people with severe asthma; poor air quality (such as high levels of O_3); or very cold air (National Heart, Lung, and Blood Institute 2024).

Prevention of Significant Deterioration and Air Quality Related Values

As set forth in the CAA, the Prevention of Significant Deterioration (PSD) regulations were developed and implemented to protect public health and welfare and to preserve, protect, and enhance the air quality in national parks, wilderness areas, monuments, and other areas of special value. The regulations apply to permitting for new or modified *major*[1] stationary sources in attainment areas. As part of the PSD, the EPA classifies airsheds as Class I or Class II. Class I areas are areas of special national or regional natural, scenic, recreational, or historic value for which the PSD regulations provide special protection. All other areas are designated Class II areas, which allow for moderate pollution increases and reasonable growth, while still applying stringent air quality constraints (NPS 2023a). Class I areas are also defined as national parks over 6,000 acres and wilderness areas and memorial parks over 5,000 acres that were established as of 1977. **Table TA 7-11** presents the Class I areas located within the analysis area, as well as those located in counties adjacent to the analysis area. For those Class I areas that are national parks, the U.S. Department of the Interior National Park Service (NPS) compiles visibility data, which are also provided in **Table TA 7-11**.

Air quality related values were established to address impacts such as acid deposition, regional haze, and the degradation of sensitive species in Class I areas.

[1] Major sources are defined as a source that emits 100 tons per year or more of any criteria pollutant for pollutants specifically listed source categories in 40 CFR 51.166(b)(a)(i)(a) or that emit 250 tons per year of any criteria pollutants and are not specifically listed sources.

Table TA 7-11
Class I Areas

State	Class I Area	Agency	County	NPS Visibility Summary
Utah	Arches National Park	USDI-NPS	Grand	Visibility is fair at Arches National Park based on the 5-year average (2018–2022) measured visibility (haze index) on mid-range days of 5.3 dv compared to NPS visibility benchmarks. This is 2.3 dv above the estimated natural condition of 3.0 dv. In 2022, the measured visual range is between 88 and 179 miles. Without the effects of pollution, estimated visual range would be between 123 to 201 miles.
	Bryce Canyon National Park	USDI-NPS	Garfield and Kane	Visibility is fair at Bryce Canyon National Park based on the 5-year average (2018–2022) measured visibility (haze index) on mid-range days of 5 dv compared to NPS visibility benchmarks. This is 2.2 dv above the estimated natural condition of 2.8 dv. In 2022, the measured visual range is between 76 and 187 miles. Without the effects of pollution, estimated visual range would be between 120 to 210 miles.
	Canyonlands National Park	USDI-NPS	Wayne, Garfield, San Juan	Visibility is fair at Canyonlands National Park based on the 5-year average (2018–2022) measured visibility (haze index) on mid-range days of 5.3 dv compared to NPS visibility benchmarks. This is 2.3 dv above the estimated natural condition of 3.0 dv. In 2022, the measured visual range is between 88 and 179 miles. Without the effects of pollution, estimated visual range would be between 123 to 201 miles.
	Capitol Reef National Park	USDI-NPS	Wayne, Garfield	Visibility is fair at Capitol Reef National Park based on the 5-year average (2018–2022) measured visibility (haze index) on mid-range days of 5.6 dv compared to NPS visibility benchmarks. This is 2.5 dv above the estimated natural condition of 3.1 dv. In 2022, the measured visual range is between 82 and 171 miles. Without the effects of pollution, estimated visual range would be between 127 to 197 miles.

State	Class I Area	Agency	County	NPS Visibility Summary
Utah *(cont.)*	Zion National Park	USDI-NPS	Washington, Iron, and Kane	Visibility is fair at Zion National Park based on the 5-year average (2018–2022) measured visibility (haze index) on mid-range days of 7 dv compared to NPS visibility benchmarks. This is 3.3 dv above the estimated natural condition of 3.7 dv. In 2022, the measured visual range is between 81 and 158 miles. Without the effects of pollution, estimated visual range would be between 122 to 203 miles.
Arizona	Petrified Forrest National Park	USDI-NPS	Apache and Navajo	Visibility is fair at Petrified Forest National Park based on the 5-year average (2018–2022) measured visibility (haze index) on mid-range days of 6.4 dv compared to NPS visibility benchmarks. This is 3.5 dv above the estimated natural condition of 2.9 dv. In 2022, the measured visual range is between 86 and 161 miles. Without the effects of pollution, estimated visual range would be between 123 to 200 miles.
	Grand Canyon National Park	USDI-NPS	Coconino and Mohave	Visibility is good at Grand Canyon National Park based on the 5-year average (2018–2022) measured visibility (haze index) on mid-range days of 4.8 dv compared to NPS visibility benchmarks. This is 1.9 dv above the estimated natural condition of 2.9 dv. In 2022, the measured visual range is between 100 and 194 miles. Without the effects of pollution, estimated visual range would be between 117 to 215 miles.
	Sycamore Canyon Wilderness	USDA-Forest Service	Yavapai and Coconino	N/A
	Pine Mountain Wilderness	USDA-Forest Service	Yavapai	N/A
	Mazatzal Wilderness	USDA-Forest Service	Yavapai and Gila	N/A
	Superstition Wilderness	USDA-Forest Service	Maricopa	N/A
	Sierra Ancha Wilderness	USDA-Forest Service	Gila	N/A

State	Class I Area	Agency	County	NPS Visibility Summary
Arizona *(cont.)*	Mount Baldy Wilderness	USDA-Forest Service	Apache	N/A
Nevada	Great Basin National Park	USDI-NPS	White Pine	Visibility is fair at Big Bend National Park based on the 5-year average (2018–2022) measured visibility (haze index) on mid-range days of 9.8 dv compared to NPS visibility benchmarks. This is 6.1 dv above the estimated natural condition of 3.7 dv. In 2022, the measured visual range is between 58 and 140 miles. Without the effects of pollution, estimated visual range would be between 120 to 207 miles.

N/A – Not available as only National Parks have a NPS Visibility Summary
dv – deciviews
USDA – U.S. Department of Agriculture
USDI – U.S. Department of the Interior

Visibility is monitored using methodologies established by the Interagency Monitoring of Protected Visual Environments Program. The particulates that contribute to haze are collected on filters at each Interagency Monitoring of Protected Visual Environments site. Samples are then measured to determine how visibility is affected over time and by which pollutants. A deciview (dv) is a unit of measurement to quantify human perception of visibility. Because visibility at any one location is highly variable throughout the year, it is characterized by three groupings: the clearest 20 percent days, average 20 percent days, and haziest 20 percent days. Visibility degradation is primarily due to sulfate, nitrate, and PM in the atmosphere, with contributions from both anthropogenic and natural sources. Measuring progress in air pollution control can be challenging, because natural sources beyond human control, such as dust storms and wildfires, can produce significant visibility impairment over large areas for days to weeks at a time. Under the 2017 Regional Haze Rule revisions, the EPA proposed a new visibility tracking metric—"most impaired days"—to better characterize visibility conditions and trends. The most impaired days are those with the most impairment from anthropogenic sources, whereas the haziest grouping now better represents days with haze from natural sources. Total haze on the most impaired days is used to track progress toward Regional Haze Rule goals. Comparing trends in the 20 percent haziest days with the 20 percent most impaired days provides a method to assess impacts from episodic events, like wildfires, which have greatly affected visibility throughout the western U.S. in recent years (Burke et al. 2021).

Visibility information can be found at the Federal Land Managers Environmental Database (FED CIRA 2023). Visibility trends for Class I areas are determined for the clearest, haziest, and most impaired categories. Visibility on the clearest days improved consistently, whereas haziest days have shown little improvement due to many years with large wildfire smoke episodes. The difference between the haziest and most impaired days has increased since the beginning of the monitoring record, indicating that episodic events are now exerting a larger impact on visibility.

Atmospheric deposition occurs when gaseous and particulate air pollutants are deposited on the ground, waterbodies, or vegetation. The NPS monitors and evaluates deposition to determine the parks that are most at risk and where conditions are declining or improving (NPS 2024). Nitrogen deposition conditions are fair to poor with no trend data available (**Table TA 7-12**). Sulfur deposition conditions are good with trend data unavailable for most locations.

Table TA 7-12
Nitrogen and Sulfur Deposition Conditions at National Parks

State	Class I Area	Nitrogen (Conditions 2018–2022/Trend 2013–2022)	Sulfur (Conditions 2018–2022//Trend 2013–2022)
Utah	Arches National Park	Poor / Trend Not Available	Good / Trend Not Available
	Bryce Canyon National Park	Fair / Relatively Unchanging	Good / Relatively Unchanging
	Canyonlands National Park	Poor / Relatively Unchanging	Good / Improving
	Capitol Reef National Park	Fair / Trend Not Available	Good / Trend Not Available
	Zion National Park	Fair / Trend Not Available	Good / Trend Not Available

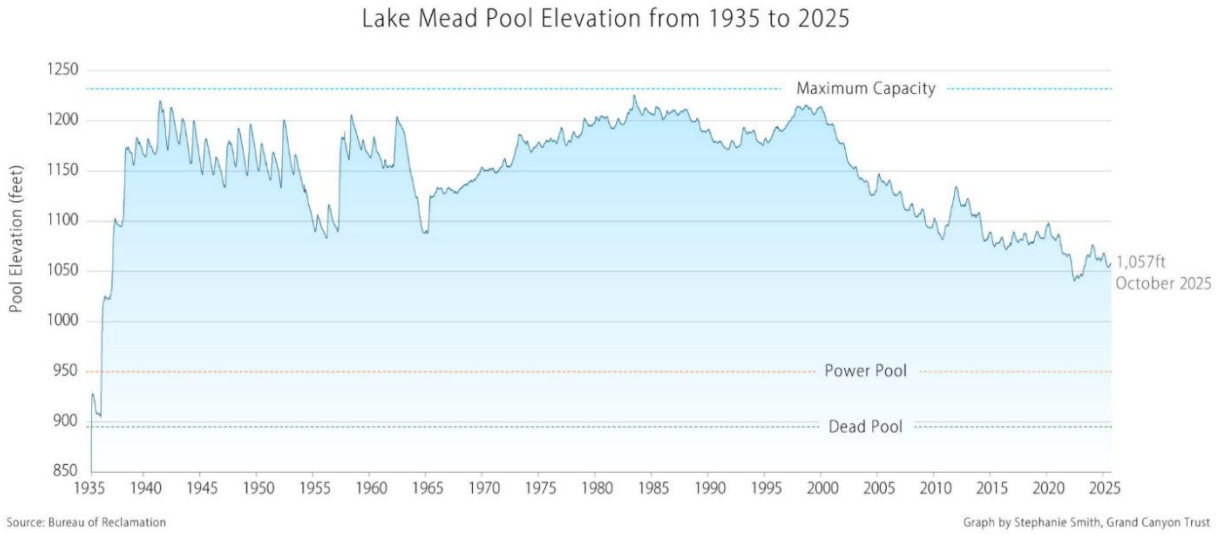
Historical to Present Lake Powell and Lake Mead Pool Elevations

The Lake Mead pool elevations for 1935 through 2025 are shown in **Figure TA 7-1**.

Regional Modeling and Studies



Lake Powell and Lake Mead Modeling

In 2024, U.S. Geological Survey (USGS) initiated a study in cooperation with NPS to model exposed shoreline area and potential dust emissions at Lake Powell and Lake Mead (Sankey et al. 2024).

Lake Mead Annual High and Low Elevations

Annual high and low elevations of Lake Mead for years 1935–2024 are available through the Bureau of Reclamation (Reclamation) with the maximum storage capacity at 1,229 feet. For 2024, the high elevation was 1,077 feet and the low was 1,061 feet. In 2014, the high elevation was 1,109 feet and the low was 1,080 feet (Reclamation 2025a).

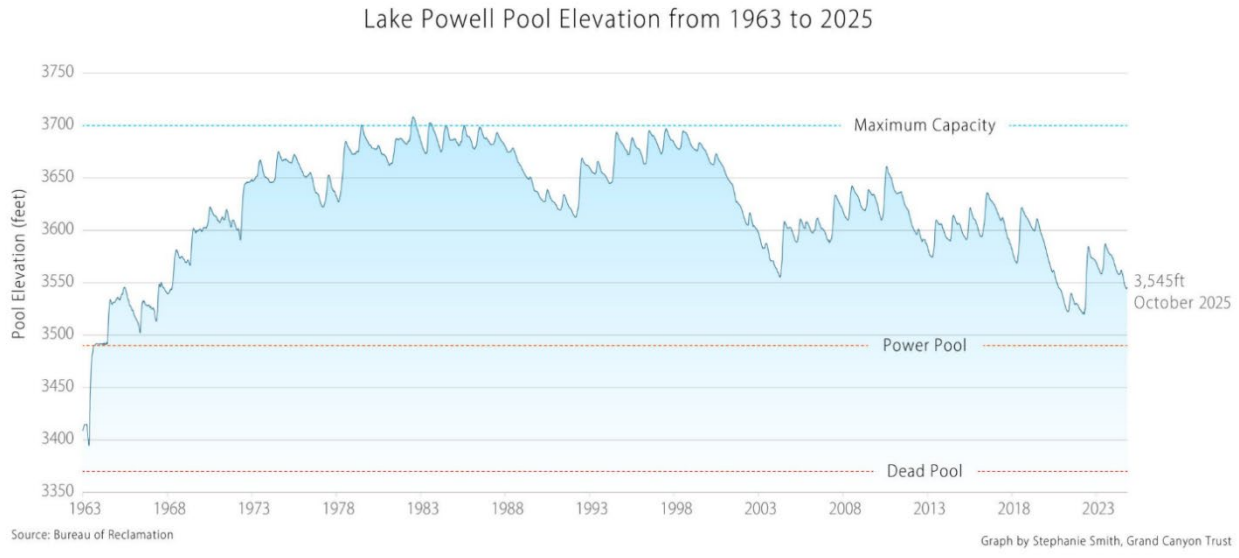


Figure TA 7-1
Lake Mead Pool Elevation from 1935 to 2025

Source: Reclamation 2026a

The Lake Powell pool elevations for 1963 through 2025 are shown in **Figure TA 7-2**.

Figure TA 7-2
Lake Powell Pool Elevation from 1963 to 2025

Source: Reclamation 2026b

Lake Powell Annual High and Low Elevations

Annual high and low elevations of Lake Powell for years 1964–2024 are available through the Reclamation with the maximum storage capacity at 3,700 feet. For 2024, the high elevation was 3,587 feet and the low was 3,558 feet. In 2014, the high elevation was 3,609 feet and the low was 3,574 feet (Reclamation 2025b).

Lake Mead Mapping

The USGS, in cooperation with the Lake Mead/Mohave Research Institute, University of Nevada, Las Vegas, completed a detailed geophysical mapping of the floor of Lake Mead during 1999, 2000, and 2001. The 1999 survey covered the Boulder Basin section of the lake, the 2000 survey focused on the northwestern portion of Las Vegas Bay, and the 2001 survey covered the eastern part of the lake. Results from these surveys have been presented in several reports. In 2003 the three datasets were integrated and presented as a composite of the entire lake in the "Mapping the floor of Lake Mead (Nevada and Arizona): Preliminary discussion and GIS data release," USGS Open-File Report 03-320. Also provided is a brief geologic overview of the floor of Lake Mead and a summary of some of the findings that have resulted from these surveys to provide a geologic perspective for the geographic information systems, which is also provided in this report.

Overall, analysis of the seismic-reflection data indicates that a large volume of sediment carried by the Colorado River has accumulated in Lake Mead since impoundment in 1935. The sediment is not uniformly distributed; rather, it is concentrated in the deepest parts of the lake and covers the floors of the valleys cut by the Colorado River and the other tributary streams that originally flowed through the area (Twichell et al. 1999, 2001, 2002, and 2003). The sediment forms a continuous cover along the entire length of the pre-impoundment Colorado River valley from the eastern extremity of the survey just east of Iceberg Canyon to the Hoover Dam at the west end of the study area. Sediment also covers the floors of the larger tributary valleys that feed the Colorado River (USGS 2003).

Lake Powell Mapping

The USGS, in cooperation with Reclamation, surveyed Lake Powell between fall 2017 and spring 2018 to produce an integrated topobathymetric dataset, which comprises topographic light detection and ranging (lidar) data (land elevation) and multibeam bathymetry (bed elevation of a waterbody), for the purposes of calculating the elevation-area-capacity relationships in Lake Powell. In 2017 and 2018, the USGS and Reclamation completed extensive surveys of the reservoir utilizing high-resolution multibeam bathymetry and lidar. These data were merged into a seamless topobathymetric dataset, which was subsequently revised to calculate new elevation-area-capacity relationships. This collaborative effort provided a revised and high-resolution estimate of storage capacity in Lake Powell and an updated topobathymetric surface to support water availability studies amid prolonged drought. The report summarizes the updated elevation-area-capacity relationships, describes the surveying methods and elevation-area-capacity calculations, and provides comparisons of the updated elevation-area-capacity relationships with previous estimates.

Storage capacity and areal extent of Lake Powell were determined for a range of elevations from 3,120 to 3,717.20 feet above the North American Vertical Datum of 1988 (NAVD 88). The updated elevation-area-capacity relationships indicate Lake Powell has lost 1,833,000 acre-feet or 6.79 percent

of its storage capacity at full pool (3,702.91 feet above NAVD 88) since construction was completed in 1963 through 2018. With consideration to potential error in the topobathymetric dataset, the loss of storage capacity ranges between 1,607,000 and 2,059,000 acre-feet. The reduction in storage capacity is attributed to sedimentation at the deltas of the Colorado and San Juan Rivers. Decreases in storage capacity were largest for the reservoir at elevations above 3,600 feet above NAVD 88, which coincide with frequent reservoir elevations since the 1970s.

Historical surveys were limited by comparatively coarser survey techniques than those used for the 2017–18 topobathymetric digital elevation model, though the average annual storage loss between surveys remained similar since impoundment in 1963. With increasing demands on water in the Colorado River Basin amid a decadal-scale drought, these results provide critical information to support water resource management in Lake Powell and beyond (Root and Jones 2022).

Impact of Lost Generation at the Glen Canyon Powerplant

This report was prepared by Argonne National Laboratory and the National Renewable Energy Laboratory (now known as National Laboratory of the Rockies [NLR]) in support of an economic and financial analysis conducted for the U.S. Department of Energy's Western Area Power Administration of the loss in Glen Canyon power generation due to the environmental requirements for the years 2024 to 2027. This report presents data showing the changes in generation sources for each of the years (2024–2027). These figures show that when there is a reduction in hydropower, the replacement generation from mostly Natural Gas Fired generation (Gas Combined Cycle) generation and Gas Combustion Turbine, with a small portion also coming from coal-fired generation. However, the compensation of natural gas and coal vary by month and year (Veselka et al. 2024).

Owens Lake California Environmental Quality Act (CEQA) Initial Study

The 2011 Supplemental Control Requirements Determination (SCRD) and 2012 SCRD projects have the objective to implement dust control measures on Owens Lake to reduce emissions, in accordance with applicable laws, without increasing water commitments while, to the extent feasible, maintaining existing habitat values; maintaining aesthetics values; providing safe, limited public access; preserving cultural resources; and utilizing existing infrastructure.

The City of Los Angeles Department of Water and Power (LADWP) is currently implementing the Owens Lake Dust Mitigation Program on Owens Lake to reduce PM_{10} emissions. LADWP constructs and operates dust control measures on the lake, in compliance with orders from the Great Basin Unified Air Pollution Control District under the authority of California Health and Safety Code Section 42316, legal settlement agreements with the Great Basin Unified Air Pollution Control District, lease agreements for use of state lands (administered by the California State Lands Commission), and other regulatory approvals.

In 2014, LADWP prepared an initial study to address the impacts of construction and operation of the Owens Lake 2011 SCRD and 2012 SCRD dust control measures projects. The initial study was prepared in accordance with the CEQA, Public Resources Code Section 21000 et seq., and the State CEQA Guidelines (Title 14 California Code of Regulations Section 15000 et seq.). The initial study

serves to identify the site-specific impacts, evaluate their potential significance, and determine the appropriate document needed to comply with the CEQA.

For this project, LADWP has determined, based on the information reviewed and contained herein, that the proposed projects could potentially have a significant environmental impact. Based on this initial study, an environmental impact report is the appropriate CEQA document for evaluating the potential environmental impacts of the Owens Lake 2011 SCRD and 2012 SCRD projects. After environmental review, if the 2011 SCRD and 2012 SCRD projects are adopted, the projects may be constructed at the same time or constructed separately, or one or both projects may not be implemented, pending further legal decisions (LADWP 2014). The potential future change for Lake Powell and Lake Mead may also highlight the need for a similar dust mitigation program, should water levels decrease below 500 square kilometers (km^2) (123,553 acres), for each lake.

TA 7.1.4 NAAQS: Regulatory Framework/Applicable Laws, Regulations, Plans, and Policies

As discussed, Section 176 of the federal CAA requires federal agencies that fund, permit, or approve an activity to ensure that the activity complies with the applicable State Implementation Plan adopted to eliminate or reduce air quality violations (42 USC 7506). In order to ensure that air pollutant emissions associated with federally approved or funded activities do not exceed emission budgets established in the applicable State Implementation Plan and do not interfere with the state's ability to attain and maintain the NAAQS in areas working to attain or maintain the standard, the EPA passed federal conformity rules. The General Conformity Rule applies to all projects that are not related to transportation. According to 40 CFR 51(W), a detailed determination of the General Conformity Rule's applicability is required when federal actions or funding of non-transportation-related activities in nonattainment areas result in emissions that exceed de minimis threshold levels (EPA 2024a). Also discussed, are the PSD regulations that are developed and implemented to protect public health and welfare and to preserve, protect, and enhance the air quality in national parks, wilderness areas, national monuments, and other areas of special value.

Arizona

Air pollutant sources in Yuma, La Paz, Coconino, Yavapai, Mohave, and Navajo Counties fall under the jurisdiction of the ADEQ Air Quality Division. ADEQ operates a network of ambient air quality monitors throughout Arizona for a variety of federal and state monitoring programs. The primary monitoring objective is to measure criteria pollutants regulated under the CAA for compliance with the NAAQS. In addition, ADEQ Air Quality Division's 'Air Permits and Compliance' section issues air quality permits to industrial facilities that emit significant quantities of air pollutants to ensure that the emissions do not harm public health or cause a significant deterioration in air quality.

Nevada

The Nevada Revised Statutes Chapter 445B focuses on air pollution in Nevada. Under this, each county in the state with a population equal to or greater than 100,000 people must establish a board of county commissioners to establish and implement an air pollution control program (NRS 445B.500). In 2001, the Clark County Board of County Commissioners established the Clark County DAQ to carry out the mandated program. There are 17 counties in the state of Nevada. All but two

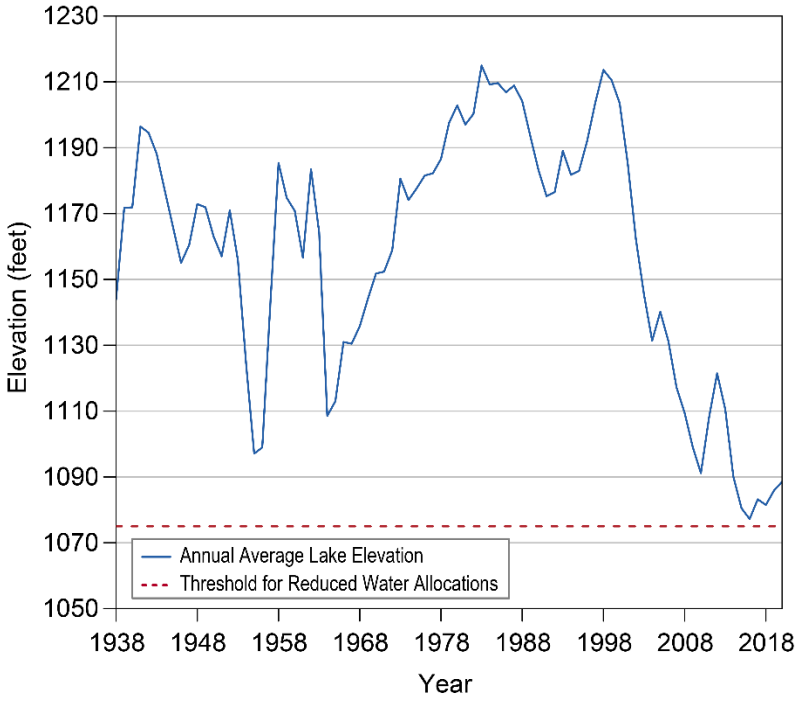
counties are overseen by the NDEP for the implementation of the CAA. Washoe and Clark Counties have a delegated authority by the governor of Nevada for the implementation of the CAA. The Clark County DAQ under the Clark County Department of Environment and Sustainability is responsible for administering the air pollution control program for Clark County under the provisions of the Clark County Air Quality Regulations and the EPA-approved State Implementation Plan for Clark County, Nevada (Clark County Air Quality Regulations Sections 00 through 94 as adopted in 40 CFR 52(DD)). In Nevada, the NDEP Bureau of Air Pollution Control and Air Quality Planning has primary responsibility under Nevada Revised Statutes 445B.100 through 445B.825 for managing air quality through state regulations. Within Clark County, emissions are regulated by the Clark County DAQ. Construction activities impacting greater than 0.25 acre in Clark County would require a dust control operating permit from Clark County DAQ. Projects larger than 10 acres would also require completion of a Dust Mitigation Plan Supplement for Clark County DAQ (Clark County 2023). In addition, Section 12.1 of the Clark County Air Quality Regulations requires the issuance of a Minor Stationary Source Permit for any applicable source located in Clark County that has a potential to emit a regulated pollutant that is equal to or greater than the thresholds listed in that section. Any mechanical equipment (e.g., backup generators, boilers, cooling towers) may trigger air quality "stationary source" permitting in accordance with Clark County Air Quality Regulations Section 12.1. Therefore, stationary source permits are obtained before commencing construction of any emissions unit when collectively (i.e., emissions from all emissions units in aggregate) meeting the thresholds for any of the regulated pollutants. The NDEP Bureau of Air Pollution Control and Air Quality Planning and Clark County DAQ have both been delegated authority by the EPA to implement federal programs of the CAA.

Utah

The EPA has delegated authority to Utah DAQ, under the Utah Department of Environmental Quality, for regulating air quality in all areas of Utah, with the exception of tribal lands, which remain under the authority of the EPA. The Utah DAQ has primary responsibility for managing air quality through state regulations. The Utah DAQ's responsibility is to ensure that the air in Utah meets the health and visibility standards established under the CAA. To fulfill this responsibility, Utah DAQ is required by the federal government to oversee compliance with the NAAQS statewide and visibility standards at Class I airsheds. Utah DAQ enacts rules pertaining to air quality standards, develops plans to meet federal standards, when necessary, administers emissions reductions incentive programs, issues preconstruction and operating permits to stationary sources, and enforces compliance with state and federal air quality rules. The Utah Air Conservation Act (UAC 19-2) delegates rulemaking power to the Utah Air Quality Board to promulgate rules pertaining to air quality issues. As of August 2020, Utah Department of Environmental Quality does not require a fugitive dust control plan for the analysis area. The UAC does not specifically require the development of a fugitive dust control plan in attainment areas. However, the UAC does require that operators take measures to limit PM emissions during construction and demolition activities greater than 0.25 acres in size (UAC R307-205). UAC R307-205 also requires fugitive dust to be controlled (regardless of the size or amount of acreage disturbed) to maintain a specified opacity.

Past and Present, and Projected Climate Trends and Impacts

An analysis of regional climate impacts concluded that the rate of average annual temperature increases in the southwest U.S. was among the most rapid nationally (IPCC 2021). This temperature



increase is causing a decline in spring snowpack and reducing flow in the four major southwest rivers. Projections of future climate trends indicate that further increases in average annual temperature could reduce precipitation. Analysis of past records and future projections indicates an overall increase in regional temperatures, including in the analysis area. The observed increase is largely the result of the warmer nights and effectively higher average daily minimum temperatures at many of the measurement sites in the region.

National Oceanic and Atmospheric Administration National Centers for Environmental Information released its climate summaries by state in 2022. The climate summaries for the analysis area states are summarized. More detailed climate discussions for each state can be found through the State Climate Summaries web page (NOAA 2022).

Arizona

Temperatures in Arizona have risen about 2.5 degrees Fahrenheit (°F; -16.4 degrees Celsius [°C]) since the beginning of the 20th century. The first 21 years of this century have been the warmest period on record for the state. The historical record indicates periodic prolonged wet and dry periods. Arizona is currently in a long-term drought that has lasted more than 20 years. Multiyear periods of high and low precipitation can cause significant variations in reservoir supplies. The latest western U.S. drought has resulted in record-low water levels in Lake Mead, which is a critical water resource for Arizona, as well as southern Nevada, southern California, and northern United Mexican States (Mexico). Since reaching high levels in the late 1990s, water levels have been falling, reaching historic lows in 2015 and 2016 (**Figure TA 7-3**). Long-term droughts also raise the risk of wildfires, already a concern for this arid state.

Figure TA 7-3
Lake Mead Water Levels at Hoover Dam

Source: Reclamation 2025a

Figure TA 7-3 shows the time series of the annual average water level (blue line) of Lake Mead at Hoover Dam from 1938 to December 2020. Water levels in Lake Mead have varied widely over the years. Low levels in the 1950s and 1960s were due to drought and the filling of Lake Powell, respectively. Recent years have seen the lowest recorded levels since the original filling of Lake Mead. The red-dashed line indicates the threshold (1,075 feet) below which a federal shortage will be declared, resulting in reduced water allocations for Nevada and Arizona. Unlike many areas of the U.S., Arizona and other southwestern states have not experienced an upward trend in the frequency of extreme precipitation events.

Under the higher and lower emissions pathways, annual average temperatures are projected to exceed historical record levels by the middle of this century. A large range of temperature increases is projected under both pathways, and under the lower pathway, a few projections are only slightly warmer than historical records.

Although projections of overall annual precipitation are uncertain, there is a risk of decreases in spring precipitation. Additionally, projected rising temperatures will raise the snow line—the average lowest elevation at which snow falls. This will increase the probability that precipitation will fall as rain instead of snow, reducing water storage in the snowpack, particularly at lower mountain elevations that are now on the margins of reliable snowpack accumulation. Higher spring temperatures will also result in earlier melting of the snowpack, further decreasing water resources needed for irrigation during the hot summer months.

Naturally occurring droughts are expected to become more intense during the cool season. Even if precipitation does not decrease, higher temperatures will intensify naturally occurring droughts by increasing water evaporation. This will further reduce streamflow, soil moisture, and water supplies. Drought will not only challenge limited agricultural resources but also increase the frequency of dust storms and the frequency of the risk of very large wildfires.

Nevada

Temperatures in Nevada have risen almost 2.4 °F (-16.4 °C) since the beginning of the 20th century. After wet conditions in the late 1990s, total annual precipitation has been near or below average since 2000 but shows no overall trend across the 126-year period of record. Seasonal precipitation patterns vary across the state, with most locations receiving the majority of their precipitation during the winter months. However, eastern and southern areas, including Clark County, can experience intense summer rainfall from the North American Monsoon system. Since 2004, the state has received multiple federal disaster declarations for wildfire events.

Drought is a critical climate threat for this arid state. Since 2000, the Colorado River Basin, the source of water for the southern part of the state, has experienced drought conditions, with impacts on Lake Mead. In addition, winter precipitation was well below average from the 2011–12 through the 2014–15 water years (WYs; October–September), and all of those years were abnormally warm. This led to a strain on water supplies in agricultural areas that rely on surface water. The majority of the counties in the state have been designated as natural disaster areas due to extreme drought conditions. Lake Mead, the largest man-made reservoir in the U.S., provides water for southern Nevada, as well as Arizona, southern California, and northern Mexico. As of October 25, 2021,

water storage in Lake Mead was at 34 percent capacity, and water levels have been dropping since 2000 (**Figure TA 7-3**). Due to aggressive conservation policies, metropolitan areas have been able to manage the reductions in water supplies. Parallel declines in snowpack have been observed over this same time period (**Figure TA 7-3**). Snowpack refills Lake Tahoe every spring, and lake levels slowly decrease throughout the year. Warm and/or dry years lead to low snowpack and associated decreases in the lake's water levels. Since 1900, the lake has fallen below the natural rim 21 times.

Under the higher and lower emissions pathway, annual average temperatures are projected to exceed historical record levels by the middle of this century. A large range of temperature increases is projected under both pathways, and under the lower pathway, a few projections are only slightly warmer than historical records. Extreme high temperatures are projected to increase, with potentially large impacts in the very hot southern deserts, particularly the Las Vegas metro area, where 70 percent of the state's population resides.

Projected rising temperatures in Nevada will raise the snow line—the average lowest elevation at which snow falls. This will increase the probability that precipitation will fall as rain rather than snow, reducing water storage in the snowpack, particularly at those lower mountain elevations that are now on the margins of reliable snowpack accumulation. Higher spring temperatures will also result in earlier melting of the snowpack, further decreasing water availability during the already dry summer months.

Projections of annual precipitation for Nevada are uncertain throughout this century, but warmer temperatures could decrease the amount of water in the mountain snowpack and increase the demand for water. Higher temperatures will also increase the evaporation rate, which will reduce streamflow and soil moisture. Thus, the intensity of future droughts is anticipated to increase, as will the risk of wildfires in some ecosystems. Increases in population and potentially decreased water flow from the Colorado River may lead to future water security issues across the state.

Utah

Temperatures in Utah have risen more than 2.5 °F (-16.4 °C) since the beginning of the 20th century. Unlike many areas of the U.S., Utah and other southwestern states have not experienced an upward trend in the frequency of extreme precipitation events. Although floods are rare in the state, both heavy rainfall and snowmelt can result in severe flooding.

Under the higher and lower emissions pathway, annual average temperatures are projected to exceed historical record levels by the middle of this century. A large range of temperature increases is projected under both pathways, and under the lower pathway, a few projections are only slightly warmer than historical records.

Climate models are not consistent in their projections of precipitation for Utah, including winter precipitation. However, projected rising temperatures will also raise the snow line—the average lowest elevation at which snow falls. Continuing recent trends, this will increase the probability that precipitation will fall as rain instead of snow, reducing water storage in the snowpack, particularly at lower elevations that are currently on the margins of reliable snowpack accumulation. In addition,

extreme precipitation is projected to increase, potentially increasing the frequency and intensity of floods.

Droughts, a natural part of Utah's climate, are expected to become more intense. Higher temperatures will amplify the effects of naturally occurring dry spells by increasing the rate of loss of soil moisture. Most of Utah's water is supplied by the snowpack; observed trends toward more winter precipitation falling as rain and less as snow could result in less water storage. Additionally, higher spring temperatures can cause early melting of the snowpack, decreasing water availability during the already dry summer months.

TA 7.2 Environmental Consequences

This section provides an analysis of the extent and magnitude of potential impacts on air quality resources for the No Action Alternative, four action alternatives, and the Continued Current Strategies (CCS) Comparative Baseline. More detail on the alternatives can be found in **Chapter 2**, Description of Alternatives, and **Appendix S**, Additional Description of Alternatives.

TA 7.2.1 Methodology

This section examines potential effects on air quality resources under the action alternatives and the No Action Alternative, compared to the CCS Comparative Baseline. Potential impacts are considered for the following air quality resources: shoreline exposure area, fugitive dust emissions, changes in CO_2e due to hydropower, and climate trends.

To support evaluating how potential changes in reservoir water storage might affect potential dust emissions from subaerially exposed reservoir sediment, the subaerial shoreline area and potential dust emissions within Lake Powell and Lake Mead were modeled for this analysis. Methods used in this modeling combined previously published topographic and bathymetric surveys and geologic mapping (Hirschberg and Pitts 2000; Jones and Root 2021, 2022; Ferrari 2001; Root et al. 2019; Root and Jones 2022; Twichell et al. 2003; Twichell and Cross 2009; Wilson et al. 1969) with new predictions of potential dust emissions using the FENGSHA model (Mallia et al. 2017). FENGSHA is an English analog of the Mandarin term for windblown dust. Resource modeling predicts (1) the area of subaerial shoreline exposed as a function of monthly water surface elevations at Lake Powell and Lake Mead, respectively, and (2) potential dust emissions (kilograms [kg] per square meter per hour) as a function of monthly water surface elevations at Lake Powell and Lake Mead modeled using FENGSHA with sustained winds for 15 meters per second (approximately 35 miles per hour) for 6 hours. The results are presented as Glen Canyon and Lake Mead exposed shoreline area and associated emission rates (Fischella et al. 2026).

Impacts on shoreline exposure area and fugitive dust emissions are described in the following section using conditional box plots and Decision Making under Deep Uncertainty robustness heat maps and vulnerability bar plots. The conditional box plots have been developed based on the Colorado River Simulation System (CRSS) model outputs and are framed using the five flow condition categories for the preceding 3-year average Lees Ferry natural flow, as described above. In a conditional box plot, the bold center line of each box represents the median value, the top and

bottom of each box captures the 25th to 75th percentile of the modeled results, the lines extend to the 10th and 90th percentiles, and the outliers are represented as dots beyond these lines.

Additional background and technical details about the Decision Making under Deep Uncertainty framework are provided in **Appendix E**, DMDU Overview and Approach. Refer to **Chapter 3**, **Section 3.2.6**, for an overview of how to interpret the Decision Making under Deep Uncertainty robustness heat maps and vulnerability bar plots.

The conditional box plot for each dam compares the median CCS Comparative Baseline generation to the median generation for each alternative and multiple natural flow groups (e.g., dry, moderately dry, and normal hydrology). In each year of every modeled future, the difference in annual hydropower generation between the CCS Comparative Baseline and each alternative was computed to determine the change in generation, whether that be an increase or decrease. The annual change in generation was multiplied by the Emissions and Generation Resource Integrated Database (eGrid)/NLR emission factor to obtain the potential CO_2e for both 2025 and 2050. **Table TA 7-13** and **Table TA 7-14** shows how the 2025 and 2050 emission factors were calculated. This emission factor represents the potential CO_2e from each resource type per megawatt-hour (MWh) and the resource mix percentages for the Western Regional Climate Center (WRCC) energy production.

As time passes and more alternative resources enter the grid, energy will be produced by a different mix of resources; therefore, the 2050 emission factor in **Table TA 7-14** shows the projected mix of resources in 2050 from the U.S. Energy Information Administration (EIA) Annual Energy Outlook 2023. However, the projected mix does not take into account more recent studies that show that when there is a reduction in hydropower, the replacement generation would most likely be from natural gas.

These NLR metric tons of CO_2e per MWh and the eGrid 2023 and EIA 2050 WRCC resource mix percentages were utilized to calculate a weighted average emission factor for 2025 and 2050. The weighted emission factors are multiplied by the changes in MWh for each alternative and flow category. Analyses for other pollutants (sulfur oxide, nitrogen oxide, and particulate matter) are not included due to limitations in the emission factor data from NLR.

Impact Analysis Area

The geographic scope of the air quality resources analysis differs for each issue but includes the Lake Powell to the SIB, which includes the Arizona counties of Mohave, Coconino, Yavapai, and Navajo; the Utah counties of Washington, San Juan, and Kane; and Clark County, Nevada. However, air pollutants tend to disperse into the atmosphere, becoming less concentrated as they travel away from a source of pollution; therefore, they cannot be confined within defined boundaries, such as county lines. Specifically, the shoreline exposure analysis area includes Lake Powell and Lake Mead. The changes in CO_2e due to hydropower generation analysis areas include Glen Canyon Glen Canyon Dam, Hoover Dam, Parker Dam, and Davis Dam. The climate trends analysis area is discussed for the western U.S.

Table TA 7-13
2025 Emission Factor Information

Units	Coal	Natural Gas	Biomass	Oil	Geothermal	Wind	Concentrating Solar Power	Hydro	Nuclear

Assumptions

- The hydrologic resources results are direct results from the CRSS model. Refer to **Appendix A**, CRSS Model Documentation, for more details related to model assumptions and documentation.
- NLR publishes life cycle assessments, which quantify environmental burdens from "cradle to grave" and based on several different studies, estimates CO_2e emission factors associated with each type of electricity generation. They are provided in grams of CO_2e per kilowatt-hour (g CO_2e/kWh; NLR 2021).
- The eGrid was utilized to determine the North American Electric Reliability Corporation resource mix (coal, natural gas, oil, nuclear, hydropower, biomass, wind, solar, and geothermal) for the Western Electricity Coordinating Council region, which includes the analysis area (EPA 2025f).

- EIA Annual Energy Outlook 2023 (EIA 2023) provide the potential generation mix for year 2050.
- Equivalency Calculator is used to convert emissions into concrete, understandable terms such as the annual CO_2 emissions of cars, households, and power plants (EPA 2025g).

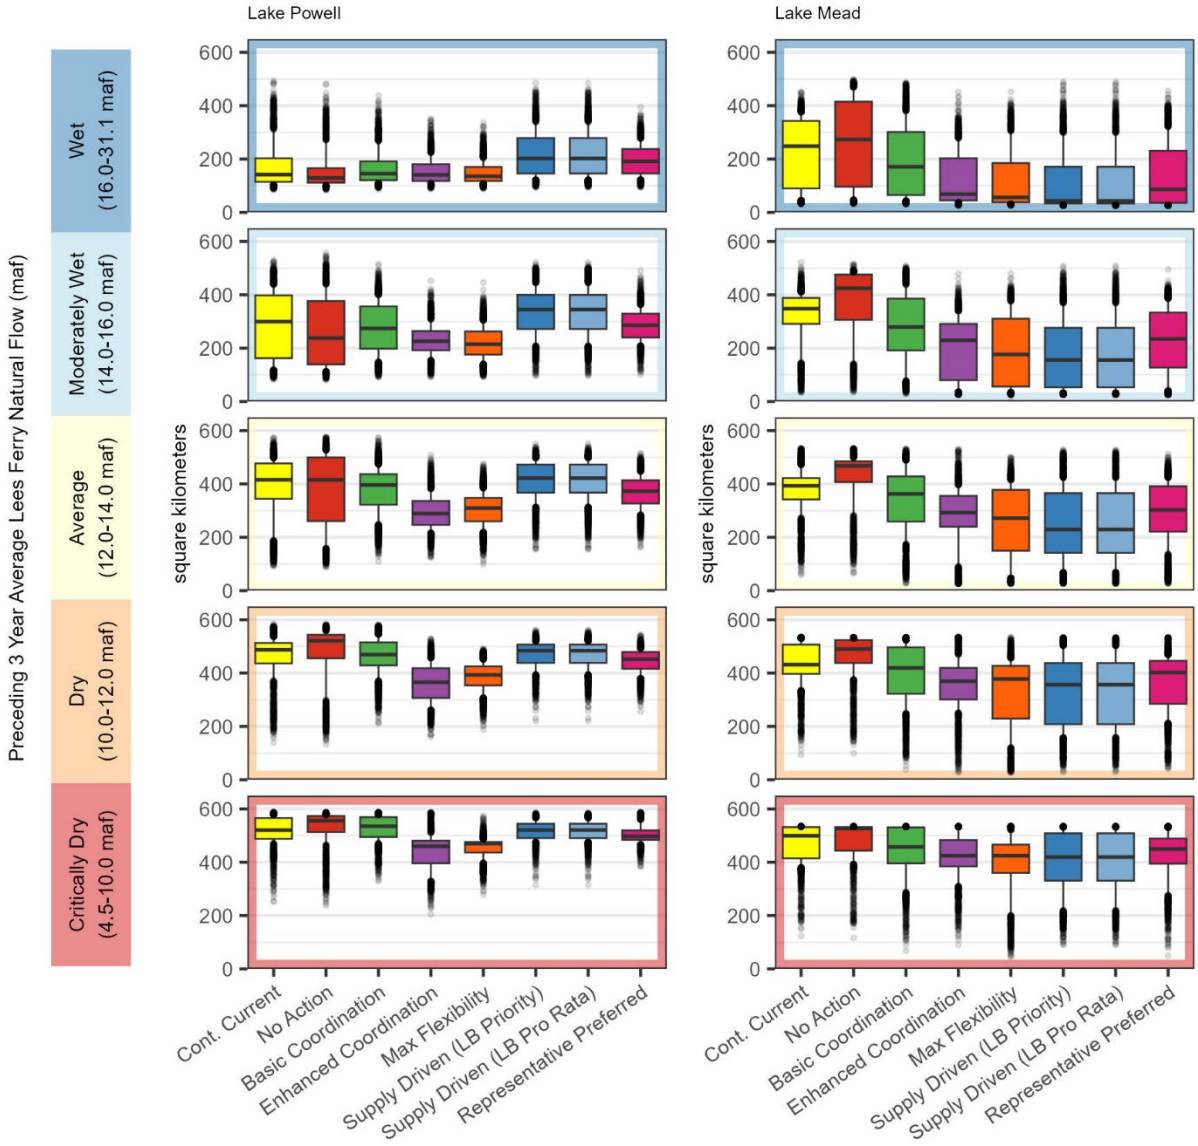
Impact Indicators

Specific impact indicators were selected to help frame the air quality resources analysis for each of the alternatives. The following indicators were used to assess impacts:

- **Shoreline Exposure**: effects on the areas of shoreline exposure due to operational activities
- **Shoreline Dust Emissions**: effects on shoreline dust emissions due to operational activities
- **Potential change of CO_2e Emissions Due to a Fluctuation of Hydropower Generation**: effects on CO_2e emissions due to operational activities

TA 7.2.2 Issue 1: How would changing flow characteristics affect the potential exposed shoreline, fallowed agricultural lands and fugitive dust?

Changes in water storage in lakes can affect the area of shoreline sediment exposed subaerially and potentially available for aeolian transport. Lake Powell and Lake Mead are two of the largest reservoirs in the United States (U.S.). Both are formed by impoundment of the Colorado River by hydroelectric dams. Lake Mead was closed by Hoover Dam in 1935. Lake Powell was closed by Glen Canyon Dam in 1963. Both reservoirs reached maximum observed water storage (water surface elevation) in 1983. Since 2020, both reservoirs have reached minimums in water storage not observed since filling. This resource modeling evaluates how potential changes in reservoir water storage might affect potential dust emissions from subaerially exposed reservoir sediment. Relationships between potential dust emissions and water storage could be useful to evaluate air quality and related resource impacts associated with Colorado River water management decisions.



Subaerially exposed shoreline area and potential dust emissions increase as water storage decreases. However, the relationships differ at the two reservoirs due to surficial geology, deposition of reservoir sediment, and topographic and bathymetric terrain; Glen Canyon Dam impounded a deep canyon-bound segment of the Colorado River at Lake Powell, whereas Hoover Dam impounded a comparably broader valley of the river at Lake Mead.

Figure TA 7-4 shows the WY maximum exposed shoreline area for Lake Powell and Lake Mead, in km^2, broken out by hydrologic conditions and categorized by the preceding three-year average Lees Ferry natural flows.

In wetter conditions, the median maximum exposed shoreline was lowest at both reservoirs across all alternatives, as higher preceding three-year average Lees Ferry flows tend to result in higher pool elevations. In the Average Flow Category, Lake Powell alternatives have varying distributions, with the 25th to 75th percentiles across all alternatives spanning from 225 to 500 km^2 (55,598 to 123,552 acres) of maximum exposed shoreline. The CCS Comparative Baseline, as well as the No Action, Basic Coordination, Representative Preferred and Supply Driven (both Lower Basin [LB] Priority and LB Pro Rata approaches) Alternatives, all show similar medians of roughly 400 km^2 (98,842 acres) of maximum exposed shoreline. The Enhanced Coordination and Maximum Operational

Flexibility Alternatives have lower and comparable medians of about 300 km^2 (74,132 acres) of maximum exposed shoreline.

Figure TA 7-4
Water Year Maximum Exposed Shoreline Area for Lake Powell and Lake Mead (square kilometers)

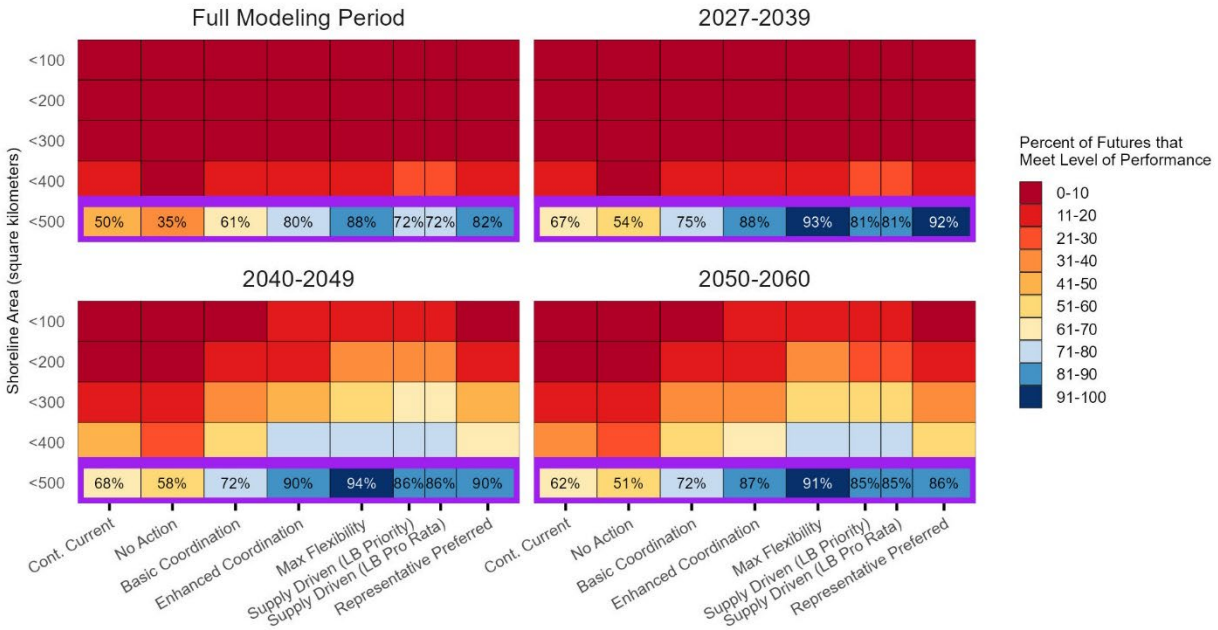
The Lake Mead alternatives have varying Average Flow Category distributions, with the 25th to 75th percentiles across all alternatives spanning from 125 to 500 km^2 (30,888 to 123,552 acres) of maximum exposed shoreline. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has the lowest median maximum exposed shoreline, at about 230 km^2 (56,834 acres). The No Action Alternative has the highest median value at roughly 470 km^2 (66,718 acres). The Representative Preferred Alternative has a median maximum exposed shoreline of about 300 km^2

(74,132 acres), with the 25th to 75th percentiles across all alternatives spanning from 220 to 390 km^2 (54,363 to 96,371 acres) of maximum exposed shoreline.

In the Dry Flow Category, the 25th to 75th percentiles across all Lake Powell alternatives span from approximately 300 to 545 km^2 (74,132 to 134,672 acres) of maximum exposed shoreline. The Enhanced Coordination and No Action Alternatives have the lowest and highest median maximum exposed shoreline at about 365 and 520 km^2 (90,194 and 128,495 acres), respectively. For Lake Mead, the 25th to 75th percentiles across all alternatives span from approximately 200 to 530 km^2 (49,421 to 130,966 acres) of maximum exposed shoreline. The Supply Driven (both LB Priority and LB Pro Rata approaches) and No Action Alternatives have the lowest and highest median maximum exposed shoreline at about 360 and 490 km^2 (88,598 and 121,082 acres), respectively.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Lake Powell maximum exposed shoreline, the median maximum exposed shoreline is about 450 km^2 (111,197 acres), with the 25th to 75th percentiles across all alternatives spanning from 415 to 475 km^2 (102,549 to 117,375 acres) of maximum exposed shoreline. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Lake Powell maximum exposed shoreline, the median maximum exposed shoreline is about 495 km^2 (122,317 acres), with the 25th to 75th percentiles across all alternatives spanning from 484 to 520 km^2 (119,599 to 128,495 acres) of maximum exposed shoreline.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Lake Mead maximum exposed shoreline, the median maximum exposed shoreline is about 400 km^2 (98,842 acres), with the 25th to 75th percentiles across all alternatives spanning from 280 to 445 (69,190 to 109,962) km^2 of maximum exposed shoreline. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Lake Mead maximum exposed shoreline, the median maximum exposed shoreline is about 450 km^2 (111,197 acres), with the 25th to 75th percentiles across all alternatives spanning from 395 to 489 km^2 (97,606 to 120,835 acres) of maximum exposed shoreline.



In the Critically Dry Flow Category, the median maximum exposed shoreline values for all alternatives at Lake Powell and Lake Mead are above 450 and 400 km^2 (98,842 acres and 111,197 acres), respectively. Generally, both reservoirs exhibit smaller interquartile ranges in comparison to the other flow categories. At Lake Powell, the CCS Comparative Baseline, as well as No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives show relatively similar median maximum exposed shoreline, ranging from roughly 520 to 535 km^2 (128,495 to 132,301 acres). At Lake Mead, the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives display similar medians, ranging from 420 to 425 km^2 (103,784 to 105,020 acres). For all alternatives and both locations, the km^2 of maximum shoreline exposure shift higher relative to their respective medians as conditions get drier.

Lake Mead Robustness

Figure TA 7-5, below depicts the ability of each alternative to maintain Lake Mead shoreline exposure below the specified area in every month. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures in which the exposed shoreline area for each alternative remains below 500 km^2 (123,553 acres) in every month. For Lake Mead, 500 km^2 (123,553 acres) is a very rough approximation of the area of shoreline exposed when the reservoir is filled to minimum power pool (950 feet). Keeping the Lake Mead shoreline exposure below 500 km^2 (123,553 acres) ensures that fugitive dust will be minimized.

Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The color of a heat map square corresponds with the percent of futures that meet the specified level of performance, which increases from a red color representing less than 10 percent of futures keeping the Lake Mead shoreline exposure area below the specified value in every month (least robust), to a dark blue color representing greater than 91 percent of futures keeping the Lake Mead shoreline exposure area below the specified value in every month (most robust).

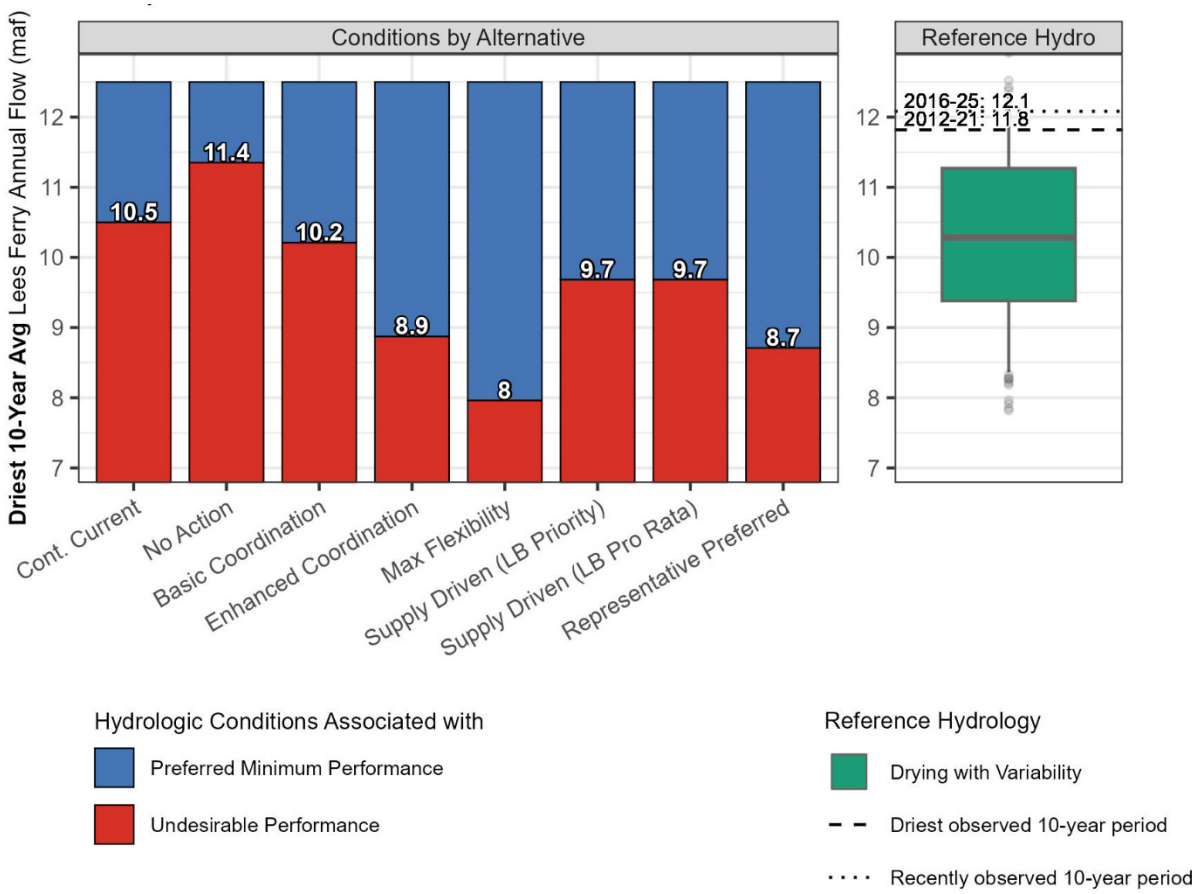
Figure TA 7-5
Lake Mead Shoreline Area in Lake Mead National Recreation Area: Robustness. Percent of futures in which the exposed shoreline area is below the value specified in each row in every month

The comparison described here focuses on the preference to stay below 500 km^2 (123,553 acres) of exposed shoreline every month. The selected value accounts for variability, while mathematically limiting the number of instances exceeding 500 km^2 (123,553 acres), which signifies likely fugitive dust minimization.

In the full modeling period, the Enhanced Coordination, Representative Preferred, and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 80 percent, 82 percent, and 88 percent of modeled futures, respectively, which is more robust than the other alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) meets the preferred minimum performance in 72 percent of modeled futures. The CCS Comparative Baseline, as well as No Action and Basic Coordination Alternatives, are only able to meet the preferred minimum performance in 50 percent, 35 percent, and 61 percent of futures, respectively. Therefore, the Maximum Operational Flexibility and Enhanced Coordination Alternatives are the most robust at staying below 500 km^2 (123,553 acres) of exposed shoreline over the full modeling period. The No Action Alternative has the worst performance over the full modeling period.

In the first decadal breakout (2027 – 2039), the Representative Preferred, Maximum Operational Flexibility, and Enhanced Coordination Alternatives meet the preferred minimum performance in 92 percent, 93 percent and 88 percent of modeled futures, respectively, which is more robust than the other alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) meets the preferred minimum performance in 81 percent of modeled futures. The CCS Comparative Baseline, as well as No Action and Basic Coordination Alternatives, are only able to meet the preferred minimum performance in 67 percent, 54 percent, and 75 percent of futures, respectively. Therefore, the Maximum Operational Flexibility and Enhanced Coordination Alternatives are the most robust at staying below 500 km^2 (123,553 acres) of exposed shoreline over the 2027 – 2039 modeling period. The No Action Alternative has the worst performance over the 2027 – 2039 modeling period. Based on the planned length of this decision, it is important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 92 percent of futures in the 2027-2039 modeling period.

The Representative Preferred Alternative meets staying below 500 km^2 (123,553 acres) of exposed shoreline robustness criteria in 82 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it's important to note that it meets the preferred minimum performance level in 92 percent of futures in the first modeling period.



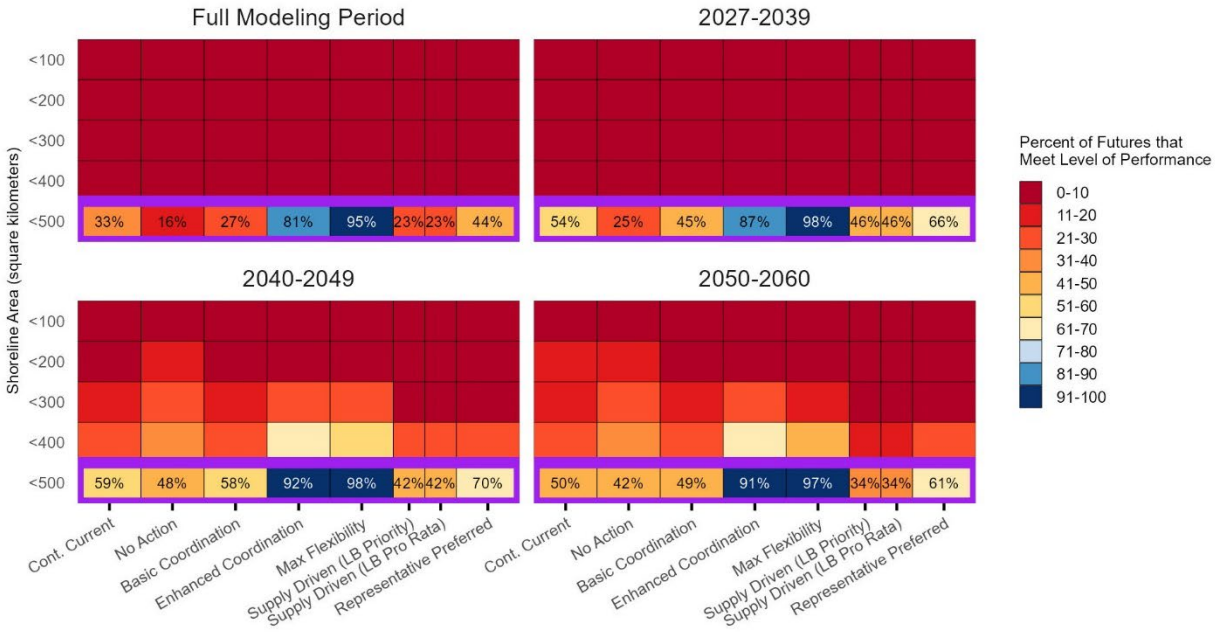
In the three subperiods, the alternatives meet the preferred minimum level of performance in greater percentages of futures because the preferred standard is easier to meet over shorter time spans than over the full 34 years. The robustness ranking across the three alternatives in each subperiod is consistent with the ranking in the full modeling period. The 2040–2049 modeling period generally has the most successful futures with all alternatives meeting the preferred minimum performance level in over 58 percent of futures.

Figure TA 7-6 below shows what flow conditions are likely to cause Lake Mead exposed shoreline area to exceed 500 km^2 (123,553 acres) in one or more months. This definition of undesirable performance is based on the highlighted row in **Figure TA 7-5** above, which defined a future as successful when exposed shoreline area for an alternative remains below 500 km^2 (123,553 acres) in every month.

For this vulnerability analysis, the driest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is

described and compared to the Drying with Variability ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 million acre-feet [maf]) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

Figure TA 7-6
Lake Mead Shoreline Area in Lake Mead National Recreation Area: Vulnerability. Conditions that Could Cause Lake Mead Exposed Shoreline Area Above 500 Square Kilometers (123,553 acres) in One or More Months



The Basic Coordination Alternative would likely be vulnerable to a Lake Mead exposed shoreline area greater than 500 km^2 (123,553 acres) under a 10-year average Lees Ferry natural flow of 10.2 maf or drier, which is slightly less vulnerable than the CCS Comparative Baseline, which is likely to be vulnerable if the 10-year average is 10.5 maf or drier. The No Action Alternative is vulnerable to a 10-year average of 11.4 maf, which is similar to the driest observed 10-year average of 11.8 maf. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven Alternatives are not likely to be vulnerable to undesirable performance unless the 10-year average flow is much drier than any observed conditions and fewer than 50 percent of the traces in the Drying with Variability ensemble include conditions that would be likely to cause vulnerability in these alternatives.

The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 8.7 maf or less. Compared to the historical periods shown in the reference hydrology panel, this flow has not occurred before. Compared to the Drying with Variability Ensemble that represents potential future hydrologic conditions, 100 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

Lake Powell Robustness

Figure TA 7-7 below depicts the ability of each alternative to maintain Lake Powell shoreline exposure below the specified area in every month. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures in which the exposed shoreline area for each alternative remains below 500 km^2 (123,553 acres) in every month. For Lake Powell, 500 km^2 (123,553 acres) is a very rough approximation of the area of shoreline exposed when the reservoir is filled to minimum power pool (3,490 feet). Keeping the Lake Powell shoreline exposure below 500 km^2 (123,553 acres) ensures that fugitive dust will be minimized.

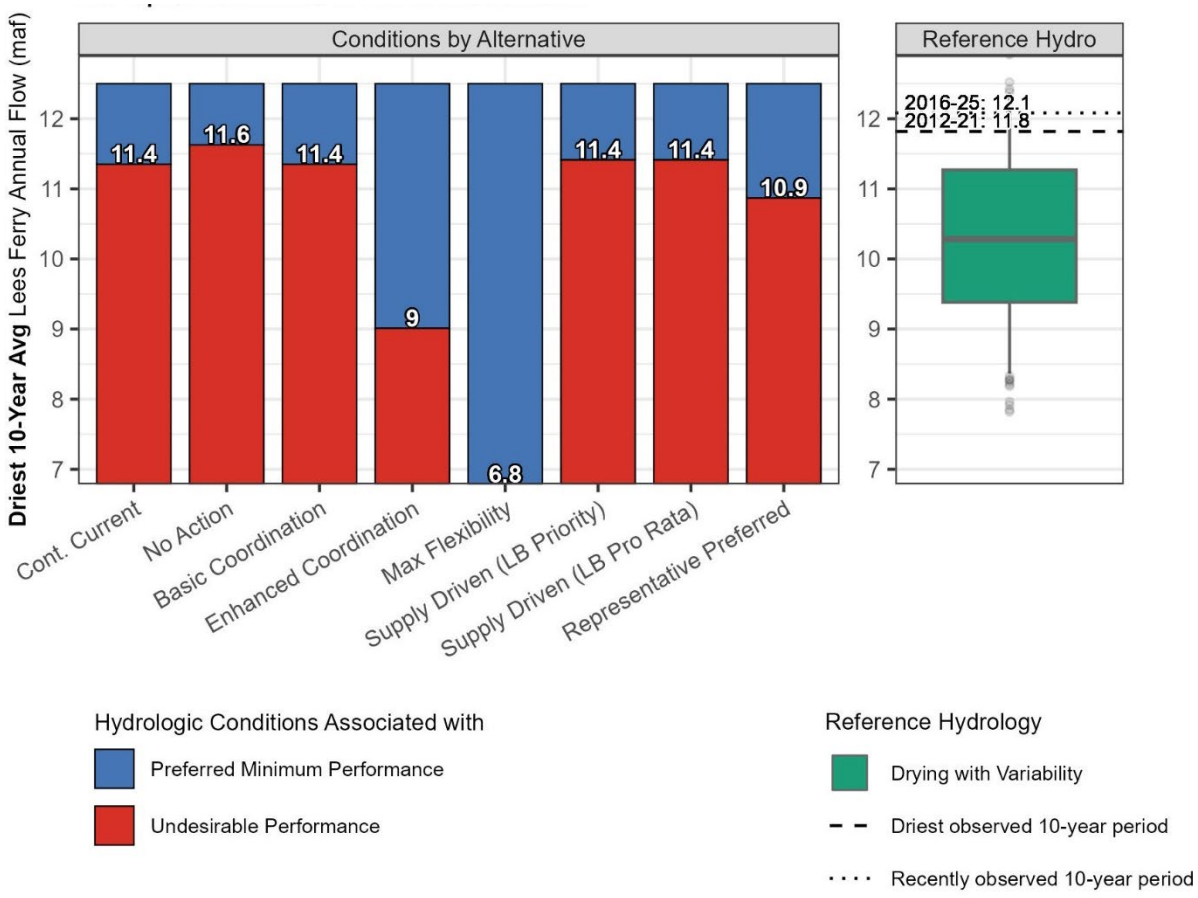
Figure TA 7-7
Lake Powell Shoreline Area in Glen Canyon National Recreation Area: Robustness. Percent of futures in which the exposed shoreline area is below the value specified in each row in every month

Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The color of a heat map square corresponds with the percent of futures that meet the specified level of performance, which increases from a red color representing less than 10 percent of futures keeping the Lake Powell shoreline exposure area below the specified value in every month (least robust), to a dark blue color representing greater than 91 percent of futures keeping the Lake Powell shoreline exposure area below the specified value in every month (most robust).

The comparison described here focuses on the preference to stay below a maximum value of 500 km^2 (123,553 acres) of exposed shoreline. The selected value accounts for variability, while mathematically limiting the number of instances exceeding 500 km^2 (123,553 acres), which signifies likely fugitive dust minimization.

In the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 81 percent and 95 percent of modeled futures, respectively. The No Action Alternative meets the preferred minimum performance in 16 percent of modeled futures. The CCS Comparative Baseline, as well as the Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives meet the preferred minimum performance in 33 percent, 27 percent, and 23 percent of futures, respectively. Therefore, the Maximum Operational Flexibility and Enhanced Coordination Alternatives are the most robust at staying below 500 km^2 (123,553 acres) of shoreline exposure over the full modeling period, while the No Action Alternative has the worst performance over the full analysis period.

In the first decadal breakout (2027 – 2039), the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 87 percent and 98 percent of modeled futures, respectively. The No Action Alternative meets the preferred minimum performance in 25 percent of modeled futures. The CCS Comparative Baseline, as well as the Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives meet the preferred minimum performance in 54 percent, 45 percent, and 46 percent of futures, respectively. Therefore, the Maximum Operational Flexibility and Enhanced Coordination Alternatives are the most robust at staying below 500 km^2 (123,553 acres) of shoreline exposure over the 2027 – 2039 modeling period, while the No Action Alternative has the worst performance over the 2027 – 2039 analysis period. Based on the planned length of this decision, it is important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 66 percent of futures in the 2027-2039 modeling period.



The Representative Preferred Alternative meets staying below 500 km^2 (123,553 acres) of exposed shoreline robustness criteria in 44 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it's important to note that it meets the preferred minimum performance level in 66 percent of futures in the first modeling period.

In the three subperiods, the alternatives meet the preferred minimum level of performance in greater percentages of futures because the preferred standard is easier to meet over shorter time spans than over the full 34 years. In the three subperiods, the Enhanced Coordination and Maximum Operational Flexibility Alternatives can meet the preferred minimum performance in more than 87 percent of futures, which is considerably more robust than the other alternatives. The robustness ranking across the three alternatives in each subperiod is largely consistent with the ranking in the full modeling period.

Figure TA 7-8 below shows what flow conditions are likely to cause Lake Powell exposed shoreline area to exceed 500 km^2 (123,553 acres) in one or more months. This definition of undesirable performance is based on the highlighted row in **Figure TA 7-7** above, which defined a future as

successful when exposed shoreline area for an alternative remains below 500 km^2 (123,553 acres) in every month.

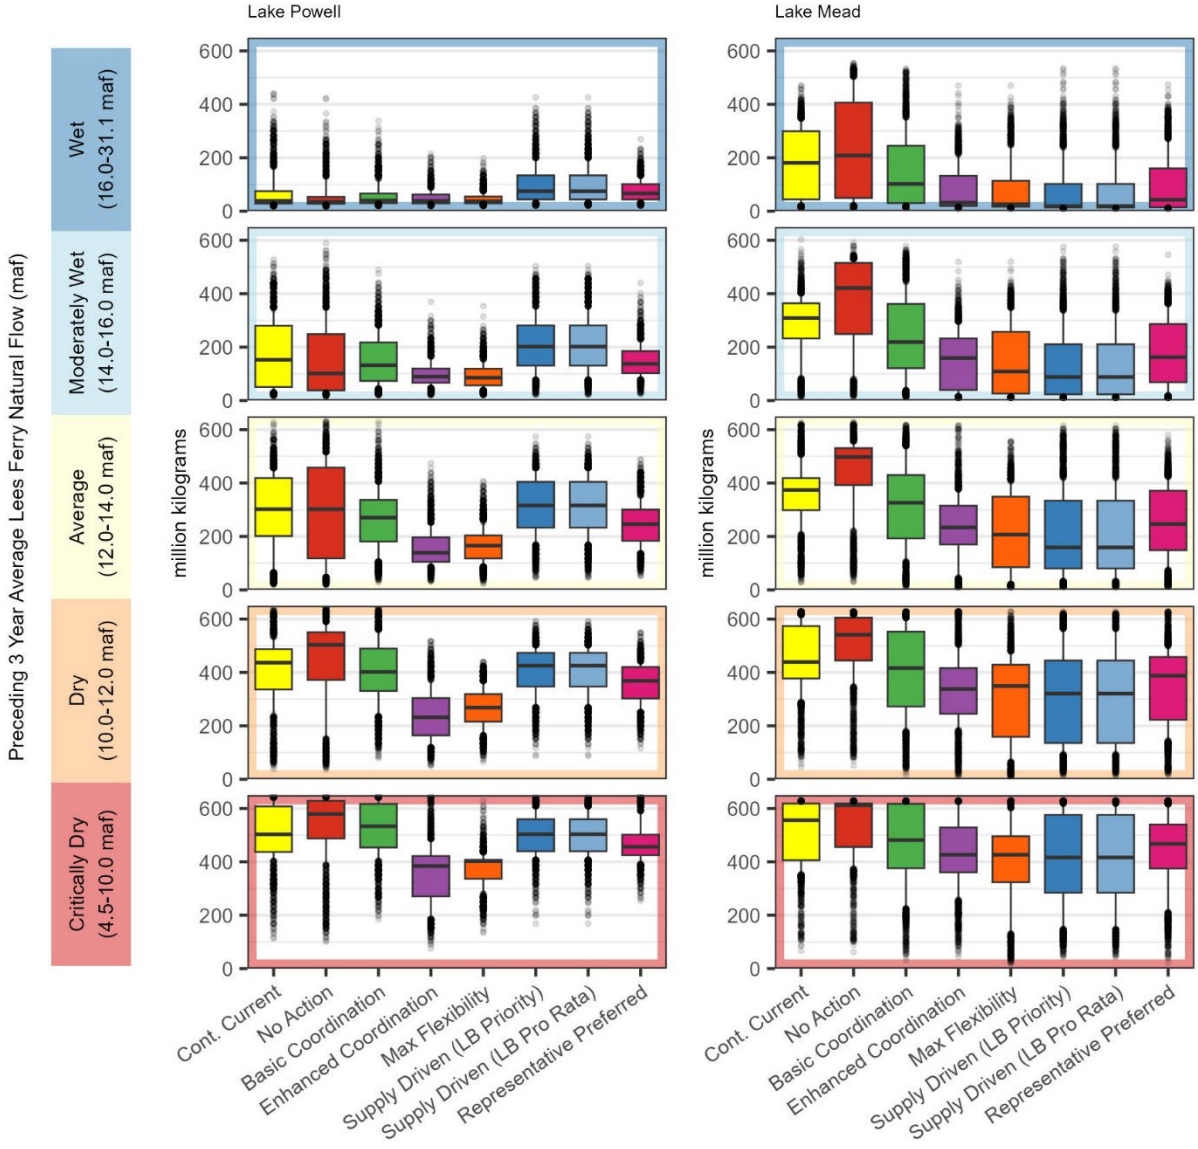
Figure TA 7-8
Lake Powell Shoreline Area in Glen Canyon National Recreation Area: Vulnerability. Conditions that Could Cause Lake Powell Exposed Shoreline Area Above 500 Square Kilometers in One or More Months

For this vulnerability analysis, the driest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

If the future includes a 10-year average flow of 11.6 maf or lower, the No Action Alternative results indicate undesirable performance. The CCS Comparative Baseline, as well as the Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata) Alternatives, are similar to the No Action Alternative, reaching undesirable performance when the 10-year average flow is 11.4 maf or lower. These conditions correspond to undesirable performance levels comparable to the driest observed

10-year average flow of 11.8 maf, with roughly 75 to 90 percent of the Drying with Variability traces occurring below these thresholds.

The Enhanced Coordination Alternative modeling results indicate undesirable performance at a 10-year average flow of 9 maf or drier, which occurs in less than 25 percent of the Drying with Variability traces. The Maximum Operational Flexibility Alternative is least vulnerable, with no Drying with Variability traces occurring below the undesirable performance level of 6.8 maf.



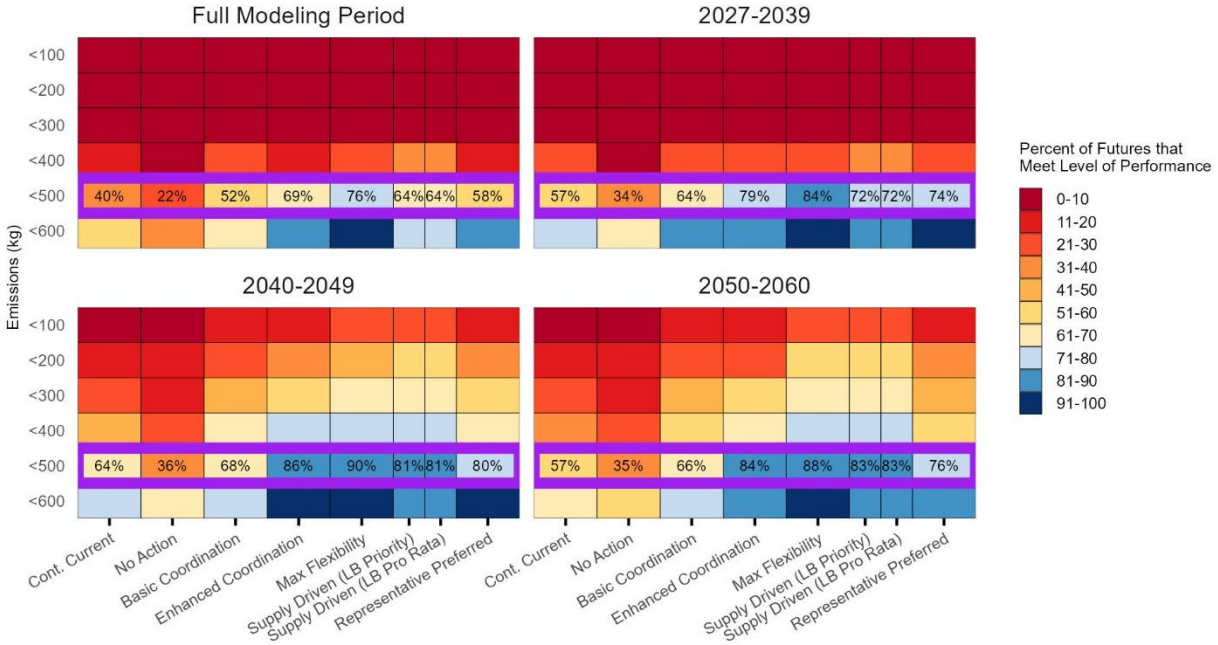
The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 10.9 maf or less. Compared to the historical periods shown in the reference hydrology panel, this flow has not occurred before. Compared to the Drying with Variability Ensemble that represents potential future hydrologic conditions, 30 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

Figure TA 7-9 shows the WY maximum monthly shoreline dust emission for Lake Powell and Lake Mead, in million kg of $PM_{2.5}$, and broken out by hydrologic conditions and categorized by the preceding three-year average Lees Ferry natural flows.

In the Average Flow Category, Lake Powell alternatives have varying distributions, with the 25th to 75th percentiles across all alternatives spanning from approximately 105 to 460 million kg (231 to 1,014 million pounds) of $PM_{2.5}$ emissions as a result of shoreline exposure. The CCS Comparative Baseline, as well as No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, have similar median maximum monthly emission rates of around 300 million kg (661 million pounds) of $PM_{2.5}$ as a result of shoreline exposure, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives display lower medians of around 150 million kg (331 million pounds) of $PM_{2.5}$. The Lake Mead alternatives have varying distributions, with the 25th to 75th percentiles across all alternatives spanning from 80 to 540 million kg (176 to 1,190 million pounds) of $PM_{2.5}$ emissions as a result of shoreline exposure. In comparison to Lake Powell, the median monthly emission rates are more variable for Lake Mead, with the No Action and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives displaying the highest and lowest values at about 500 and 160 million kg (1,102 and 353 million pounds) of $PM_{2.5}$, respectively.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Lake Powell $PM_{2.5}$ emissions as a result of shoreline exposure, the median $PM_{2.5}$ emissions is about 369 million kg (814 million pounds), with the 25th to 75th percentiles across all alternatives spanning from 303 to 421 million kg (668 to 928 million pounds) of $PM_{2.5}$ emissions as a result of shoreline exposure. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Lake Powell $PM_{2.5}$ emissions as a result of shoreline exposure, the median $PM_{2.5}$ emissions is about 456 million kg (1,005 million pounds), with the 25th to 75th percentiles across all alternatives spanning from 425 to 502 million kg (937 to 1,107 million pounds) of $PM_{2.5}$ emissions as a result of shoreline exposure.

Figure TA 7-9
Water Year Maximum Monthly Shoreline Dust Emissions for Lake Powell and Lake Mead (million kilograms)



The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Lake Mead $PM_{2.5}$ emissions as a result of shoreline exposure, the median $PM_{2.5}$ emissions is about 388 million kg (855 million pounds), with the 25th to 75th percentiles across all alternatives spanning from 223 to 458 million kg (492 to 1,010 million pounds) of $PM_{2.5}$ emissions as a result of shoreline exposure. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Lake Mead $PM_{2.5}$ emissions as a result of shoreline exposure, the median $PM_{2.5}$ emissions is about 468 million kg (1,032 million pounds), with the 25th to 75th percentiles across all alternatives spanning from 375 to 540 million kg (827 to 1,191 million pounds) of $PM_{2.5}$ emissions as a result of shoreline exposure.

As conditions become wetter, the maximum monthly shoreline dust emissions show lower median rates, with the Wet Flow Category also displaying the smallest interquartile ranges. On the other hand, maximum monthly shoreline dust emissions shift higher during drier conditions when more shoreline is exposed.

Lake Mead Robustness

Figure TA 7-10, below depicts the performance of each alternative to maintain Lake Mead shoreline dust ($PM_{2.5}$) emissions below the specified value in every month. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures in which the shoreline dust emissions are less than 500 million kg (1,102 million pounds) in every month. Keeping the Lake Mead emissions below 500 million kg (1,102 million pounds) minimizes fugitive dust; therefore, protecting air quality in the area and represents the reasonable approximation of the emission value that would occur when the lake is full enough with water to operate the dam to generate power.

Figure TA 7-10
Lake Mead Shoreline Dust (PM 2.5) Emissions in Lake Mead National Recreation Area: Robustness.
Percent of futures in which emissions are less than the value specified in each row in every month

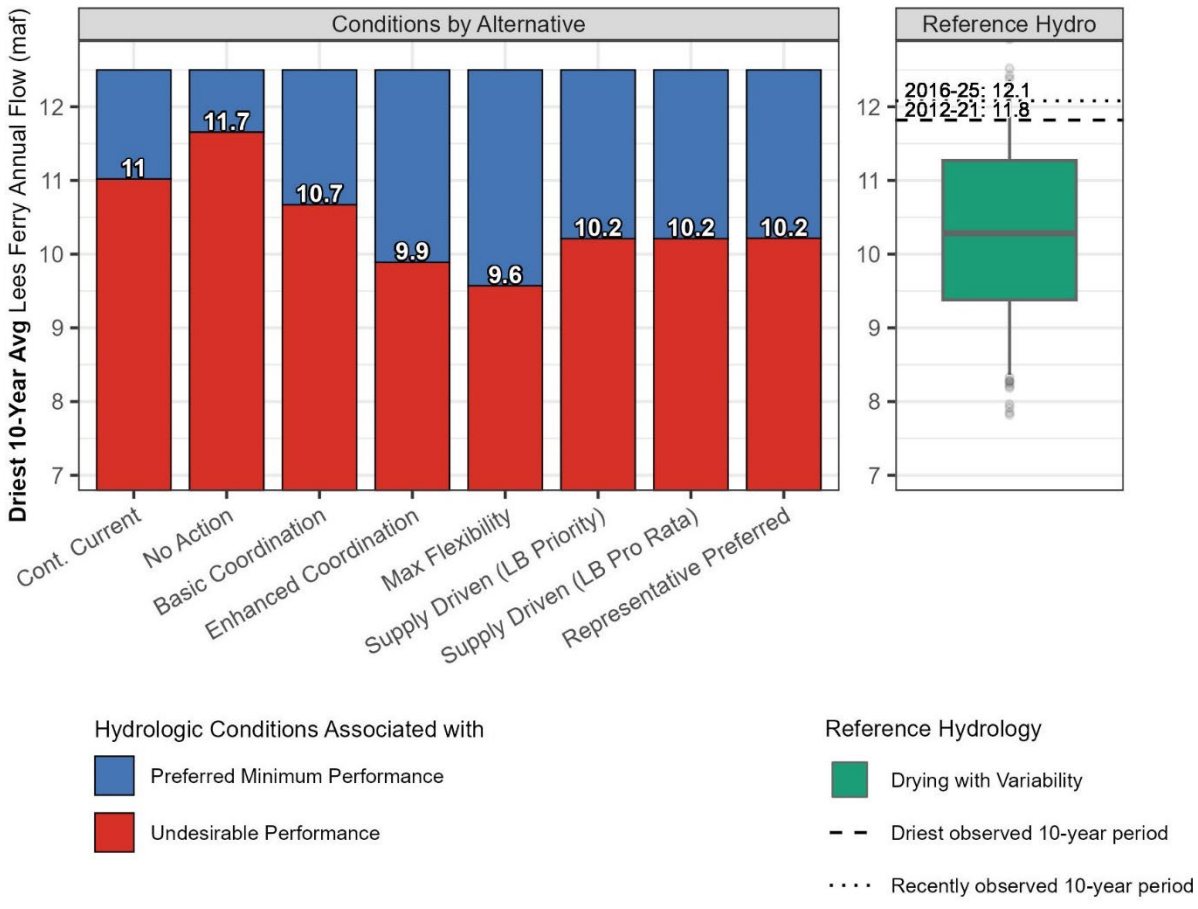
Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The color of a heat map square corresponds with the percent of futures that meet the specified level of performance, which increases from a red color representing less than 10 percent of futures keeping the Lake Mead shoreline dust emissions below the specified value in every month (least robust), to a dark blue color representing greater than 91 percent of futures keeping the Lake Mead shoreline dust emissions below the specified value in every month (most robust).

The comparison described here focuses on the preference to stay below 500 million kg (1,102 million pounds) of shoreline dust emissions. The selected value accounts for variability, while mathematically limiting the number of instances exceeding 500 million kg (1,102 million pounds), which signifies likely fugitive dust minimization.

In the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives can meet the preferred minimum performance in 69 percent and 76 percent of modeled futures, respectively, which is more robust than the other alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) can meet the preferred minimum performance in 64 percent of modeled futures. The CCS Comparative Baseline, as well as the No Action and Basic Coordination Alternatives, are only able to meet the preferred minimum performance in 40 percent, 22 percent, and 52 percent of futures, respectively.

In the first decadal breakout (2027 – 2039), the Enhanced Coordination and Maximum Operational Flexibility Alternatives can meet the preferred minimum performance in 79 percent and 84 percent of modeled futures, respectively, which is more robust than the other alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) can meet the preferred minimum performance in 72 percent of modeled futures. The CCS Comparative Baseline, as well as the No Action and Basic Coordination Alternatives, are only able to meet the preferred minimum performance in 57 percent, 34 percent, and 64 percent of futures, respectively. Based on the planned length of this decision, it is important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 74 percent of futures in the 2027-2039 modeling period.

The Representative Preferred Alternative meets staying below 500 million kg (1,102 million pounds) of shoreline dust emissions robustness criteria in 58 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it's important to note that it meets the preferred minimum performance level in 74 percent of futures in the first modeling period.



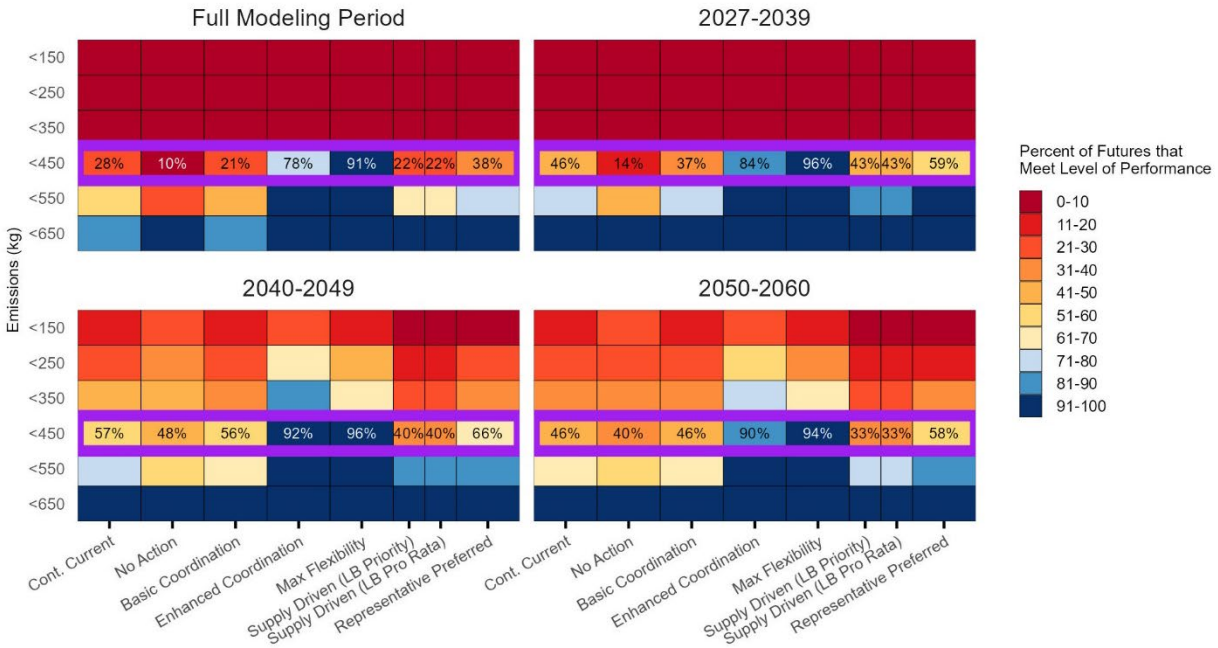
In the three subperiods, the alternatives meet the preferred minimum level of performance in greater percentages of futures because the preferred standard is easier to meet over shorter time spans than over the full 34 years. The robustness ranking across the three alternatives in each subperiod is consistent with the ranking in the full modeling period.

Figure TA 7-11 below shows what flow conditions are likely to cause Lake Mead shoreline dust ($PM_{2.5}$) emissions to exceed 500 million kg (1,102 million pounds) in one or more months. This definition of undesirable performance is based on the highlighted row in **Figure TA 7-10** above, which defined a future as successful when shoreline dust emissions for an alternative are less than 500 million kg (1,102 million pounds) in every month.

For this vulnerability analysis, the driest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

The No Action Alternative would likely be vulnerable to undesirable shoreline dust emissions under a driest 10-year average Lees Ferry flow of 11.7 maf or drier, which is similar to the driest observed 10-year average of 11.8 maf. The CCS Comparative Baseline, as well as Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives reach undesirable performance at a driest 10-year average flow that occurs in 50 to 75 percent of the Drying with Variability traces, suggesting these alternatives are reasonably likely to be vulnerable. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are not likely to be vulnerable to undesirable performance unless the 10-year average flow is much drier than any observed conditions, and fewer than 50 percent of the traces in the Drying with Variability ensemble include conditions that would be likely to cause vulnerability in these alternatives.

Figure TA 7-11
Lake Mead Shoreline Dust (PM 2.5) Emissions in Lake Mead National Recreation Area: Vulnerability.
Conditions that Could Cause Lake Mead Emissions Above 500 million kilograms in One or More Months



The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 10.2 maf or less. Compared to the historical periods shown in the reference hydrology panel, this flow has not occurred before. Compared to the Drying with Variability

Ensemble that represents potential future hydrologic conditions, 20 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

Lake Powell Robustness

Figure TA 7-12, below depicts the performance of each alternative to maintain Lake Powell shoreline dust ($PM_{2.5}$) emissions below the specified value in every month. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures in which the shoreline dust emissions are less than 450 million kg (992 million pounds) every month. Keeping the Lake Powell emissions below 450 million kg (992 million pounds) ensures that fugitive dust would be minimized protecting air quality in the area and represents the reasonable approximation of the emission value that would occur when the lake is full enough with water to operate the dam to generate power.

Figure TA 7-12
Lake Powell Shoreline Dust (PM 2.5) Emissions in Glen Canyon National Recreation Area: Robustness.
Percent of futures in which emissions are less than the value specified in each row in every month

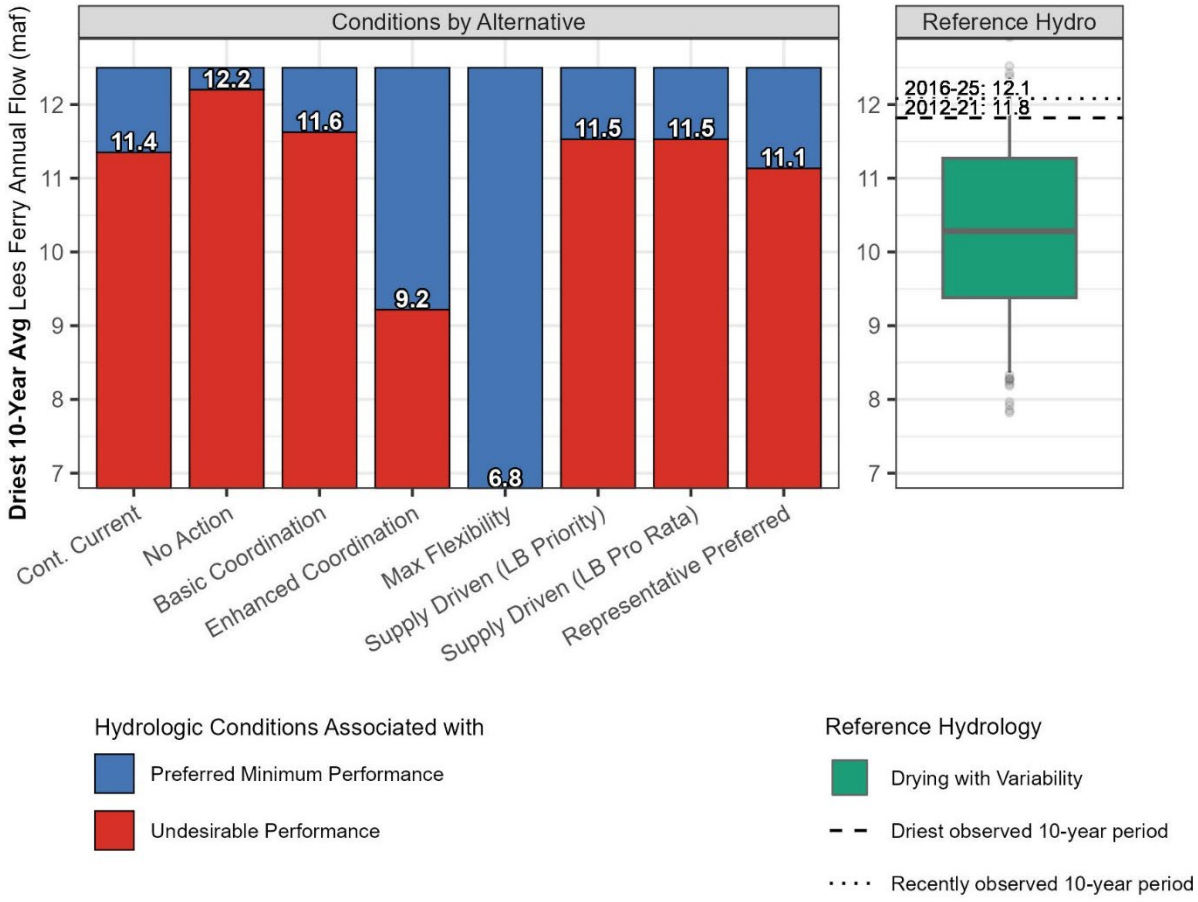
Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The color of a heat map square corresponds with the percent of futures that meet the specified level of performance, which increases from a red color representing less than 10 percent of futures keeping the Lake Powell shoreline dust emissions below the specified value in every month (least robust), to a dark blue color representing greater than 91 percent of futures keeping the Lake Powell shoreline dust emissions below the specified value in every month (most robust).

The comparison described here focuses on the preference to stay below a maximum value of 450 million kg (992 million pounds) of shoreline dust emissions. The selected value accounts for variability, while mathematically limiting the number of instances exceeding 450 million kg (992 million pounds), which signifies likely fugitive dust minimization.

In the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 78 percent and 91 percent of modeled futures, respectively, which is considerably more robust than the other alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) can meet the preferred minimum performance in 22 percent of modeled futures. The CCS Comparative Baseline, as well as No Action and Basic Coordination Alternatives, are only able to meet the preferred minimum performance in 28 percent, 10 percent, and 21 percent of futures, respectively.

In the first decadal breakout (2027 – 2039), the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 84 percent and 96 percent of modeled futures, respectively, which is considerably more robust than the other alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) can meet the preferred minimum performance in 43 percent of modeled futures. The CCS Comparative Baseline, as well as No Action and Basic Coordination Alternatives, are only able to meet the preferred minimum performance in 46 percent, 14 percent, and 37 percent of futures, respectively. Based on the planned length of this decision, it is important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 59 percent of futures in the 2027-2039 modeling period.

The Representative Preferred Alternative meets staying below 450 million kg (992 million pounds) of shoreline dust emissions robustness criteria in 38 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it's important to note that it meets the preferred minimum performance level in 59 percent of futures in the first modeling period.



In the three subperiods, the alternatives meet the preferred minimum level of performance in greater percentages of futures because the preferred standard is easier to meet over shorter time spans than over the full 34 years. In the three subperiods, the Enhanced Coordination and Maximum Operational Flexibility Alternatives can meet the preferred minimum performance in more than 80 percent of futures, which is considerably more robust than the other alternatives.

Figure TA 7-13 below shows what flow conditions are likely to cause Lake Powell shoreline dust ($PM_{2.5}$) emissions to exceed 450 million kg (992 million pounds) in one or more months. This definition of undesirable performance is based on the highlighted row in **Figure TA 7-12** above, which defined a future as successful when shoreline dust emissions for an alternative are less than 450 million kg (992 million pounds) in every month.

For this vulnerability analysis, the driest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 maf) and the average flow

from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

Figure TA 7-13
Lake Powell Shoreline Dust (PM 2.5) Emissions in Glen Canyon National Recreation Area: Vulnerability.
Conditions that Could Cause Lake Powell Emissions Above 450 million kilograms in One or More Months

The No Action Alternative would likely be vulnerable to undesirable shoreline dust emissions under a 10-year average Lees Ferry natural flow of 12.2 maf or drier, which is similar to the recently observed 10-year average of 12.1 maf. The CCS Comparative Baseline, as well as Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, have similar results, indicating undesirable performance during a 10-year average flow ranging from 11.4–11.6 maf or lower. These results are also similar to the driest observed 10-year average flow (11.8 maf), with roughly 75 to 90 percent of the Drying with Variability traces including conditions that would be likely to cause vulnerability in these alternatives. The Enhanced Coordination Alternative modeling results indicate undesirable performance at a 10-year average flow of 9.2 maf or lower, which occurs in less than 25 percent of the Drying with Variability traces. The Maximum Operational Flexibility

Alternative is least vulnerable, with no Drying with Variability traces occurring below the undesirable performance level of 6.8 maf.

The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 11.1 maf or less. Compared to the historical periods shown in the reference hydrology panel, this flow has not occurred before. Compared to the Drying with Variability Ensemble that represents potential future hydrologic conditions, 40 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

When reservoir elevations are low and there is more dust mobilization and potential acceleration of runoff, snow in locations like the Rockies could be subject to dust on snow effects. Dust darkens the snow surface, reducing its albedo (reflectivity). Clean snow reflects up to 90 percent of sunlight, but when dust is present, more sunlight is absorbed instead of reflected. As a result, snow melts faster, even if temperatures remain low. This effect is especially pronounced in spring, when the sun is stronger. This has the potential to alter water timing in the watersheds. Because snow melts earlier and faster due to dust, the rivers and streams may experience earlier peak flows. This can lead to less water availability in summer when it is most needed (e.g., for agriculture, ecosystems, and human consumption).

Changing flow characteristics can affect the fallowing of agricultural lands, especially in regions that rely on consistent irrigation from reservoirs. If the changing flows result in reduced dam releases, there could be less irrigation water available to downstream farmers. Reduced dam releases could also result in forced fallowing, which occurs when water is insufficient and farmers fallow (intentionally leave idle) some or all of their fields to conserve water for high-value crops and avoid costs associated with planting and irrigation they cannot support.

Information on potential fallowed acreage is presented in **TA 16.2.2** in **TA 16**, Socioeconomics, including **Figure TA 16-1**. As described in that section, estimates of fallowed acreage are based on simplifying assumptions regarding water availability, crop profitability, and agricultural decision-making, and are intended to support regional-scale economic analysis. These estimates are inherently uncertain and do not represent site-specific or on-the-ground predictions of fallowing patterns, which would vary based on localized conditions, such as water availability, soil characteristics, market conditions, and individual farm management decisions.

Fallowed agricultural lands may be a source of fugitive dust emissions, particularly under dry and unvegetated conditions. At a screening level, windblown dust emissions from fallow lands can be estimated using generalized emission factors derived from U.S. EPA AP-42 guidance (EPA 2026). Typical emission factors for fallow or bare agricultural lands range from approximately 0.1 to 0.5 tons of PM_{10} per acre per year, depending on site-specific conditions. Lower emissions within this range would be expected where soils are crusted, vegetated, or otherwise stabilized, while higher emissions may occur in areas with dry, loose soils and greater wind exposure, such as arid environments in the Southwest. $PM_{2.5}$ emissions are generally a fraction of PM_{10} emissions (commonly on the order of 10 to 20 percent), though this proportion may also vary.

Actual emissions from fallowed lands would depend on numerous factors not known at this programmatic stage of analysis, including soil type, surface disturbance, vegetation cover, wind

speed, and the presence or absence of dust control measures (e.g., irrigation, soil stabilizers, or conservation practices). In addition, the spatial distribution and timing of fallowing are uncertain and cannot be predicted with sufficient specificity to support detailed emissions modeling. Therefore, while the emission factor range provided above offers a general indication of the potential magnitude of fugitive dust emissions, it should be considered a screening-level approximation only.

Clark County, Nevada is the only county in the analysis area that has been designated as serious nonattainment for the 2015 eight-hour O_3 standard and a maintenance area for CO and PM_{10} (EPA 2025b). In addition, the design value for O_3 for Clark County exceeds the NAAQS for O_3 (0.70 ppm) and the Clark County number of exceedances of the PM_{10} NAAQS exceeds the standard (EPA 2024a). Therefore, shoreline exposure that has the potential to increase particulate matter could further exacerbate the current PM_{10} issue in Clark County.

TA 7.2.3 Issue 2: How would lake reservoir elevations and releases impact power generation and CO_2e emissions?

Issue 2 addresses how operational activities for the various alternatives affect reservoir elevations and therefore impact hydropower generation. When there is a reduction of hydropower, there would be a potential increase of CO_2e emissions due to more emissive alternative energy generation compensating for this reduction (Veselka et al. 2024). There will be a comparison of the four action alternatives and the No Action Alternative to the CCS Comparative Baseline. Power generation depends on the same factors as power capacity, but generation reflects the amount of power created over a certain period. The power generation is more dependent on plant operations through scheduled releases, as these releases, along with other natural factors like rainfall and water availability, determine how much water flows through the turbines over a given amount of time. These models simulate releases and lake reservoir elevations to calculate an estimated generation.

Energy capacity is the maximum possible electric output at a given time. Installed hydropower plant capacity is dependent on generator capacity and turbine efficiency, but the actual capacity is also dependent on the flow rate of water moving through the system. Therefore, the reservoir storage and lake elevation impact capacity for hydropower. Capacity for hydropower is dependent on the time of year as well as water availability differs between the summer and winter months. Lake elevation impacts the head, and a larger head leads to greater potential energy. The maximum capacity of hydropower will be the most instantaneous power generated in a second with the highest water flow possible through the turbines of a hydropower plant. The critical elevations for Lake Powell and Lake Mead are presented in tables in **TA 15**, Dams and Electrical Power Resources. At Lake Powell the minimum power pool is 3,490 feet and when water elevations go below this, Glen Canyon Dam is no longer able to produce hydropower. As described in **Chapter 1**, **Section 1.8.4.1**, this threshold is also important to protect critical infrastructure and water supply. At Lake Mead the minimum power pool is 950 feet and when water elevations go below this, Hoover Dam is no longer able to produce hydropower. This is typically measured in megawatts. This section will consider how the different alternatives impact the generation capacities of the hydropower plants at the Glen Canyon, Hoover, Davis, and Parker dams.

The box plots below report metric tons of CO_2e based on the 2025 resource mix emission factor on the left axis and the 2050 resource mix emission factor on the right axis, utilizing the MWh increase

or decrease for each alternative and flow category. Only the 2025 resource mix is discussed in detail, as the 2050 resource mix results would have lower metric tons of CO_2e as the emission factor includes more alternative energy resources.

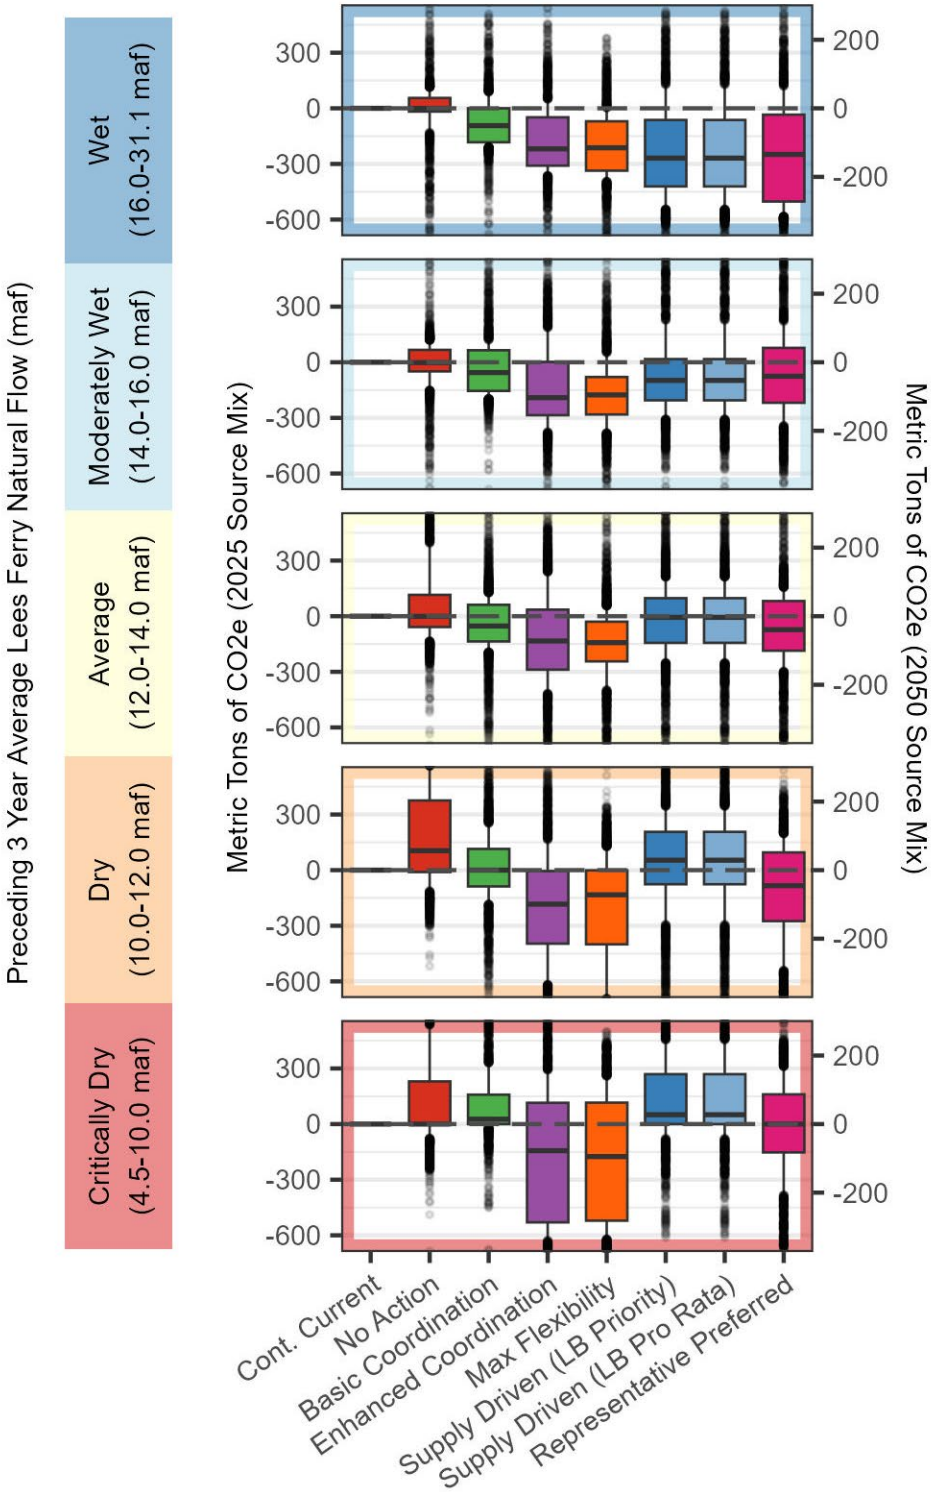


Figure TA 7-14 shows the change of CO_2e emissions due to a fluctuation of hydropower generation at Glen Canyon Dam, broken out by hydrologic conditions and categorized by the preceding three-year average Lees Ferry natural flows.

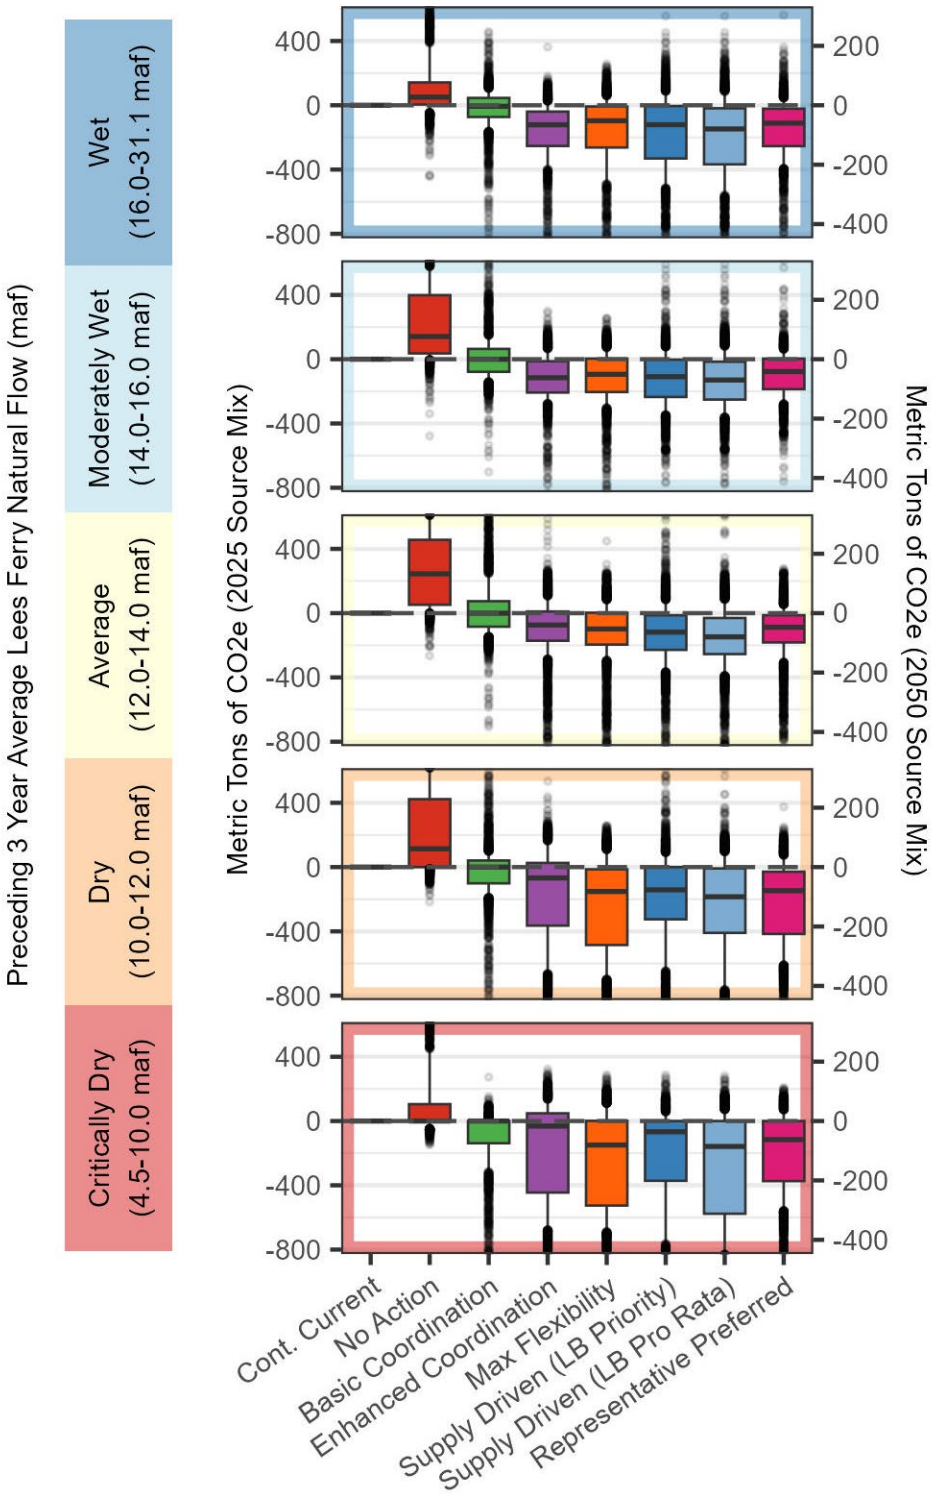
A positive or negative CO_2e value indicates an increase or decrease in CO_2e compared to the CCS Comparative Baseline, respectively. In the Average Flow Category, the Glen Canyon Dam alternatives have varying distributions of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 288-metric-ton decrease to a 115-metric-ton increase of CO_2e emissions. The No Action Alternative has a median close to zero, representing the smallest decrease relative to the CCS Comparative Baseline. The Enhanced Coordination (134 metric tons decrease of CO_2e) and Maximum Operational Flexibility (143 metric tons decrease of CO_2e) Alternatives have similar medians, resulting in the largest decrease in CO_2e emissions relative to the CCS Comparative Baseline. While the Maximum Operational Flexibility Alternative has an interquartile range similar to the other alternatives, the Enhanced Coordination Alternative has the largest interquartile range among all alternatives. The Average Flow Category 75th percentile values result in no more than a 115 metric ton increase in CO_2e emissions, which is equivalent to 23.3 gasoline-powered passenger vehicles driven for 1 year or 20.8 homes' electricity for 1 year.

In the Critically Dry Flow Category, the Glen Canyon Dam alternatives exhibit variations in both their medians and interquartile ranges. The No Action Alternative has a median value of zero CO_2e emissions relative to the CCS Comparative Baseline. The Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives show medians above zero, indicating an increase in CO_2e emissions relative to the CCS Comparative Baseline. The Enhanced Coordination and Maximum Operational Flexibility Alternatives both result in a decrease in CO_2e emissions, displaying medians below zero. The interquartile range for these two alternatives is the largest among all alternatives, with the middle 50 percent spanning from an approximate decrease of 530 to an increase of 115 metric tons of CO_2e. The Critically Dry Flow Category 75th percentile values result in no more than a 269 metric ton increase in CO_2e (Supply Driven Alternative), which is equivalent to 65.5 gasoline-powered passenger vehicles driven for 1 year or 58.6 homes' electricity for 1 year.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Glen Canyon Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about an 84-metric-ton decrease of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 275-metric-ton decrease to a 96-metric-ton increase of CO_2e emissions. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Glen Canyon Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions results in a zero-metric-ton increase or decrease of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 153-metric-ton decrease to a 160-metric-ton increase of CO_2e emissions.

Figure TA 7-14
Change of CO2e Emissions Due to a Fluctuation of Hydropower Generation at Glen Canyon



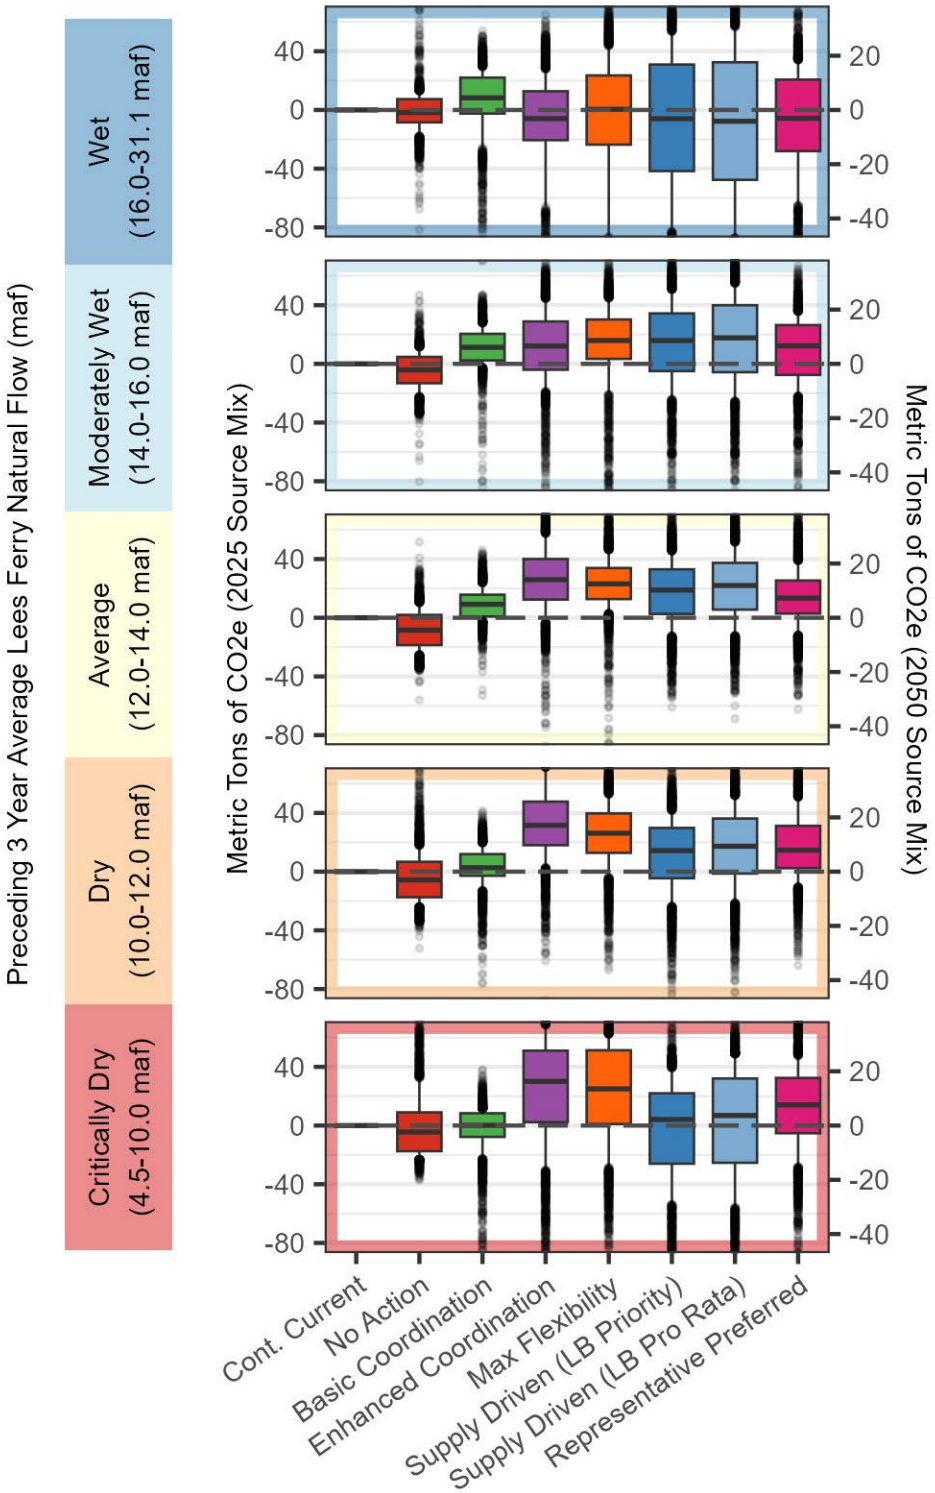
The median change in CO_2e emissions resulting from a loss of hydropower generation at Glen Canyon Dam generally shifts upward as hydrologic conditions move from Wet (16.0–31.1 maf) to Critically Dry (4.46–10.0 maf) Flow conditions; however, the magnitude of this shift varies among alternatives. The Enhanced Coordination and Maximum Operational Flexibility Alternatives exhibit relatively small changes in median CO_2e emissions across flow conditions, whereas the Supply Driven Alternative (both the LB Priority and LB Pro Rata approaches) shows a more substantial increases in median emissions under drier conditions.

Figure TA 7-15 shows the change of CO_2e emissions due to a fluctuation of hydropower generation at Hoover Dam, broken out by hydrologic conditions and categorized by the preceding three-year average Lees Ferry natural flows. The Hoover Dam power plant has 17 commercial generators with a maximum combined capacity of 2,074 megawatts. The power plant requires a minimum Lake Mead elevation of 950 feet to produce power. At minimum power pool, the power plant has an estimated capacity of 117 megawatts. At Lake Mead elevation of 1,035 feet, Hoover Dam's generating capacity is drastically reduced from 1,274 to 382 megawatts.

A positive or negative CO_2e value indicates an increase or decrease in CO_2e compared to the CCS Comparative Baseline, respectively. In the Average Flow Category, the Hoover Dam alternatives have varying distributions of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 255-metric-ton decrease to a 456-metric-ton increase in CO_2e emissions. The Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives have medians showing a decrease in metric tons of CO_2e emissions. The No Action Alternative has a median showing an increase in metric tons of CO_2e emissions, and the Basic Coordination Alternative shows a median near zero metric tons of CO_2e emissions. The No Action Alternative has the highest median, with a 244-metric-ton increase in CO_2e emissions, and the largest interquartile range, with the 25th percentile at 52 metric tons and the 75th percentile at 456 metric tons of CO_2e. The Average Flow Category 75th percentile values result in no more than a 456 metric ton increase in CO_2e (No Action Alternative), which is equivalent to 90.3 gasoline-powered passenger vehicles driven for 1 year or 80.6 homes' electricity for 1 year.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Hoover Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 146-metric-ton decrease of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 416-metric-ton decrease to a 75-metric-ton increase of CO_2e emissions. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Hoover Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 115-metric-ton decrease of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 374-metric-ton decrease to a zero-metric-ton increase or decrease of CO_2e emissions.

Figure TA 7-15
Change of CO2e Emissions Due to a Fluctuation of Hydropower Generation at Hoover Dam



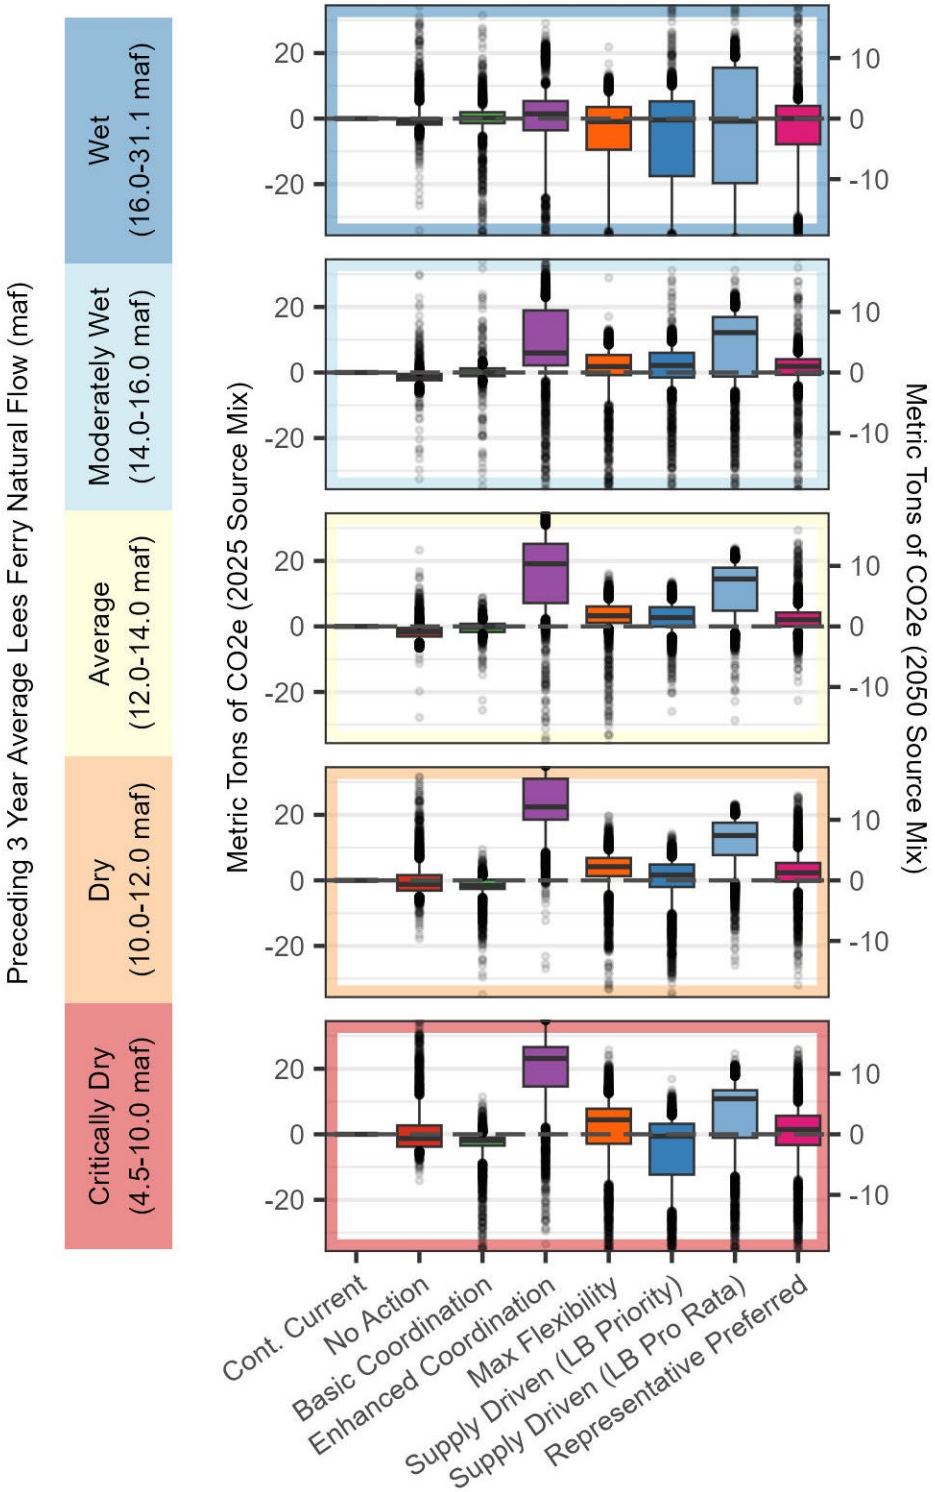
In the Critically Dry Flow Category, Hoover Dam alternatives exhibit variations in both their medians and interquartile ranges. The medians for the No Action and Basic Coordination Alternatives display no change in CO_2e emissions relative to the CCS Comparative Baseline. The Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives all have medians showing a decrease in metric tons of CO_2e emissions, with Supply Driven (LB Pro Rata) showing the largest decrease at 158 metric tons of CO_2e. The 25th to 75th percentiles across all alternatives span from a decrease of 577 metric tons to an increase of 105 metric tons of CO_2e emissions. The No Action Alternative has the smallest interquartile range, while the Supply Driven (LB Pro Rata) Alternative has the largest. The Critically Dry Flow Category 75th percentile values result in no more than a 105 metric ton increase in CO_2e (No Action Alternative), which is equivalent to 38.5 gasoline-powered passenger vehicles driven for 1 year or 34.4 homes' electricity for 1 year.

Figure TA 7-16 shows the change of CO_2e emissions due to a fluctuation of hydropower generation at Davis Dam, broken out by hydrologic conditions and categorized by the preceding three-year average Lees Ferry natural flows.

A positive or negative CO_2e value indicates an increase or decrease in CO_2e compared to the CCS Comparative Baseline, respectively. In the Average Flow Category, the Davis Dam alternatives exhibit varying distributions of CO2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 19-metric-ton decrease to a 40-metric-ton increase in CO_2e emissions. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives display similar medians ranging from 19 to 26 metric tons of CO_2e increase. The Representative Preferred Alternative and Basic Coordination Alternative medians are similar at around 10 metric tons of CO_2e increase, while the No Action Alternative has an 8 metric ton decrease in CO_2e emissions. The No Action Alternative is the only alternative with both a median and 25th percentile below zero. All other alternatives have medians and 25th to 75th percentiles that result in an increase in CO_2e, with the Basic Coordination Alternative having the smallest interquartile range. The Average Flow Category 75th percentile values result in no more than a 40-metric-ton increase in CO_2e (Enhanced Coordination Alternative), which is equivalent to 10 gasoline-powered passenger vehicles driven for 1 year or 9 homes' electricity for 1 year.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Davis Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 15-metric-ton increase of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 2-metric-ton increase to a 31-metric-ton increase of CO_2e emissions. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Davis Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 14-metric-ton increase of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 5-metric-ton decrease to a 32-metric-ton increase of CO_2e emissions.

Figure TA 7-16
Change of CO2e Emissions Due to a Fluctuation of Hydropower Generation at Davis Dam



In the Critically Dry Flow Category, Davis Dam alternatives exhibit variations in both their medians and interquartile ranges. The median for the Basic Coordination Alternative displays very little change in CO_2e emissions, while the No Action Alternative shows a 4 metric ton decrease of CO_2e emissions relative to the CCS Comparative Baseline. The Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives all have medians showing an increase in CO_2e emissions, ranging from 4 to 30 metric tons. The 25th to 75th percentiles across all alternatives span from a decrease of 26 metric tons of CO_2e to an increase of 51 metric tons of CO_2e emissions. The Basic Coordination Alternative has the smallest interquartile range, while the Maximum Operational Flexibility Alternative has the largest. The Critically Dry Flow Category 75th percentile values result in no more than a 51-metric-ton increase in CO_2e (Enhanced Coordination Alternative), which is equivalent to 11 gasoline-powered passenger vehicles driven for 1 year or 9.8 homes' electricity for 1 year.

Figure TA 7-17 shows the change of CO_2e emissions due to a fluctuation of hydropower generation at Parker Dam, broken out by hydrologic conditions and categorized by the preceding three-year average Lees Ferry natural flows.

A positive or negative CO_2e value indicates an increase or decrease in CO_2e compared to the CCS Comparative Baseline, respectively. In the Average Flow Category, Parker Dam alternatives exhibit varying distributions of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 3-metric-ton decrease to a 25-metric-ton increase in CO_2e. Only the No Action and Basic Coordination Alternatives have medians that result in a decrease in CO_2e emissions; though, both are near a zero metric-ton change in CO_2e. The Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives have similar medians, ranging from near zero to a 5-metric-ton CO_2e increase. The Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives have the highest medians, exceeding an increase of 14 metric tons of CO_2e emissions. The Enhanced Coordination Alternative has the largest interquartile range, while the Basic Coordination Alternative has the smallest range. The Average Flow Category 75th percentile values result in no more than a 25-metric-ton increase in CO_2e (Enhanced Coordination Alternative), which is equivalent to 5.4 gasoline-powered passenger vehicles driven for 1 year or 4.8 homes' electricity for 1 year.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category : For the Parker Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 2-metric-ton increase of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a zero-metric-ton increase to a 5-metric-ton increase of CO_2e emissions. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Parker Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 1-metric-ton increase of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 3-metric-ton decrease to a 6-metric-ton increase of CO_2e emissions.

Figure TA 7-17
Change of CO2e Emissions Due to a Fluctuation of Hydropower Generation at Parker Dam

In the Critically Dry Flow Category, Parker Dam alternatives exhibit variations in both their medians and interquartile ranges. The medians for No Action, Basic Coordination, Supply Driven (LB Priority), and Representative Preferred Alternatives are similar, displaying a decrease in CO_2e emissions ranging from 2 to nearly zero metric tons. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (LB Pro Rata) Alternatives all have medians showing an increase in metric tons of CO_2e emissions, with the Enhanced Coordination Alternative showing the largest increase at 23 metric tons of CO_2e. The 25th to 75th percentiles across all alternatives span from a decrease of 12 metric tons of CO_2e to an increase of 27 metric tons of CO_2e. The Basic Coordination Alternative has the smallest interquartile range, while the Supply Driven Alternative (LB Priority) has the largest. The Critically Dry Flow Category 75th percentile values result in no more than a 27-metric-ton increase in CO_2e (Enhanced Coordination Alternative), which is equivalent to 6.1 gasoline-powered passenger vehicles driven for 1 year or 5.4 homes' electricity for 1 year.

TA 7.2.4 Issue 3: How would climate trends affect lake reservoir elevations?

Climate trends affect lake reservoir elevations in several interrelated ways, driven largely by changes in temperature, precipitation patterns, and hydrological cycles. Climate trends typically result in more variability and extremes in lake reservoir elevations—lower lows during droughts, higher highs during storm events, and greater management complexity overall.

Reduced Snowpack and Earlier Snowmelt

In many regions, especially mountainous areas, snowpack acts as a natural reservoir, slowly releasing water into rivers and lakes as it melts. Climate trends may cause warmer temperatures, which can result in less snow accumulation and earlier snowmelt, shifting the timing of runoff. Reservoirs may fill earlier in the season, but levels drop later in summer when demand (especially for irrigation and cooling) is highest.

Increased Evaporation

Potentially higher temperatures increase evaporation rates from both lake surfaces and surrounding land. As a result, greater water loss from reservoirs, especially in arid and semi-arid regions, leads to lower water levels.

Changes in Precipitation Patterns

Climate trends show potential disruption of rainfall patterns with some areas experiencing more intense storms, while others face prolonged droughts. The intense rainstorms may cause runoff that does not efficiently recharge reservoirs, and the droughts reduce inflow from rivers and streams, lowering reservoir levels over time.

Increased Water Demand

Hotter temperatures and more extreme weather increase demand for agricultural irrigation, municipal use, and power generation (cooling). Reservoir drawdown increases, reducing water levels faster, especially in peak summer months.

Decreased Hydropower

As discussed in Issue 2, hydropower may be affected by climate trends. Any reduction in hydropower would require other power generation sources to increase to compensate. The regional power mix can be analyzed to determine the region's potential capacity to replace hydropower with other alternative energy sources. The eGrid is a comprehensive inventory of environmental attributes of electric power systems. The eGrid is based on available plant-specific data for all U.S. electricity generating plants that provide power to the electric grid and report data to the U.S. government. It provides the generation resource mix for the North American Electric Reliability Corporation regions.

The project is located in the Western Electricity Coordinating Council North American Electric Reliability Corporation region. The latest version of eGrid (eGrid 2023) was released in January 2025 with data from 2023 (EPA 2025f). **Table TA 7-15** shows that renewables such as hydropower, biomass, wind, solar, and geothermal are 42.8 percent of the Western Electricity Coordinating Council resource mix compared to nonrenewable resources, such as coal, oil, nuclear, and gas, totaling 57.3 percent. If the 19.8 percent hydropower is reduced, both renewable and nonrenewable resources would compensate. However, as discussed, a recent Argonne National Laboratory study shows that when there is a reduction in hydropower at Glen Canyon Powerplant, the replacement is generated from mostly natural gas–fired generation (gas combined cycle) and gas combustion turbine, with a small portion also coming from coal-fired generation for 2024 through 2027 (Veselka et al. 2024).

In addition, as climate trends are further observed and monitored, Reclamation has opportunity to discuss any strategies to increase management flexibility, enhance climate adaptation planning and improve infrastructure resilience.

Table TA 7-15
eGrid 2023 WRCC Resources Mix Percentages

Resource	Generation Percentage
Coal	14.0%
Oil	0.1%
Gas	35.5%
Nuclear	7.7%
Hydropower	19.8%
Biomass	1.1%
Wind	10.2%
Solar	9.5%
Geothermal	2.2%

TA 7.2.5 Summary of Comparison of Alternatives

Potential impacts on air quality resources for the No Action Alternative, the four action alternatives, and the CCS Comparative Baseline vary depending on the shoreline exposure area and the reduction of hydropower for each alternative.

Issue 1: How would changing flow characteristics affect the potential exposed shoreline, fallowed agricultural lands and fugitive dust?

For the Lake Powell WY maximum exposed shoreline area Average Flow Category, the alternatives all have similar medians and small variabilities, except the Enhanced Coordination and Maximum Operational Flexibility Alternatives, which have the lowest median km^2 of exposed shoreline and the smallest variability. For the Lake Mead WY maximum exposed shoreline area Average Flow Category, the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives performed the best, with the lowest median shoreline exposure area. The CCS Comparative Baseline and No Action Alternative perform the worst and have the smallest variability. The Basic Coordination Alternative performs in the middle. These results are within the range analyzed across the other alternatives from the Final Environmental Impact Statement.

For the full modeling period, the Lake Mead shoreline area robustness figure shows that the No Action Alternative performs the worst, with only 35 percent of the futures below 500 km^2 (123,553 acres) of shoreline area. The CCS Comparative Baseline performs slightly better at 50 percent, then the Basic Coordination Alternative at 61 percent, and then the Supply Driven Alternatives (both LB Priority and LB Pro Rata approaches) at 72 percent. The Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with 80 percent or more of the futures below 500 km^2 (123,553 acres) of shoreline area. These same trends were seen for the 2027–2039, 2040–2049, and 2050–2060 modeling periods with higher percentages. For the 2027–2039 modeling period and 2040–2049 modeling period, the Maximum Operational Flexibility and Enhanced Coordination Alternatives have 88 percent or more of the futures below 500 km^2 (123,553 acres) of shoreline area.

The Lake Mead vulnerability plot shows that the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are vulnerable to similar conditions and less than 50 percent of the Drying with Variability traces include a driest 10-year average Lees Ferry annual flow this dry or drier. The Basic Coordination Alternative is similar to the median of the Drying with Variability ensemble, and the CCS Comparative Baseline and No Action Alternative are the most vulnerable at 10-year average flows of 10.5 maf and 11.4 maf, respectively.

For the full modeling period, the Lake Powell shoreline area robustness figure shows that the No Action Alternative performs the worst, with only 16 percent of the futures below 500 km^2 (123,553 acres) of shoreline area. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs slightly better at 23 percent, then the Basic Coordination Alternative at 27 percent, and then CCS Comparative Baseline at 33 percent. The Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with over 80 percent of the futures below 500 km^2 (123,553 acres) of shoreline area. Similar trends were seen for the 2027–2039, though

with higher percentages. The 2040–2049 and 2050–2060 modeling periods show that the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs the worst, then the No Action Alternative. For the 2027–2039, 2040–2049, and 2050–2060 modeling periods, the Maximum Operational Flexibility and Enhanced Coordination Alternatives have 87 percent or more of the futures below 500 km^2 (123,553 acres) of shoreline area.

The Lake Powell vulnerability plot shows that the Enhanced Coordination and Maximum Operational Flexibility Alternatives are least vulnerable, as fewer than 25 percent of the Drying with Variability traces include a driest 10-year average Lees Ferry annual flow this dry or drier. The CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are vulnerable under flow conditions associated with more than 75 percent of the Drying with Variability traces and are therefore the most vulnerable.

For the Lake Powell WY maximum shoreline dust emissions Average Flow Category, several alternatives have similar medians, though Enhanced Coordination and Maximum Operational Flexibility Alternatives have the lowest median shoreline dust emissions and the smallest variability.

For the Lake Mead WY maximum shoreline dust emissions Average Flow Category, the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives performed the best, with the least shoreline dust emissions. The CCS Comparative Baseline and No Action Alternative perform the worst, with the highest shoreline dust emissions. The Basic Coordination Alternative performs in the middle.

For the full modeling period, the Lake Mead shoreline dust emissions robustness figure shows that the No Action Alternative performs the worst, with only 22 percent of the futures below 500 million kg (1,102 million pounds) of $PM_{2.5}$. The CCS Comparative Baseline performs slightly better at 40 percent, then the Basic Coordination Alternative at 52 percent, and then the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) at 64 percent. The Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with 76 percent and 69 percent, respectively, of the futures below 500 million kg (1,102 million pounds) of $PM_{2.5}$. These same trends were seen for the 2027–2039, 2040–2049, and 2050–2060 modeling periods with higher percentages, and the Maximum Operational Flexibility and Enhanced Coordination Alternatives have 79 percent or more of the futures below 500 million kg (1,102 million pounds) of $PM_{2.5}$.

The Lake Mead vulnerability plot shows that the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are least vulnerable, with vulnerability thresholds corresponding to conditions associated with roughly 25 to 50 percent of the Drying with Variability traces. The CCS Comparative Baseline and Basic Coordination Alternative are vulnerable to conditions associated with roughly 50 to 75 percent of the Drying with Variability traces. The No Action Alternative has a vulnerability threshold of 11.7 maf, which is similar to the driest observed 10-year period of 11.8 maf.

For the full modeling period, the Lake Powell shoreline dust emissions robustness figure shows that the No Action Alternative performs the worst, with only 10 percent of the futures below 450 million kg (992 million pounds) of $PM_{2.5}$. The Basic Coordination Alternative performs slightly better at 21

percent, then the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) at 22 percent, and then CCS Comparative Baseline at 28 percent. The Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with 78 percent or more of the futures below 450 million kg (992 million pounds) of $PM_{2.5}$. These same trends were seen for the 2027–2039 with higher percentages. The 2040–2049 and 2050–2060 modeling periods show that the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) perform the worst, then the No Action Alternative. For the 2027–2039, 2040–2049, and 2050–2060 modeling periods, the Maximum Operational Flexibility and Enhanced Coordination Alternatives have 84 percent or more of the futures below 450 million kg (992 million pounds) of $PM_{2.5}$.

The Lake Powell vulnerability plot shows that the Enhanced Coordination and Maximum Operational Flexibility Alternatives are vulnerable to conditions associated with less than 25 percent of the Drying with Variability traces. The CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives have vulnerability thresholds corresponding to conditions associated with 75 to 100 percent of the Drying with Variability traces and are therefore the most vulnerable alternatives. The No Action Alternative has a vulnerability threshold of 12.2 maf, which is similar to the recently observed 10-year flow of 12.1 maf.

Issue 2: How would lake reservoir elevations and releases impact power generation and CO_2e emissions?

For the Average Flow Category, both Glen Canyon Dam and Hoover Dam show that the Enhanced Coordination and Maximum Operational Flexibility Alternatives have median decreases in CO_2e emissions, with these alternatives having the largest median decrease at Glen Canyon Dam. The Supply Driven Alternatives (both LB Priority and LB Pro Rata approaches) also displays a median decrease in CO_2e emissions, with the LB Pro Rata approach showing the largest median decrease at Hoover Dam. The No Action Alternative displays very little change at Glen Canyon Dam but the largest median increase in CO_2e emissions at Hoover Dam. The Basic Coordination Alternative generally results in smaller median CO_2e emission changes that remain near zero. The Representative Preferred Alternative for both Hoover Dam and Glen Canyon Dam generally result in similar median CO_2e emissions decreases.

For the Average Flow Category, Davis Dam and Parker Dam exhibit similar patterns. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives show median increases in CO_2e emissions and generally the widest interquartile ranges. The No Action, Basic Coordination, and Representative Preferred Alternatives display the smallest median changes in CO_2e emissions, with the No Action Alternative being the only alternative to have a negative median change at both dams.

Issue 3: How would climate trends affect lake reservoir elevations?

Climate trends affects lake reservoir elevations in several interrelated ways, driven largely by changes in temperature, precipitation patterns, and hydrological cycles. Climate trends typically result in more variability and extremes in lake reservoir elevations, which may not be captured specifically in the modeling, but the five flow condition categories help to visualize the different potential states of the system throughout the 34-year period of analysis. Dry flow conditions could represent the lower

lows present during droughts and the wet flow conditions could represent the higher highs during storm events. General discussion of the effects of climate trends on lake reservoirs is discussed but due to uncertainty these effects cannot be determined for each specific alternative. In addition, **TA 3**, Hydrologic Resources, details the lake reservoir elevations for flow categories and alternatives.

Figures

TA 8-1 Inundation of Critical Habitat of Colorado Pikeminnow and Razorback Sucker by Colorado River Inflow: Robustness. Percentage of futures in which the Lake Powell elevation is below 3,598 feet in the percentage of months specified by each row 8-42
TA 8-2 Inundation of Critical Habitat of Colorado Pikeminnow and Razorback Sucker by Colorado River Inflow: Vulnerability. Conditions that could cause Lake Powell to go above 3,598 feet in more than 30 percent of months 8-43
TA 8-3 Inundation of Critical Habitat of Colorado Pikeminnow and Razorback Sucker by San Juan River Inflow: Robustness. Percentage of futures in which the Lake Powell elevation is below 3,600 feet in the percentage of months specified by each row 8-44
TA 8-4 Inundation of Critical Habitat of Colorado Pikeminnow and Razorback Sucker by San Juan River Inflow: Vulnerability. Conditions that could cause Lake Powell to go above 3,600 feet in more than 30 percent of months 8-46
TA 8-5 Piute Farms Waterfall remains a barrier to upstream fish passage: Robustness. Percentage of futures in which the Lake Powell elevation is below 3,666.5 feet in the percentage of months specified by each row 8-47
TA 8-6 Piute Farms Waterfall remains a barrier to upstream fish passage: Vulnerability. Conditions that could cause Lake Powell elevation to go above 3,666.5 feet in 1 or more Months 8-49
TA 8-7 Smallmouth Bass Entrainment: Robustness. Percentage of futures for each alternative in which the October 1st Lake Powell elevation is above 3,570 feet in percent of years specified by each row 8-51
TA 8-8 Smallmouth Bass Entrainment: Vulnerability. Conditions that could cause the October 1 Lake Powell Elevation to go below 3,570 feet in more than 30 percent of years 8-52
TA 8-9 Water Temperature at Lees Ferry Based on 3-year Preceding Average River Temperatures at Lees Ferry Exceeding 12° C, 16 °C, and 20 °C Under Each Alternative 8-58
TA 8-10 Rainbow Trout and Native Grand Canyon Fishes Survival: Robustness. Percentage of futures in which the number of days exceeding 20 °C at Lees Ferry is less than the number of days specified by each row 8-60

TA 8-11 Rainbow Trout and Native Grand Canyon Fishes Survival: Vulnerability. Conditions that could cause the temperature at Lees Ferry to exceed 20°C in one or more days 8-62
TA 8-12 Water Temperature at the Little Colorado River Confluence Based on 3-year Preceding Average River Temperatures at Lees Ferry Exceeding 12 °C, 16 °C, and 20 °C Under Each Alternative 8-63
TA 8-13 Humpback Chub Growth at the Little Colorado River Confluence: Robustness. Percentage of modeled futures in which water temperature at the Little Colorado River confluence exceeds 12 °C for at least the number of days per year specified in each row in 90 percent or more of years. 8-65
TA 8-14 Humpback Chub Spawning at the Little Colorado River Confluence: Robustness. Percentage of futures in which the temperature at the Little Colorado River confluence exceeds 16 °C in the days per year specified by each row in 90 percent or more of years. 8-67
TA 8-15 Water Temperature at the Havasu Creek Confluence Based on 3-year Preceding Average River Temperatures at Lees Ferry Exceeding 12 °C, 16 °C, and 20 °C Under Each Alternative 8-68
TA 8-16 Humpback Chub Growth at the Havasu Creek Confluence: Robustness. Percentage of futures in which the temperature at the Havasu Creek confluence exceeds 12 °C in the days specified by each row in 90 percent or more of years. 8-70
TA 8-17 Humpback Chub Spawning at the Havasu Creek Confluence: Robustness. Percentage of futures in which the temperature at the Havasu Creek confluence exceeds 16 °C in the days specified by each row in 90 percent or more of years. 8-71
TA 8-18 Water Temperature at Pearce Ferry Based on 3-year Preceding Average River Temperatures at Lees Ferry Exceeding 12 °C, 16 °C, and 20 °C Under Each Alternative 8-73
TA 8-19 Humpback Chub Growth at Pearce Ferry: Robustness. Percentage of futures in which the temperature at Pearce Ferry exceeds 12 °C in the days specified by each row in 90 percent or more of years 8-74
TA 8-20 Humpback Chub Spawning at Pearce Ferry: Robustness. Percentage of futures in which the temperature at Pearce Ferry exceeds 16 °C in the days per year specified by each row in 90 percent or more of years. 8-76
TA 8-21 5-Year Smallmouth Bass Growth Rate: Robustness. Percentage of futures in which the 5-year product of Smallmouth Bass growth rate (lambda) at Lees Ferry is always less than the value specified by each row 8-78
TA 8-22 5-Year Smallmouth Bass Growth Rate: Vulnerability. Conditions that could cause the 5-year smallmouth bass population growth rate to be at least 1 in one or more years 8-79
TA 8-23 Smallmouth Bass Entrainment and Survival: Robustness. Percentage of futures in which the annual count of adult smallmouth bass that are entrained and survive is always less than amount specified by each row 8-81
TA 8-24 Smallmouth Bass Entrainment and Survival: Vulnerability. Conditions that could cause the count of smallmouth bass entrained and surviving in any year to be 50 individuals or more 8-82
TA 8-25 Pearce Ferry Rapids as Nonnative Fish Barrier: Robustness. Percentage of futures in which Lake Mead elevation stays below 1,090 feet in the percentage of months specified by each row 8-84

TA 8-26 Pearce Ferry Rapid remains a barrier to upstream fish passage: Vulnerability. Conditions that could cause Lake Mead elevation to go above 1,090 feet in more than 10 percent of months 8-86
TA 8-27 Lake Mead Historical Minimum Shoreline Habitat: Robustness. Percentage of futures in which Lake Mead elevation remains above the historical minimum elevation (1,040.92 feet) in the percentage of months specified by each row 8-88
TA 8-28 Lake Mead Historical Minimum Shoreline Habitat: Vulnerability. Conditions that could cause Lake Mead to fall below 1040.92 feet in more than 10 percent of months 8-90
TA 8-29 Below Hoover Monthly Flows: Robustness. Percentage of futures in which monthly releases from Hoover Dam are within the range observed during the 2007 Interim Guidelines period in the percentage of months specified by each row 8-92
TA 8-30 Hoover Dam Monthly Releases Under Varying 3-Year Average Lees Ferry Inflows with Alternative Futures. Boxplots Show the Distribution of Annual Minimum (Left) and Annual Maximum (Right) Monthly Releases Across Simulated Futures, Thousand Acre-Feet 8-94
TA 8-31 Summary of Robustness Results across Issues by Indicator at Reported Thresholds for Each Alternative 8-96

TA 8. Biological Resources – Fish and Other Aquatic Species

TA 8.1 Affected Environment

The affected environment includes a diverse range of aquatic organisms, including foundational elements of the food web that support native and nonnative fish populations. Native fish species analyzed in this section are special status species, including federally threatened and endangered species, range-wide conservation species, Bureau of Land Management sensitive species, and Lower Colorado River Multi-Species Conservation Program (LCR MSCP) covered species. Nonnative fish species analyzed in this section include cold-water and warmwater species (see **TA 8 Attachment 1** for detailed life histories and distributions), including state-regulated sportfish. By affecting areas within the channel, along the shorelines, in backwaters, and at the mouths of tributaries, variations in river flow can impact these aquatic organisms and their habitats.

TA 8.1.1 Aquatic Food Base

The basic components of the aquatic food base are invertebrates, algae, rooted plants, and organic matter (Gloss et al. 2005). Although most of this food base is produced within the aquatic system, terrestrial inputs of organic matter and invertebrates also contribute. In turn, in-stream production of algae and invertebrates supports terrestrial consumers, such as grasshoppers and spiders, insectivorous birds and bats, reptiles, amphibians, mammals, and waterfowl. Indirect links include peregrine falcons, belted kingfishers, osprey, great blue herons, and bald eagles, which feed on fish or waterfowl that consume aquatic food base organisms (Bastow et al. 2002; Baxter et al. 2005; Sabo and Power 2002; Shannon et al. 2003; Stevens and Waring 1986; Yard et al. 2011). A description of the aquatic food base prior to and following Glen Canyon Dam's construction and operation can be found in the 2016 Glen Canyon Dam Long-Term Experimental and Management Plan (LTEMP) Final Environmental Impact Statement (EIS; Reclamation and NPS 2016) and was supplemented in the Glen Canyon Dam LTEMP Final Supplemental EIS (2024 LTEMP Final SEIS; Reclamation 2024). The following discussion includes invasive aquatic species that have affected or may affect food base organisms of the Colorado River ecosystem.

The aquatic food base's major groups include (1) periphyton (e.g., algae and cyanobacteria that live attached to rocks and other surfaces) and rooted aquatic plants, (2) plankton (very small plants [phytoplankton] and animals [zooplankton] that occur in the water column), and (3) macroinvertebrates (invertebrates that are visible to the naked eye). Large mainstream dams on the Colorado River have altered the river's physical, chemical, and biological characteristics by changing the flow, temperature, sediment, and salinity regimes (Cross et al. 2013). Nutrients and sediments have become trapped in reservoirs, such as Lake Powell, which has depleted the downstream reaches of important carbon sources for primary and secondary production and the foundational

sands and silts for the establishment of rooted vegetation that supports diverse riparian animal communities (Johnson and Carothers 1987). These changes have altered riverine food webs, reduced biodiversity, and often led to the extirpation of native species while facilitating the invasion of nonnative species (Miller 1961).

After Glen Canyon Dam was constructed, the combination of altered flows and temperatures, reduced organic inputs from areas upstream, decreased turbidity, and the altered thermal regime led to a shift in the Colorado River's aquatic food base downstream of the dam (Benenati et al. 2002; Blinn et al. 1995; Kennedy and Gloss 2005). In general, aquatic invertebrate diversity declined while density and biomass increased (Kennedy and Gloss 2005). The influence of Glen Canyon Dam, coupled with sediment inputs from tributary streams, resulted in a stepwise decrease in food base biomass in the Colorado River due to clear, cold hypolimnetic dam releases and downstream increases in turbidity from tributary sediment inputs. In the post-dam period, the 16-mile reach of Glen Canyon from the dam to Lees Ferry accounted for 69 percent of the algal and 50 percent of the macroinvertebrate mass collected throughout a 224-mile section of river downstream of the dam (Melis 2011). High sediment inputs from tributary streams downstream of the Paria River have resulted in an aquatic food base with lower biomass and species diversity. Suspended sediments increase turbidity, and deposited sediments alter substrate characteristics (Shannon et al. 1994; Shannon et al. 2001; Melis 2011). Thus, the aquatic food bases of the tailwater section (between the dam and the Paria River [Lees Ferry sub-reach]) differ from the rest of the mainstem (between the Paria River and Diamond Creek). In the clear tailwaters of the Lees Ferry sub-reach, aquatic productivity is driven primarily by photosynthetic production of algae, diatoms, and macroinvertebrates. The Colorado River downstream of the Paria River is seasonally influenced by tributary sediment and organic matter inputs, making the river more like pre-dam conditions, particularly as the distance from the dam increases (Rosi-Marshall et al. 2010) and water temperatures equilibrate with air temperature (i.e., warm in summer and cool in winter).

Most aquatic insects have complex life cycles with a terrestrial winged adult stage, while the egg, larval, and pupal stages are aquatic. Approximately 80 percent of adult aquatic insects (Kennedy et al. 2016) use river edge habitats for egg laying, whereby eggs are cemented onto rocks or vegetation along the river edge and just under the water surface. Brief desiccation of insect eggs (on a scale of hours), as is typical of eggs laid in the varial zone (water-shoreline interface that is wet and dry daily due to dam operations), leads to high mortality (Kennedy et al. 2016). This egg mortality effect is evident throughout the Grand Canyon, with aquatic insects more abundant where the timing of daily low flows coincides with peak egg-laying activity (i.e., late afternoon), because eggs laid in these locations are never subjected to desiccation-induced mortality. Additional evidence of this egg mortality effect is seen by comparing insect diversity downstream of dams throughout the western United States (U.S.), with insect diversity being strongly and negatively correlated to the degree of hydropower production (Kennedy et al. 2016). Thus, the varial zone downstream of hydropower dams, such as Glen Canyon, reduces the quality and availability of river edge habitats that aquatic insects use for their egg laying; this constrains both the diversity and abundance of aquatic insects present in these ecosystems and affects food sources for sensitive fish species. "Bug flows" were implemented as experimental releases from Glen Canyon Dam to increase the abundance (number of individuals) and diversity (number of species) of insects in the Grand Canyon by improving egg-

laying conditions (GCMRC 2022). These experiments were conducted in compliance with the 2016 LTEMP and are not associated with this EIS.

The Colorado River system is near large human population centers and is susceptible to the introduction of invasive aquatic species. Recreational boaters and anglers have inadvertently spread quagga mussels (*Dreissena bugensis*), New Zealand mud snails (*Potamopyrgus antipodarum*), and numerous aquatic plants into numerous locations of the Colorado River. Other nonnative and invasive species that have potentially detrimental effects on both the food base and fish communities have been established in the Colorado River. Nonnative and invasive species introductions, as related to the Colorado River food base, are discussed in detail in the 2024 LTEMP Final SEIS (Reclamation 2024).

TA 8.1.2 Fish Species

The Colorado River and its tributaries have supported a unique and highly indigenous native fish assemblage, as well as approximately 67 nonnative species introduced over the last century (Valdez and Muth 2005), primarily to sustain and support recreational sport fisheries. Because of a prolonged period of geologic isolation, particularly in the Upper Basin, the Colorado River had only 35 native fish species that were freshwater or euryhaline species (Miller 1955, 1958), including 14 in the Upper Basin (Valdez and Muth 2005). Of the 35 species native to the Colorado River system, 26 (74 percent) were endemic, or found in no other river basin on earth (Miller 1958). Of the 35 species, 3 are extinct, and 12 are listed as federally endangered or threatened (Bestgen et al. 2020; Minckley et al. 2003; Reclamation 2024). The fish species analyzed in this section are included in the 35 native species.

Native Fish Species

There are eight native fish species in the analysis area. Five of these species—the humpback chub (*Gila cypha*), razorback sucker (*Xyrauchen texanus*), Colorado pikeminnow (*Ptychocheilus lucius*), bonytail *(Gila elegans),* and desert pupfish (*Cyprinodon macularius*)—are federally listed, and the bluehead sucker (*Pantosteus discobolus*) and flannelmouth sucker (*Catostomus latipinnis*) are conservation species. The speckled dace (*Rhinichthys osculus*) is a sensitive species. The status and distributions of these native species in the analysis area are shown in **Table TA 8-1**. The roundtail chub (*Gila robusta*) was reported downstream of Lava Cliff Rapid (river mile [RM] 246) in the 1940s before the area was inundated by Lake Mead (Miller 1958), but it has not been subsequently observed in the mainstem downstream of Lake Powell. The species persists in the Little Colorado River in reaches outside the analysis area and is not included in the analyses.

Table TA 8-1
Native Fish of the Colorado River in the Analysis Area

Species	Listing Status[1]	Presence in Analysis Area[2] (river miles downstream from Lees Ferry)
Humpback chub (*Gila cypha*)	ESA-T, CH; AZ-SGCN	30-Mile Spring (29.8) to Pearce Ferry (280.7); Little Colorado River (61.8); translocated to Shinumo (109.2), Havasu (157.3), and Bright Angel (88.3) creeks. Some individuals occur downstream of Pearce Ferry and Pearce Ferry Rapid.

Species	Listing Status[1]	Presence in Analysis Area[2] (river miles downstream from Lees Ferry)
Razorback sucker (*Xyrauchen texanus*)	ESA-E, CH; AZ-SGCN	Bright Angel Creek (88.3) confluence to Pearce Ferry (280.7); few upstream of Lava Falls (179.7); much of Lake Powell, Lake Mead, Lake Mohave, and Lake Havasu, as well as the much of the Lower Colorado River proper
Bonytail (*Gila elegans*)	ESA-E, CH; AZ-SGCN	Stocked in Lake Powell and Lower Colorado River reservoirs, the Lower Colorado River proper and its backwaters; recent bonytail larvae in Lake Powell indicate reproduction.
Colorado pikeminnow (*Ptychocheilus lucius*)	ESA-E, CH; AZ-SGCN	Colorado River and San Juan River inflows to Lake Powell as extensions of upstream populations
Desert pupfish (*Cyprinodon macularius*)	ESA-E, CH; AZ-SGCN	No natural, extant populations found in or along the Lower Colorado River. Isolated, constructed refuge ponds in the Bill Williams and Cibola National Wildlife Refuges
Flannelmouth sucker (*Catostomus latipinnis*)	NL; CSp; AZ-SGCN	Glen Canyon Dam (-15.8) to Pearce Ferry (280.7), including tributaries, inflow areas of Lake Powell and Lake Mead, as well as the reintroduced population downstream of Davis Dam
Bluehead sucker (*Pantosteus discobolus*)	NL; CSp; AZ-SGCN	Paria River (0.8) to Pearce Ferry (280.7), including tributaries
Speckled dace (R*hinichthys osculus*)	NL; AZ-SGCN	Paria River (0.8) downstream to Pearce Ferry (280.7), including tributaries

[2]Habitat and life-history information is presented in species-specific descriptions in this section.

Nonnative Fish Species

Generally, nonnative fish species in the Colorado River system pose risks to native fish species through competition for resources, predation, and habitat alteration. In limited cases, nonnative fish species in the Colorado River Basin can provide beneficial effects (i.e., fishing and providing forage for other sportfish [see **TA 14.1.11**, Sportfishing, in **TA 14**, Recreation]) depending on their location in the system and their recreational value. Reservoirs frequently support large populations of nonnative sportfish, and the tailwater of Glen Canyon Dam supports a high-value trout fishery. When nonnative species move outside of these sportfishing areas, they pose threats to native fish communities. In 2021 the National Park Service (NPS) Expanded Nonnative Aquatic Species Management Plan in Glen Canyon National Recreation Area (NRA) and Grand Canyon National Park (2018) was updated to better reflect the threat level of nonnative fish in Glen Canyon NRA and Grand Canyon National Park, below Glen Canyon Dam, based on their potential for predation, competition, or other adverse interactions with native and federally listed species, as well as to the

recreational rainbow trout (*Oncorhynchus mykiss*) fishery in the Lees Ferry sub-reach (NPS 2021). Four species were assigned a threat level of "(1) Very High," including smallmouth bass (*Micropterus dolomieu*), walleye (*Sander vitreus*), flathead catfish (*Pylodictis olivaris*), and brown trout (*Salmo trutta*). Five species were assigned a threat level of "(2) High," including rainbow trout (high in Grand Canyon National Park, low in Glen Canyon NRA), northern pike (*Esox lucius*), green sunfish (*Lepomis cyanellus*), striped bass (*Morone saxatilis*), white sucker (*Catostomus commersonii*), and burbot (*Lota lota*).

Nonnative, predatory species known to occur within the Upper and Lower Colorado River are black bullhead (*Ameiurus melas*), black crappie (*Pomoxis nigromaculatus*), white crappie (*Pomoxis annularis*), channel catfish (*Ictalurus punctatus*), common carp (*Cyprinus carpio*), largemouth bass (*Micropterus salmoides*), striped bass, walleye, yellow bullhead (*Ameiurus natalis*), bluegill (*Lepomis macrochirus*), green sunfish, northern pike, and tiger muskie (*Esox lucius* × *Esox masquinongy*) (UDWR 2023).

TA 8.1.3 Reaches

Table TA 8-2 provides a complete list of the native and nonnative fish species within the analysis area, including the Colorado River from Lake Powell downstream to the Southerly International Boundary (SIB). The scientific name and conservation status of each species is presented in the table, and species present within each reach are shown in the table and described in more detail in the respective sections.

Lake Powell

For this analysis, the Lake Powell reach includes approximately 250 mi² covered by the lake (Root and Jones 2022) at its full elevation of 3,700 feet, including the inflows of two major rivers, the Colorado River and the San Juan River. Low levels of Lake Powell, starting with a receding reservoir in the year 2000, resulted in the creation of approximately 35 miles of additional riverine habitat for each of these rivers. As the lake recedes, the rivers carve through the existing sediment deposits, periodically deviating from their historical channels to carve new channels and in some cases, forming waterfalls that block the upstream movement of fish. On the San Juan River, there is an approximately 30-foot waterfall at Piute Farms acting as a major fish barrier (Cathcart et al. 2018; Pennock et al. 2024). The rapid incision rates in the Colorado River channel near the mouth of the Dirty Devil have eroded lake deposits, but the underlying bedrock has not yet been reached. If, upon further incision, the river encounters bedrock or another resistant layer, it is possible that rapids or waterfalls could form on the order of ~1 meter to ~10 meters (~3.3 to 33 feet; Arens 2023; Grams and Tusso 2023). At full pool, Lake Powell has a maximum depth of 568 feet. Lake Powell warms seasonally with the warmest surface temperatures of about 30 degrees Celsius (°C; 86 degrees Fahrenheit [°F]) in July and the coldest of about 5.5 °C (41.9 °F) in January. There is some ice formation along shorelines and sheltered bays in winter, but most of the lake remains ice-free. Lake Powell is a monomictic reservoir with strong thermal stratification through much of the spring, summer, and early fall, with the warmest surface layer (epilimnion) persisting from about May to October, a middle layer (metalimnion) where there is a steep transition between warm and colder water, and the lowest level (hypolimnion) with colder, typically hypoxic, conditions. Inflow from the Colorado River and the San Juan River generally flows into the hypolimnion but may mix with other layers depending on inflow density. At lower reservoir elevations, the metalimnion or epilimnion layers can extend down to the depth of the penstocks (3,470 feet elevation), resulting in warmer

Table TA 8-2
Native and nonnative fish species in the Colorado River from Lake Powell downstream to the SIB

Common Name	Scientific Name	Status[a]	Lake Powell	Glen Canyon Dam to Pearce Ferry	Lake Mead	Downstream of Hoover Dam to Lake Mohave	Davis Dam to Parker Dam	Parker Dam to Imperial Dam	Imperial Dam to the SIB
					LCR MSCP Reach 1	LCR MSCP Reach 2	LCR MSCP Reach 3	LCR MSCP Reach 4, 5	LCR MSCP Reach 6, 7
Native Species									
bluehead sucker	*Pantosteus discobolus*	RWCS, BLM	Present in small numbers in reservoir and river inflows [1]	Abundant in tributaries and tributary mouths, present in mainstem [2]	Occasionally found at the Colorado River inflow area. [3, 4, 5]	Absent	Absent	Absent	Absent
bonytail	*Gila elegans*	FE, BLM, LCR MSCP	Juveniles (<111 mm total length) stocked by UDWR in 2022; rarely captured [6]	Two individuals captured in Lees Ferry sub-reach in 2023, likely pass through the dam from Lake Powell [6]	Only one record from Las Vegas Bay. [3, 4, 5]	Repatriation efforts; limited numbers. [3, 4]	Topock Gorge and upper Lake Havasu; annual stocking; occasionally found in backwaters downstream of Davis Dam. [3, 4]	Stocked; utilize backwater and riverine habitat. [3, 4]	Absent
Colorado pikeminnow	*Ptychocheilus lucius*	FE	Rare in the reservoir; numerous in Colorado River and San Juan River inflows drifting from upstream [7, 8]	Absent	Absent	Absent	Absent	Absent	Absent

release temperatures. Historically, the warmest release temperatures occurred in October and November as the reservoir cooled and mixed (Hueftle and Stevens 2001). In recent years, with lower reservoir elevations, the warmest months are early in the year, during September and October.

Preliminary analyses of long-term trends in limnological (aquatic ecosystem) data reveal directional changes in several parameters in Lake Powell over recent decades (Deemer et al. 2023). These initial data analyses suggest an increase in surface phytoplankton biovolume (algal biomass), which may be accompanied by changes in community composition and could have cascading effects on ecosystem function and water quality management. For example, cyanobacterial genera across all sites appear to have shifted considerably since the beginning of monitoring (1993–1997) compared to recent years (2017–2021). These community shifts could translate into changes in algal toxin formation and/or in the edibility of aquatic grazers. With the increasing frequency of harmful algal blooms, this could mean critical changes to Lake Powell's water quality for human use and aquatic life.

Altogether, there are six species of native fish analyzed in Lake Powell, including bonytail, bluehead sucker, Colorado pikeminnow, flannelmouth sucker, razorback sucker, and speckled dace (**Table TA 8-2**; Mueller et al. 2001). Bonytail were intentionally introduced into Lake Powell in 2022 by the Utah Division of Wildlife Resources (Smith 2022), and fish stocked upstream in the Upper Colorado and Green Rivers have moved into the reservoir (FWS 2024a). Colorado pikeminnow were found in the lake as it was reaching maximum pool elevation in 1980; these fish were likely migrating upstream to spawning sites in the Colorado River (Persons et al. 1982; Valdez et al. 1982). Today, Colorado pikeminnow in the lake are found mostly in the inflows of the Colorado and San Juan Rivers (Pennock et al. 2024; FWS 2022). Bluehead sucker and flannelmouth sucker are present in small numbers in the reservoir and river inflows, and razorback sucker are found in small numbers in the reservoir but are more common in the river inflows (Schleicher et al. 2024). Durst and Francis (2016) reported four razorback suckers moving from the San Juan Arm across Lake Powell and up the Colorado River, indicating movement across the Basin. The speckled dace is found in small numbers along the shoreline and canyons of the lake. Humpback chub were found in Lake Powell as the reservoir was filling and inundating the lower Cataract Canyon population (Valdez et al. 1982), but the species is not a lake species and has not persisted in the reservoir (Valdez 1990; Mueller et al. 2001).

There are at least 17 nonnative fish species in Lake Powell, including 12 state-regulated sportfish and 5 forage fish species (**Table TA 8-2**). Lake Powell is one of the more popular warmwater recreational lake fisheries in the southwestern U.S. The most common and popular sportfish caught by anglers are largemouth bass, black crappie, channel catfish, smallmouth bass, striped bass, walleye, bluegill, green sunfish, and bullheads (UDWR 2023).

Two species of nonnative bivalves have been discovered in Lake Powell: the Asian clam (*Corbicula fluminea*) and the quagga mussel. The Asian clam was first found in Lake Powell in 1991 (USGS 2024), and the quagga mussel was found in 2012 (Verde 2017). Both species are filter feeders that can alter the composition of plankton communities in lakes and reservoirs. Zebra mussels (*Dreissena polymorpha*), a close relative of the quagga mussel, have been implicated in promoting *Microcystis* in noneutrophic waters (Verde 2017). *Microcystis* is a genus of freshwater cyanobacteria that includes the harmful algal bloom-forming *Microcystis aeruginosa*. Many members of a *Microcystis* community can

produce neurotoxins and hepatotoxins, such as microcystin and cyanopeptolin, that pose a human health risk when ingested via untreated water.

Quagga mussels can disrupt the pelagic arm of the food web by interfering with the link between phytoplankton and herbivorous zooplankton (Verde 2017). This will likely have negative impacts on pelagic fish, such as striped bass and their main prey, threadfin shad (*Dorosoma petenense*), which rely on mid-water plankton. Quagga mussels may also boost benthic productivity in the littoral zone by diverting nutrients from the water column to the benthos following filtration and fecal output. This may have positive impacts on littoral fishes, such as largemouth bass, smallmouth bass, bluegill, and green sunfish.

Glen Canyon Dam to Pearce Ferry at Lake Mead

The Colorado River from Glen Canyon Dam to Pearce Ferry at Lake Mead spans approximately 295 miles through Arizona (USGS 2023). As the Colorado River exits Glen Canyon Dam, it flows through a series of rugged and steep canyons, including Glen Canyon (from the dam to the Paria River), Marble Canyon (from the Paria River to the Little Colorado River), and Grand Canyon (from the Little Colorado River to the Grand Wash Cliffs, RM 276). Pearce Ferry (RM 280) is 4 miles downstream of Grand Wash Cliffs. The river corridor in this reach is included in or borders Glen Canyon NRA, Grand Canyon National Park, the Hualapai Indian Reservation, the Navajo Nation, and Lake Mead NRA. This reach of the Colorado River has several major tributaries, including the Paria River, Little Colorado River, Clear Creek, Bright Angel Creek, Shinumo Creek, Tapeats Creek, Deer Creek, Kanab Creek, Havasu Creek, Diamond Creek, and Spencer Creek, along with numerous ephemeral tributaries.

Since the closure of Glen Canyon Dam in 1963, the Grand Canyon reach of the Colorado River has supported few native fish species due to extreme seasonal changes in flow and temperature, with substantial ecological shifts occurring in this reach (see **TA 8 Attachment 1** for details). Currently, the Grand Canyon supports a native-dominated fish community, with the highest abundance of humpback chub anywhere in its current range and flourishing populations of bluehead and flannelmouth sucker. The fish community is influenced by the river's complex flow patterns, variable water temperatures, and a diversity of habitats that reflect shoreline geology (Valdez and Ryel 1995). Today, five of the originally common species are known to persist in the Grand Canyon reach (**Table TA 8-2**). Native fish species analyzed in this reach include the endangered razorback sucker, the threatened humpback chub, as well as bluehead sucker, flannelmouth sucker, and speckled dace (NPS 2023a) (**Table TA 8-2**). Colorado pikeminnow, roundtail chub, and bonytail are extirpated from this reach. However, two bonytail have recently been detected in the reach and most likely moved from Lake Powell through Glen Canyon Dam. A proposal was also developed to evaluate the feasibility of stocking Colorado pikeminnow in the Grand Canyon, aiming to boost the recovery and resilience of this endangered species. An expert science panel reviewed current river conditions and concluded that the Grand Canyon now offers suitable habitat for adult and subadult pikeminnow, though limited juvenile survival may constrain recruitment. The panel recommended that experimental stocking, monitoring, and further research could help determine the viability of reintroduction in this changing environment (Dibble et al. 2023).

Nonnative fish species include rainbow trout, brown trout, largemouth bass, green sunfish, channel catfish, fathead minnow (*Pimephales promelas*), smallmouth bass, and other less common species (NPS 2023a; Shollenberger et al. 2025) (**Table TA 8-2**). Results from 2024 sampling (Shollenberger et al. 2025) indicate that smallmouth bass detections were highest between Glen Canyon Dam and the Paria River, with capture rates decreasing substantially downstream; however, the majority of sampling efforts were concentrated within the first 24 river miles downstream of Glen Canyon Dam. Electrofishing and netting efforts confirmed that smallmouth bass were rare in the lower reaches, with the most downstream detection at RM 16.4 in 2023 and 15.27 in 2024. The furthest downstream eDNA detection was at RM 37.5. Juvenile smallmouth bass were captured in 2022 and 2023 in the Lees Ferry sub-reach, which indicated reproduction (Reclamation 2025). In 2024, experimental low-temperature dam releases (cool mix flows) were initiated to prevent the establishment of a smallmouth bass population below Glen Canyon Dam (Reclamation 2024). No smallmouth bass nests were observed, no young-of-year were captured, and no evidence of recruitment was detected in 2024 following that experiment (Reclamation 2025). A significant increase in green sunfish captures was observed during the fall of 2023 compared to previous years, suggesting a strong recruitment and/or entrainment event. However, cooler conditions in 2024 likely prevented a similar influx of juvenile green sunfish, as suggested by lower capture rates in fall months. Green sunfish also exhibited reduced recruitment and/or entrainment and larger average sizes in 2024, suggesting minimal reproduction (Reclamation 2025). Entrainment modeling (Eppehimer et al. 2025) shows that the risk of smallmouth bass invasion below Glen Canyon Dam increases as Lake Powell elevation drops below 3,530 feet. It is especially hard to control entrainment below 3,510 feet with penstock releases. Keeping reservoir elevations above 3,570 feet can substantially reduce this risk. Lower lake levels also result in warmer downstream water, which favors nonnative fish that threaten native and Endangered Species Act (ESA)-listed species. If smallmouth bass establish downstream, removal would be difficult and costly (Eppehimer et al. 2025).

Flannelmouth sucker and bluehead sucker are "conservation species" that are included in a range-wide conservation agreement among six states (UDWR 2006). These species are found as self-sustaining populations and are locally common in the Colorado River from Glen Canyon Dam to Lake Mead (Kegerries et al. 2020). They are seasonally abundant during spring spawning runs into tributaries of the Colorado River, such as the Paria River, Havasu Creek, Kanab Creek, and Tapeats Creek. Both species have adjusted to changing riverine conditions following the construction of Glen Canyon Dam (Paukert and Rogers 2004; Valdez and Carothers 1998). Speckled dace are common to abundant within tributaries and near tributary inflows, as well as on rocky debris fans formed by debris flows from side canyons (Valdez and Ryel 1995; Kegerries et al. 2020). Flannelmouth sucker and bluehead sucker abundance typically increases with distance downstream of the Little Colorado River and is generally high near major tributary confluences, such as the Little Colorado River, Paria River, Kanab Creek, and Bright Angel Creek (Johnstone et al. 2003; Johnstone and Lauretta 2004; Rogowski et al. 2017).

The humpback chub population expanded in the western Grand Canyon in 2016. This is likely due to the warmer water and the lack of predators in the lower Grand Canyon (Dzul et al. 2023; Van Haverbeke et al. 2017; Rogowski et al. 2018; Kegerries et al. 2020; Rogers et al. 2023). As of 2022, a growing population of 50,000-84,000 adults between Havasu Rapids and Pearce Ferry was reported

(Van Haverbeke et al. 2023) and considered a single genetic population (Dzul et al. 2025). Since 2000, larvae and adult razorback suckers have also been found in the Colorado River inflow at the lower end of the Grand Canyon (and within Lake Mead proper), including sonic-tagged adults moving from one of the three Lake Mead populations (Kegerries et al. 2017a, 2017b). A confirmed spawning site was discovered in 2010 about 10 miles downstream of Pearce Ferry (Albrecht et al. 2010; Valdez et al. 2012; Albrecht et al. 2017). Although annual surveys for larval and small-bodied razorback suckers have been conducted in the Grand Canyon since 2014, no small-bodied fish have been detected, and larval fish have not been detected since 2019. The razorback sucker in the Grand Canyon is found primarily downstream of Lava Falls Rapid, with individuals rarely found upstream (Kegerries et al. 2020; Rogers et al. 2023). In 2024, 790 razorback suckers tagged with a passive integrated transponder (PIT) were stocked into the Little Colorado River; 70 were detected near the confluence with the Colorado River, and another 6 were recaptured in the Little Colorado River and the mainstream Colorado River (Ward and Wood 2025).

A total of 18 nonnative fish species have been reported between Glen Canyon Dam and Lake Mead from 1957 through 2023 (Valdez and Ryel 1995; Trammell et al. 2002; Fonken et al. 2023; Fennell et al. 2024). Native fish continue to dominate abundance, as total fish numbers, in the Grand Canyon fish community (Kegerries et al. 2020; Dzul et al. 2023). Small-bodied, nonnative fish like the fathead minnow, red shiner (*Cyprinella lutrensis*), and plains killifish *(Fundulus zebrinus*) are predominantly found downstream of the Little Colorado River confluence. Nonnative fish, including the golden shiner (*Notemigonus crysoleucas*), redside shiner, striped bass, and threadfin shad, infrequently occur in this reach. Evidence strongly indicates that this tributary is the primary source of these species in the Colorado River ecosystem (Johnstone et al. 2003), although additional sources include entrainment through Glen Canyon Dam, upstream movement from Lake Mead, and other tributaries (Rogowski et al. 2017).

The primary sportfish in the Colorado River between Glen Canyon Dam and Lake Mead inflow is the rainbow trout, which is maintained by the NPS and Arizona Game and Fish Department (AZGFD) in Lees Ferry as a recreational fishery. Natural reproduction of rainbow trout that move downstream in the Grand Canyon is dependent on cool water temperatures, access to tributaries for spawning, and continued availability of suitable mainstream habitat. These variables are directly affected by patterns and temperatures of water released from Lake Powell. McKinney and Speas (2001) found that *Gammarus*, chironomids, and Cladophora constituted about 90 percent of rainbow trout's food by volume during cold releases. In more recent warm releases, the diet of rainbow trout has shifted toward a greater variety of invertebrate and algal species, with midges and blackflies as major components (Cross et al. 2013).

Humpback chub rely on *Gammarus* and chironomids, but also consume larval simuliids (blackflies), which become more common downstream of the Paria River (Gloss et al. 2005). *Cladophora*, *Oscillatoria* spp., and terrestrial organic matter serve as key energy sources for aquatic invertebrates between Glen Canyon Dam and Lake Mead. *Cladophora* and *Oscillatoria* are also consumed by fish, largely because of the dense populations of lipid-rich diatoms (Gloss et al. 2005).

In 2012, the quagga mussel was found in Lake Powell (Verde 2017) and was identified in sampling locations between Glen Canyon Dam and Lees Ferry in November 2014. Mussels continue to be

found in the river downstream of the dam. Their distribution is patchy and highly influenced by fluctuating water levels and location-specific flow regimes (NPS 2023b). Kennedy (2007) reported that the risk of quagga mussels establishing within the Grand Canyon is generally low, except for the Lees Ferry tailwater reach, where the risk is high. Conditions within the Lees Ferry tailwater generally appear suitable for quagga mussel establishment, except for the high average water velocity. High suspended sediment, high ratios of suspended inorganic to organic material, and high-water velocities limit the quagga mussel's ability to establish at high densities within the Grand Canyon or its tributaries. Additionally, the rapids in the Grand Canyon contribute to high mortality rates for larval quagga mussels, limiting their ability to disperse and colonize downstream reaches.

The New Zealand mud snail has rapidly spread across the western U.S. and was first detected in the tailwaters downstream of Glen Canyon Dam in March 2002. Further investigations in the Grand Canyon revealed its presence more than 225 miles downstream from the dam (Cross et al. 2013), suggesting that it had been introduced several years prior. In suitable habitats, mud snail populations can exceed densities of 100,000 individuals per square meter. The species is known to cause ecological changes, including alterations in primary production and reductions in native invertebrate populations in the rivers it invades. New Zealand mud snail populations can increase quickly with suitable temperatures and riverine conditions and are of concern due to their potential impacts on native species, fisheries, and food web dynamics within the Grand Canyon (Cross et al. 2013; NPS 2015).

LCR MSCP Reaches

The LCR MSCP planning area comprises areas up to and including the full-pool elevations of Lakes Mead (1,229 feet), Mohave (647 feet), and Havasu (450 feet), and the historical floodplain of the Colorado River from Lake Mead to the SIB. Downstream of Hoover Dam to the SIB, mitigation and conservation measures to address potential impacts of reduced river flows have already been identified through recent ESA consultation processes. The 2023 biological assessment (LCR MSCP 2023) and the subsequent 2024 biological opinion (BO; FWS 2024b) prepared for the 2024 LTEMP Final SEIS (Reclamation 2024) evaluated the effects of reduced flows between approximately 1.574 and 2.083 maf and identified impacts on approximately 109 acres of backwater habitat and 41 acres of marsh habitat. As part of that consultation, Reclamation and FWS agreed to habitat creation to offset these impacts. The BO also established conservation measures to address potential ecological effects associated with low-flow conditions. These include actions to minimize impacts on covered species habitats at Topock Marsh while longer-term habitat measures are implemented, as well as additional short-term measures that would be implemented if flows were reduced between approximately 2.083 and 3 maf. These measures include minimizing the potential for stranding of native fishes due to reduced river stage, reducing impacts on entrained or stranded native fishes, minimizing effects on fish augmentation activities, and coordinating with mainstem national wildlife refuges to enhance and protect existing habitat areas.

For purposes of the Fish and Other Aquatic Species section of this document, we utilize the following reaches, as defined within LCR MSCP (2004):

Reach 1—from Separation Canyon (Grand Canyon RM 240) in the lower end of the Grand Canyon to Hoover Dam (Colorado RM 342.2), including Lake Mead up to full-pool elevation.

Reach 2—from Hoover Dam to Davis Dam (RM 276), including Lake Mohave up to full-pool elevation.

Reach 3—from Davis Dam (RM 276) to Parker Dam (RM 192.3), including Lake Havasu up to full-pool elevation.

Reach 4—from Parker Dam (RM 192.3) to Adobe Ruin and Bureau of Reclamation (Reclamation) Cibola Gage (RM 87.3) at the lower end of Reclamation's maintenance Cibola Division.

Reach 5—from Reclamation Cibola Gage (RM 87.3) to Imperial Dam (RM 49.2).

Reach 6—from Imperial Dam (RM 49.2) to the Northerly International Boundary (RM 23.1); and

Reach 7—portion of the Lower Colorado River from Northerly International Boundary (RM 23.1) to SIB (RM 0.0) within the U.S.

Note that due to the nature of the river downstream of LCR MSCP Reaches 4 and 5, particularly the scarcity of native and ESA-listed fishes and their survival, along with the current allocation of LCR MSCP fish sampling efforts primarily in Reaches 4–5 (J. Stolberg, LCR MSCP, personal communication; LCR MSCP 2024), we will present information from Reaches 4–5 as the lowest-most combined reach routinely sampled (from Parker Dam [RM 192.3] to Imperial Dam [RM 49.2]). We will not present data for Reaches 6–7 of the LCR MSCP.

LCR MSCP Reach 1- Lake Mead

Lake Mead has four major basins that tend to be separated by narrow connective canyons. In order from upstream to downstream, these include Gregg Basin, Virgin Basin, Boulder Canyon, and Boulder Basin, and can be classified as deep, subtropical, monomictic basins that become thermally stratified at times and typically for a brief period in July. The Muddy (Moapa) River and the Virgin River both discharge into the Overton Arm of the Virgin Basin, and Las Vegas Wash, which carries treated wastewater from the Las Vegas area, discharges into Las Vegas Bay of the Boulder Basin. These are considered the only perennial tributaries of Lake Mead (Baker et al. 1977).

The full-pool footprint of Lake Mead extends up to just upstream of Separation Canyon (RM 240 within the Grand Canyon) and encompasses the inflow area of the Colorado River into Lake Mead. For this document, given the current conditions at Pearce Ferry Rapid, we use it to separate the Grand Canyon from Lake Mead. We also note that Lake Mead, when full, encompasses various portions of the inflow areas of the Muddy River, the Virgin River, and Las Vegas Wash, all of which are perennial tributaries to the reservoir. We note that these inflow areas are highly dynamic, sometimes riverine and at other times lake-like, and provide diverse and important habitats for both native and nonnative fishes, resulting in a robust fish community at the Lake Mead inflow areas (Albrecht et al. 2017).

Lake Mead has a diverse fish community (**Table TA 8-2**) (Renner and Day 2022), as would be expected from the largest reservoir by volume within the U.S. (Rosen et al. 2012). Among all the ESA-listed fishes native to the Colorado River, the razorback sucker is the most prominent species in Lake Mead. This reservoir hosts a unique population of wild, naturally recruiting razorback

suckers. At the time of writing, Lake Mead is the only known location supporting a recruiting population of this species (Albrecht et al. 2010, 2020; Rogers et al. 2025a). Additionally, the NDOW, in collaboration with the LCR MSCP maintains the Lake Mead Fish Hatchery, which rears razorback sucker and bonytail. This fish production, when available, is used by the LCR MSCP for augmentation purposes throughout the LCR MSCP reaches (LCR MSCP 2024).

This document analyzes species **Table TA 8-2** provides a summary of fish species that are likely to be routinely present in the analysis area since Hoover Dam closed. Following the closure of Hoover Dam, NDOW stocked Lake Mead with largemouth bass and sunfishes (*Lepomis* spp.), establishing a popular bass fishery that began to decline by the 1940s. To improve sportfish conditions, threadfin shad were introduced in 1954 as a forage species.

The construction of upstream impoundments, including Lake Powell in 1963, altered flow regimes and water storage patterns, resulting in lower spring flows and higher winter flows, which negatively affected largemouth bass spawning and affected temperature and nutrient dynamics in Lake Mead (NDOW 2023). In response to the declining bass fishery, cold-water fish species such as rainbow trout, cutthroat trout (*Oncorhynchus clarkii)*, hybrid bowcutt trout (*Oncorhynchus mykiss* × *Oncorhynchus clarkii)*, silver salmon (*Oncorhynchus kisutch)*, and striped bass were introduced between 1969 and 1972, with striped bass establishing a self-sustaining population. Since surveys began in 1991, nonnative species have been regularly captured in Lake Mead, including striped bass, channel catfish, and common carp. NDOW documented the first walleye in 2001 and gizzard shad (*Dorosoma cepedianum*) in 2009. Red shiners continue to be routinely observed by researchers (Pennock et al. 2023; Rogers et al. 2025a). Smallmouth bass, first detected in 1999, have since become as abundant as largemouth bass despite not being officially stocked. Today, Lake Mead's sport fishery includes striped bass, largemouth bass, smallmouth bass, channel catfish, and a small population of black crappie (NDOW 2023).

The Muddy River and Virgin River inflows are not only used to varying degrees by razorback suckers but also have the potential to contain Virgin River chub (*Gila seminuda*), woundfin (*Plagopterus argentissimus*) (Virgin River only at present), flannelmouth sucker (Virgin River only at present), desert sucker (*Catostomus clarkii*) (Virgin River only at present), as well as speckled dace (Virgin River only at present), a likely extirpated subspecies of speckled dace, the Moapa speckled dace (*Rhinichthys osculus moapae*) (Muddy River), Moapa dace (*Moapa coriacea*) (Muddy River), populations of Moapa White River springfish (*Crenichthys baileyi moapae*) (Muddy River), and various headwater associated thermal spring associated endemic macroinvertebrates (Muddy River). Most of these species are documented in reaches higher up within these two river systems, as are Virgin spinedace (L*epidomeda mollispinis*), which is primarily a tributary-oriented species found within the tributaries to the mainstream Virgin River (e.g., Holden et al. 2005, Kegerries et al. 2022, and Handtke et al. 2024 for details on the Muddy River fish community; Albrecht et al. 2020 and Rogers et al. 2025a for details on the lower Virgin River fish community). In recent years, only Virgin River chub have been captured from within Lake Mead proper, a single specimen originating from within the Overton Arm (Rogers et al. 2025a).

Rogers et al. (2024 and previous annual reports) discuss Lake Mead razorback sucker history and trends since before dam construction. A study initiated in 1996 focused on long-term monitoring of

the Lake Mead razorback sucker population (Rogers et al. 2025a). This effort has continued through 2024, providing a consistent database and expanding sampling to new areas. By using data gathered from sonic-tagged fish in conjunction with long-term trammel-netting and larval-sampling data, information regarding primary spawning sites has been obtained for three long-term monitoring study areas (Las Vegas Bay, Echo Bay, and the Virgin River/Muddy River inflow area), and research sites (the Colorado River inflow area and Bonelli Bay) within Lake Mead. In addition to primary spawning site information, sonic-tagged fish have confirmed reservoir-wide and seasonal movement patterns within the long-term monitoring and research study areas.

Razorback suckers continue to spawn and recruit in Lake Mead (e.g., Rogers et al. 2025a). Multiple age classes of razorback suckers, including larvae, juveniles, and adults, are documented annually. The Lake Mead razorback sucker population consists of individuals ranging from 2 to 30+ years old, demonstrating relatively high growth rates indicative of a young, recruiting population. Population estimates have ranged from around 250 to nearly 1,400 razorback sucker in Lake Mead, with adult annual apparent survival rates of this largely wild population consistently documented at just under 80 percent (Rogers et al. 2025b)

It is important to note that since 1966, at least some razorback sucker recruitment has occurred nearly annually in Lake Mead. This suggests that lake elevations observed to date have not prevented this population from successfully recruiting. However, it is unclear whether a lower-end threshold exists, either defined bathymetrically by the availability of suitable spawning and recruitment habitat, or due to other recruitment-limiting factors at lake elevations lower than those observed to date.

Recently, both larvae and adult razorback suckers have been discovered utilizing both the lower Grand Canyon and the inflows to Lake Mead; razorback suckers have been documented to be spawning at least 100 river miles from Lake Mead consistently between 2014 and 2019 (Albrecht et al. 2014; Kegerries et al. 2017a, 2017b, 2020). Recent data from the Colorado River inflow (Rogers et al. 2023) suggests that Lake Mead razorback suckers move throughout not only Lake Mead, but also up into the Las Vegas Wash, and into the Grand Canyon when conditions allow. Major findings for this and previous studies to date include (1) multiple age classes of unmarked, wild razorback suckers (including juvenile fish) occupy the Colorado River inflow, and adults spawn there; (2) razorback suckers spawn within Grand Canyon or its associated tributaries; (3) sonic-tagged razorback sucker (stocked and wild) utilize both the Colorado River inflow and Grand Canyon; and (4) native fish dominate the fish community in Grand Canyon despite the presence of numerous nonnative fishes in Lake Mead and Lake Powell. Within the study period (2014–2023), as described in Rogers et al. (2023), razorback sucker use of the Grand Canyon and Colorado River inflow was documented. Overall, study results indicate an apparent interconnected, recruiting population of razorback suckers in Lake Mead that may demonstrate sufficient plasticity to allow for lentic and lotic habitat use in Lake Mead and the Grand Canyon.

In addition to razorback suckers, several other native fish occur in Lake Mead, including flannelmouth suckers, which were first captured in 2001, hybrid suckers (razorback x flannelmouth) documented in 2010, bluehead suckers in 2011, bonytail in 2020, and both humpback chub and Virgin River chub in 2021. Notably, humpback chub are relatively common upstream and

downstream of Pearce Ferry Rapid when riverine habitats are present (Hedden et al. 2022; Pennock et al. 2023; Rogers et al. 2024).

Dibble et al. (2021) describe geomorphic changes in the lower Grand Canyon resulting from recent declines in Lake Mead's elevation, which have extended the Colorado River by more than 62 river miles and shifted habitat conditions in favor of native fish species. When the elevation of Lake Mead dropped below 1,135 feet, the river downcut through the reservoir delta outside of its historic channel, forming Pearce Ferry Rapid, a bedrock ledge that acts as a barrier to the upstream movement of nonnative fishes from Lake Mead. This physical feature has significant implications for fish populations. If water management prioritizes Lake Powell storage, Pearce Ferry Rapid is likely to persist, thereby blocking or deterring the movement of nonnative fish upstream. Conversely, prioritizing Lake Mead storage could inundate the rapid and lower elevations of Lake Powell, which would warm the river, improving conditions for native fish but increasing the risk of nonnative fish invasions. An intermediate approach could maintain the current balance of barriers, deterrents, and thermal conditions, supporting native fish while limiting nonnative species (Dibble et al. 2021; Bruckerhoff et al. 2022).

Fish capture and movement data of razorback sucker, flannelmouth sucker, striped bass, and common carp collected or detected between 2012 and 2023 (Kegerries and Albrecht 2013a, 2013b; Albrecht et al. 2014; Kegerries et al. 2015; Rogowski et al. 2025), validate that Pearce Ferry Rapid likely functions as a barrier to fish movement, depending on lake elevation. Upstream movement was observed when mean monthly Lake Mead elevations exceeded approximately 1,090 feet. Rogowski et al. (2025) conclude that the rapid likely effectively restricts the upstream movement of nonnative fish species, thus protecting native habitats, although it may also impede the movement of some native species, potentially creating downstream population sinks. While some native species, such as humpback chub, appear to benefit from reduced predation and competition, the rapid also appears to limit connectivity for other native fish populations (e.g., razorback sucker and flannelmouth sucker). The barrier function of Pearce Ferry Rapid is dynamic and may shift over time due to geomorphic and environmental factors, such as changes in reservoir elevation, channel migration, or potential downcutting. Overall, the formation and persistence of Pearce Ferry Rapid demonstrate how a decline in reservoir elevation can create complex barriers with both positive and negative consequences for native fish conservation in the Grand Canyon (Dibble et al. 2021; Rogowski et al. 2025).

Quagga mussels were found in Lake Mead in January 2007, with the initial colonization likely occurring 3–4 years earlier, and are considered a biological threat to the lake (NPS 2023b). Significant impacts on water quality, lake biology, and infrastructure were expected based on experiences with zebra mussels in other parts of the country, but to date, no significant impacts on either water quality or lake biota have been published that can be directly attributed to quagga mussels (Renner and Day 2022; NPS 2023b). Another invasive bivalve in Lake Mead, the Asian clam, has also been observed during razorback sucker field monitoring and research (Rogers et al. 2025a), as have red swamp crayfish (*Procambarus clarkii*) (Renner and Day 2022).

Asian clams are an invasive species native to Asia that have spread widely in freshwater systems across North America and other parts of the world (Renner and Day 2022). Known for their rapid

reproduction and ability to form dense populations, Asian clams can outcompete native species, disrupt local ecosystems, and clog water intake pipes, leading to substantial ecological and economic impacts (Renner and Day 2022). They were first detected in 1948 in Lake Mead (Renner and Day 2022). The New Zealand mud snail is a small, invasive freshwater snail originally from New Zealand that has spread to various parts of the world, including North America and Europe (Renner and Day 2022). These snails reproduce rapidly and can form dense colonies, outcompeting native species for food and habitat, and disrupting local ecosystems by altering nutrient cycles and food webs. They were first reported north of Lake Mead in 2007 but continue to threaten downstream habitats (Renner and Day 2022). Another invasive snail (Malaysian trumpet snail [*Melanoides tuberculata*]) has been detected in Lake Mead, as well as other locations downstream (USGS 2025).

LCR MSCP Reach 2- Downstream of Hoover Dam to Lake Mohave

The Hoover Dam reach extends from the downstream end of Lake Mead, just downstream of Hoover Dam, and continues to Davis Dam, which impounds Lake Mohave. The extent of analysis for this reach is consistent with LCR MSCP Reach 2 and includes approximately 67 miles of riverine habitat (LCR MSCP 2004).

Lake Mohave is managed as a sport fishery by the states of Arizona and Nevada for largemouth bass, smallmouth bass, striped bass, rainbow trout, bluegill, green sunfish, channel catfish, and others (FWS 2018). Lake Mohave is operated by Reclamation as a reregulation reservoir. It fluctuates annually within a 15-foot vertical range, filling by mid-May and lowering to an annual minimum in October. Wave action redistributes sediment from desert washes and shapes it into sandbars or natural berms. In some areas, these sandbars isolate the lower portions of the desert washes from the lake proper, and when the lake is at full pool, lakeside ponds form. Reclamation and its partners in the Lake Mohave Native Fish Work Group have been using these lakeside ponds since 1992 to rear razorback suckers and bonytail (LCR MSCP 2024). As such, Lake Mohave serves as a fisheries backbone for razorback sucker and bonytail management in the Lower Colorado River.

Lake Mohave supports a diverse fishery, including striped bass, stocked rainbow trout, largemouth bass, smallmouth bass, bluegill, green sunfish, channel catfish, yellow bullhead, threadfin shad, gizzard shad, and common carp (**Table TA 8-2**). The native species present include bonytail and razorback sucker (**Table TA 8-2**). The lake was historically stocked year-round with rainbow trout until hatchery issues caused a pause from October 2013 to February 2017. Striped bass, introduced in the early 1980s, have become a major part of the sport fishery, preying on the stocked rainbow trout and other forage species, including shad, whose populations have declined due to predation (NDOW 2022).

Lake Mohave is home to the most genetically diverse population of razorback sucker left in the world, and as such is an important focus of the LCR MSCP (Marsh et al. 2015; LCR MSCP 2024). Because of the importance of preserving genetic diversity, and despite persistent challenges with the survival of repatriated razorback suckers, comprehensive genetic monitoring is conducted on wild-captured larvae, individuals reared in lakeside backwaters, and the repatriate adult population. These genetic monitoring efforts are ongoing (Bestgen et al. 2020; LCR MSCP 2024). The Lake Mohave population of razorback sucker spawns annually, but recruitment has not been documented since the 1950s (Marsh and Langhorst 1988; Mueller 2006; Karam and Marsh 2010). Striped bass, as well

as sunfish, may play a role in population declines throughout Lake Mohave (Karam and Marsh 2010; Kesner et al. 2012; Ehlo et al. 2017); predation of a 500 millimeter (mm; 19.7 inches) razorback sucker by striped bass was documented when an angler found an acoustic transmitter in a striped bass stomach. Sunfish have been implicated in the lack of young razorback sucker survival (FWS 2018). Renner and Day (2022) provide a historical account of all aquatic species detected in Lake Mead and Lake Mohave, but for purposes of this document, we plan to analyze species that have been routinely and recently documented by NDOW and AZGFD.

To combat the overall lack of razorback sucker recruitment in Lake Mohave and based on work done by the Lake Mohave Native Fish Work Group (Marsh et al. 2015), the LCR MSCP has maintained a stocking/augmentation program, providing for the stocking of up to 660,000 subadult razorback suckers and up to 620,000 subadult bonytail into the Lower Colorado River over a 50-year term. Since 2005, 137,030 bonytail have been stocked into Reaches 2 through 5. In addition, 157,990 razorback suckers have been stocked into Reach 2 during this period in support of maintaining the population in Lake Mohave as a genetic refuge for the species. This stocking rate is expected to meet the goals of the LCR MSCP Fish Augmentation Program (Bestgen et al. 2020; LCR MSCP 2024).

To obtain sufficient numbers of young fishes for grow-out and eventual stocking, an adult broodstock for each species is maintained by the LCR MSCP. Because the adult razorback sucker population in Lake Mohave is the most genetically diverse among razorback sucker populations, it is used as the primary broodstock for this species. Under the LCR MSCP, razorback sucker larvae are captured from this stock and reared at hatcheries in Arizona and Nevada before being stocked into Lake Mohave or other places within the Lower Colorado River. A second broodstock, developed from Lake Mohave offspring, is maintained at the Southwestern Native Aquatic Resources and Recovery Center in New Mexico, with additional rearing facilities in Arizona and Nevada (LCR MSCP 2024). The Southwestern Native Aquatic Resources and Recovery Center also maintains the world's only bonytail broodstock for species propagation, supported by a genetic management plan and funding for maintenance, augmentation, and distribution. A second bonytail broodstock is held at the Mora National Fish Hatchery as a refuge population to safeguard against catastrophic events. While stocked native fishes persist in some reaches of the Lower Colorado River, low post-stocking survival rates mean augmentation efforts remain focused on improving survival outcomes (LCR MSCP 2024).

Additionally, FWS, in collaboration with the LCR MSCP, maintains the Willow Beach National Fish Hatchery near the base of Hoover Dam. Under the LCR MSCP, offspring from Lake Mohave razorback sucker are captured directly from Lake Mohave and are reared at the Willow Beach National Fish Hatchery. These genetically diverse razorback suckers are then stocked back into the LCR MSCP reaches, including Lake Mohave, to help increase razorback sucker survival and recruitment bottlenecks created by nonnative fish predation and competition (LCR MSCP 2024).

Based on the captures reported in 2023, the repatriated population of razorback sucker in Lake Mohave appears stable to slightly increasing. It is thought that a combination of higher post-stocking and adult survival accounts for recent increases in population size. Post-stocking survival of smaller (less than 400 millimeters [mm; 15.7 inches] total length) fish continues to be low, but an increase in fish released at greater than 400 mm (15.7 inches) total length in recent years may

contribute to higher-than-average post-stocking survival (Reap et al. 2023; LCR MSCP 2024). Survival of razorback suckers in the Lower Basin is overall low and follows a size-at-release curve, as outlined in Schooley and Marsh (2007).

The razorback sucker population in Lake Mohave was recently estimated from two data sources: (1) trammel net capture data obtained during the annual, multiagency March roundup and (2) remote PIT scanning data collected during the sample year. Based on trammel net capture data, the repatriate population estimate for Lake Mohave was 1,720 individuals (95 percent confidence interval [CI], 950–3,440). Based on 2022–2023 remote PIT scanning, the lake-wide Lake Mohave repatriate population was estimated at 5,761 individuals (95 percent CI, 5,590–5,931). Subpopulation estimates using zone-specific scanning were also calculated and estimated the basin (reservoir miles 13–29) population at 3,295 individuals (95 percent CI, 3,173–3,416) and the river (reservoir miles 43–63) population at 3,603 individuals (95 percent CI, 3,379–3,826) (LCR MSCP 2024).

Reclamation and its partners in the Lake Mohave Native Fish Work Group have been using lakeside ponds since 1992 to rear razorback suckers and bonytail. The ponds are stocked with juvenile fishes each year as the reservoir fills (typically stocked in late January), and the LCR MSCP monitors and manages the ponds throughout the growing season. This work includes periodic monitoring of plankton production; removal of weeds and debris; population monitoring using remote sensing technologies; and routine monitoring of physical, chemical, and biological parameters. The ponds are normally harvested in late spring and again in the fall as the lake elevation declines. Fishes from these ponds are then released back into Lake Mohave or elsewhere within the Lower Colorado River. While annual pond harvests can be variable, lake-wide monitoring has consistently shown higher long-term contact rates for pond-reared versus hatchery-reared razorback suckers in Lake Mohave. Pond rearing provides an opportunity for fish to attain larger sizes prior to release into the lake, and contact data suggest that this larger size may improve post-stocking survival, increasing the likelihood that these fish will contribute to the adult broodstock (LCR MSCP 2024).

Bonytail, the other ESA-listed fish species within Reach 2 (Lake Mohave), were not stocked in 2024. In fact, within the past 20 years, approximately 3,500 bonytail have been stocked into Lake Mohave. This species is monitored through ongoing razorback sucker netting and PIT scanning efforts with a few capture records over time (J. Stolberg, LCR MSCP, personal communication). No recent population or survival estimates have been calculated for bonytail in Lake Mohave (or within any other reach of the Lower Colorado River) due to limited contacts and the overall rarity in terms of survival of this species in the Lower Basin (LCR MSCP 2024).

Currently, all reservoirs, lakes, and watersheds receiving raw Colorado River water have been exposed to quagga mussels (Renner and Day 2022; CDFW 2024). Asian clams and the New Zealand mud snail continue to threaten downstream habitats (Renner and Day 2022). Renner and Day (2022) also indicate that freshwater shrimp (*Gammarus fasciatus*) and big-ear radix (*Radix auricularia)* have established populations in Lake Mohave. The invasive Malaysian trumpet snail is also known from locations downstream of Lake Mead (USGS 2025).

LCR MSCP Reach 3- Davis Dam to Parker Dam

The LCR MSCP's Reach 3 extends from Davis Dam (RM 276) to Parker Dam (RM 192.3), including Lake Havasu up to full-pool elevation. This reach comprises a riverine component and a reservoir component (Lake Havasu). The Bill Williams River is a notable tributary draining into Lake Havasu, providing diversity in inflow habitats, including potentially important aquatic habitats, areas of vegetative cover, and, at times, turbidity near the inflow. In 2008, multiple agencies, including Reclamation, NDOW, and the Southern Nevada Water Authority, collaborated to secure the Boy Scout Camp property, incorporating it into the LCR MSCP as the Big Bend Conservation Area (LCR MSCP 2024). This effort resulted in the creation of 15 acres of backwater habitat beneficial to native fish species like razorback suckers, bonytail, and flannelmouth suckers in Reach 3 of the LCR MSCP. The area, located approximately 30 miles south of Laughlin, Nevada, is crucial for sustaining the flannelmouth sucker population. These represent some of the LCR MSCP's areas of interest and the typical habitats created by this program for the benefit of ESA-listed fishes.

Reach 3 contains ESA-listed fishes, including the razorback sucker and bonytail. An important population of flannelmouth sucker (a LCR MSCP covered species and an Arizona species of greatest conservation need) can also be found within this reach of the Lower Colorado River (**Table TA 8-2**) (LCR MSCP 2004). The Colorado River downstream of Davis Dam, to the inflow area of Lake Havasu, supports one of the largest populations of razorback sucker in the Lower Colorado River and is monitored by ongoing LCR MSCP and partner agency efforts (LCR MSCP 2024). This same area is also home to flannelmouth sucker, reintroduced in 1976 by AZGFD, and, for years, represented one of the most successful reintroductions of a native fish within the Lower Colorado River (Mueller and Wydoski 2004; Best and Lantow 2012). Reach 3 has also received bonytail stockings by the LCR MSCP (LCR MSCP 2024), although these bonytail stockings have produced little evidence of long-term survival, reproduction, or recruitment except for within isolated, predator-free environments (Marsh et al. 2024).

The reach 3 razorback sucker population in 2023 was estimated at 7,224 individuals (95 percent CI from 6,931 to 7,517). Survival of razorback suckers in the Lower Basin is overall low and appears to follow a size-at-release curve, as outlined in Schooley and Marsh (2007), with larger fish, even those with a total length greater than 500 mm (19.7 inches), having higher survival. This is the largest population estimate for razorback suckers in Reach 3 since program implementation began in 2005. Due to the limited number of bonytail and flannelmouth suckers detected, no recent population estimates have been generated for those species (LCR MSCP 2024). Recent surveys have suggested that flannelmouth sucker captures are unfortunately becoming quite rare in the Lower Colorado River, and it remains a species of concern (J. Stolberg, LCR MSCP, personal communication; LCR MSCP 2024). A total of 2,764 razorback suckers and 2,070 bonytail were stocked into Reach 3 during 2023 (LCR MSCP 2024).

The LCR MSCP currently collects larval razorback sucker from Lake Mohave to rear at various hatcheries and lakeside ponds on Lake Mohave. The result of these efforts, as well as larvae reared at the Southwest Native Aquatic Resources and Recovery Center hatchery, provides razorback sucker of sufficient size and quantity to stock this species into Reach 3. Similarly, bonytail, from hatchery sources supported by the LCR MSCP, are also stocked into Reach 3. Capture and contact data for Reach 3 are acquired through multiple projects, ongoing multiagency native fish roundups, and from

other annual surveys conducted by LCR MSCP partners. Fall and spring netting surveys are conducted throughout Topock Gorge and upper Lake Havasu. PIT scanners are used, and active sampling within the Mohave Valley Conservation Area, a 63-acre backwater created by the LCR MSCP, is also conducted to support understanding of the fish community in Reach 3. Backwater habitats created in Reach 3 by the LCR MSCP will continue to be connected to the mainstream river to address the life-history requirements of flannelmouth suckers, as well as other native fishes. Finally, there are numerous projects dedicated to habitat creation and conservation efforts, for and on behalf of the LCR MSCP fish species in this reach, as further outlined within LCR MSCP (2024). The Colorado River downstream of Davis Dam is the lowermost reach of the river managed by the AZGFD Region III Aquatics Program. This portion of the Colorado River from Davis Dam (RM 276.0) to the Interstate 40 crossing (RM 233.9) at Topock, Arizona, corresponds with the LCR MSCP's Reach 3. Lake Havasu is managed as a sport fishery by the state of Arizona, which supports populations of largemouth bass, smallmouth bass, striped bass, bluegill, and redear sunfish (*Lepomis microlophus*). Other nonnatives present in Lake Havasu, but which are not actively managed, include green sunfish, yellow bullhead, flathead catfish, and channel catfish (**Table TA 8-2**) (FWS 2018). More specifically, during routine electrofishing trend surveys in 2024, AZGFD captured redear sunfish, bluegill, gizzard shad, largemouth bass, green sunfish, common carp, sunfish hybrids (*Lepomis* spp.), striped bass, smallmouth bass, flathead catfish, black crappie, goldfish (*Carassius auratus*), threadfin shad, yellow bullhead, and channel catfish (**Table TA 8-2**) (AZGFD 2024a). In 2021, AZGFD conducted a creel census in the upper portion of this reach, from Davis Dam (RM 276) to the Avi Bridge crossing (RM 257). This survey reports that the fishery primarily consists of rainbow trout, striped bass, and channel catfish. Other species included smallmouth bass, largemouth bass, sunfishes (*Lepomis* spp.), common carp, razorback sucker, and the introduced population of flannelmouth sucker. Rainbow trout is the only sportfish species currently stocked in this reach, originating from Willow Beach National Fish Hatchery, and routinely being stocked into this location (**Table TA 8-2**) (AZGFD 2023).

Sampling in the 12 miles downstream of Davis Dam indicates that the sport fishery in this area is mainly supported by striped bass, largemouth bass, smallmouth bass, redear sunfish, and regularly stocked rainbow trout (NDOW 2020). Additionally, efforts to repatriate and monitor native species, such as the razorback sucker, bonytail, and flannelmouth sucker, are ongoing in the river and its backwaters. Although flannelmouth suckers are native to the Colorado River, they are believed to have been introduced to this specific section (Mueller and Wydoski 2004). Bonytail, while present in Lake Havasu, are not commonly found in this part of the river but occasionally appear in backwaters (NDOW 2020). Other species present include common carp, channel catfish, bluegill, and gizzard shad (**Table TA 8-2**) (Ozborn et al. 2021).

Anglers primarily target striped bass and rainbow trout. During the spring and early summer, striped bass migrate upstream from Lake Havasu to spawn, concentrating near the tailwater of Davis Dam, where their migration is halted (NDOW 2020). Catch rates for game fish in the surveyed section of the Colorado River typically increase with rising temperatures in the spring (Ozborn et al. 2021). Species diversity is higher in the backwaters, which tend to harbor large bass spp., and redear sunfish; while large striped bass are occasionally caught in the main channel of Laughlin Lagoon, but most are found in the river's main channel (Ozborn et al. 2021).

In 2021, largemouth bass in both the backwater and riverine areas were in very good condition; in contrast, striped bass appeared in poor to fair condition (Ozborn et al. 2021). Although anecdotal due to the small sample sizes, a representative sample would require at least 250 individuals per species. Sampling methods and management activities from downstream of Davis Dam to Parker Dam include trammel-netting, electrofishing, angler use, and harvest surveys (NDOW 2020).

The fish community of Topock Marsh includes self-sustaining populations of largemouth bass, channel catfish, black crappie, striped bass, bluegill, green sunfish, and redear sunfish. Gizzard shad were first caught in 2012 and are now the most abundant species sampled (**Table TA 8-2**). It should be noted that razorback suckers have been stocked into Topock Marsh five times since 2010 and have been caught every year since the first stocking, except in 2015 (AZGFD 2022).

A population of desert pupfish (*Cyprinodon macularius*) occurs at Bill Williams National Wildlife Refuge in a constructed and maintained pond established in 2006. In all cases of pupfish presence in the Lower Basin, ponds were established with the intent to provide outreach and educational opportunities, as well as to provide replicates for the El Doctor/Santa Clara Slough lineage of desert pupfish and a source for stockings and augmentations of additional sites. In the construct of the 1993 pupfish recovery plan (FWS 1993) and the 2019 amendment to the recovery plan (FWS 2019a), these highly managed artificial ponds are considered to be tier 3 replicates that contribute to the required number of replicates (by pupfish lineage) necessary for desert pupfish to be downlisted or delisted. As such, these ponds are an important conservation tool that contributes to recovery (FWS 2012).

Flathead catfish are of particular concern as they are voracious predators and pose a substantial threat to native fishes of the Lower Colorado River. This species appears to be expanding its use of habitats within Reach 3 (potentially due to temperature) and is routinely monitored by U.S. Fish and Wildlife Service (FWS) personnel. Through 2022, this species had been captured nearly as far upstream as the area between Needles and Fort Mohave in the Lower Colorado River (near Boundary Cone Road crossing) (Rasset and Love-Chezem 2024).

Since quagga mussels were discovered in Lake Mead in Nevada in 2007, subsequent surveys have found smaller numbers of quagga mussels in Lake Havasu and in the Colorado River Aqueduct System, which serves Southern California. Currently, all reservoirs, lakes, and watersheds receiving raw Colorado River water have been exposed to quagga mussels at this point (Renner and Day 2022; CDFW 2024). Crayfish (various species) are invasive freshwater crustaceans originally introduced as fishing bait and for biological control of aquatic vegetation (Renner and Day 2022; AZGFD 2024b) and are assumed to be present within Reach 3. The Asian clam was first detected in 1948 in Lake Mead and threatens downstream ecosystems (Renner and Day 2022); thus, present within Reach 3. As with upstream reaches, the New Zealand mudsnail and Malaysian trumpet snail continue to be a threat (Renner and Day 2022; USGS 2025).

LCR MSCP Reaches 4 and 5- Parker Dam to Imperial Dam

The Colorado River within the LCR MSCP Reaches 4–5, extending from Parker Dam (RM 192.3) to Imperial Dam (RM 49.2), represents the lowest combined reach regularly sampled by the LCR MSCP. This section was historically characterized as a wide, turbid river abundant in sediment,

featuring large woody debris and lacking large boulders (Mueller and Marsh 2002; Mueller et al. 2005). It operated as a dynamic ecosystem influenced by extreme water temperature fluctuations (0–35°C; 32–95°F) and by fluctuations between flooding and drought that shaped the life histories of native Colorado River fishes (Reclamation 2004; Mueller 2006).

Today, this reach of the river extends roughly 100 miles south to Yuma, AZ, and is heavily utilized for recreation, particularly boating and other activities (Mueller and Marsh 2002). It has been notably altered, becoming a channelized waterway that often spans up to 10 miles, predominantly used for agricultural purposes (Mueller and Marsh 2002). The original riparian landscape, characterized by large willows and cottonwood trees, has been replaced by tamarisk due to altered flood management practices, resulting in salt crusts on the ground from inadequate drainage (Mueller and Marsh 2002).

The introduction of nonnative fish species has substantially displaced native fauna throughout much of the area (Mueller 2006). However, some native fish populations persisted in isolated habitats such as the Cibola High Levee Pond, a 5-acre oxbow pond semi-connected to the mainstream river. This pond provided a refuge for native fish species, allowing them to survive despite the challenges posed by nonnative species (Mueller and Marsh 2002; Mueller 2006). Today, Cibola High Levee Pond contains an important wild, recruiting population of bonytail. Additionally, Imperial Ponds Conservation Area, an 80-acre pond complex created by the LCR MSCP, also provides predator-free habitats for razorback sucker and bonytail (Kesner et al. 2012). Similar to Cibola High Levee Pond, these ponds have experienced successful spawning and recruitment of native fishes; however, nonnative fish invasions remain a threat (Kesner et al. 2012). Such environments also serve as crucial research sites for biologists studying the dynamics of native fish populations in altered river ecosystems (Mueller 2006).

Currently, this reach contains ESA-listed fishes, including the razorback sucker and bonytail (**Table TA 8-2**); each is primarily sustained by stocking efforts. Although stocked native fish have been found to persist in this reach, research and monitoring have shown that post-stocking survival rates are low. Therefore, native fish augmentation efforts will continue to focus on improving post-stocking survival (LCR MSCP 2024). From 2007–2023, a total of 152,515 razorback suckers and 65,303 bonytail were stocked in reaches 4–5 (LCR MSCP 2024). Many of the bonytail stocked appeared to disperse downstream, while razorback sucker appeared to disperse upstream of the stocking location. Both species often utilize backwater habitats; however, razorback sucker also use riverine habitats (Kelley et al. 2022). Bonytail post-stocking survival has been low and often immeasurable (Heishman et al. 2023), and bonytail mortality is likely high immediately after stocking (Kelley et al. 2022). On the other hand, razorback sucker stockings have seemed more successful with population growth and relatively high post-stocking survival (0.44–0.85) in this location (Heishman et al. 2023). The population estimate was 2,208 in 2023 (95 percent CI: 2,062–2,355), the largest population estimate in this reach since the stocking program's inception in 2005 (LCR MSCP 2024). Native fish management in these reaches has primarily focused on off-channel, predator-free habitats and stocking efforts.

The LCR MSCP currently collects larval razorback sucker from Lake Mohave to rear at various hatcheries. These efforts, as well as larvae reared at the Southwest Native Aquatic Resources and Recovery Center, provide razorback sucker of sufficient size and quantity to stock this species into

Reach 4–5. Similarly, bonytail, from hatchery sources supported by the LCR MSCP, are also stocked into Reach 4–5. Backwater habitats created in this reach by the LCR MSCP will continue to be disconnected from the mainstream river to address the life-history requirements of bonytail and razorback suckers. There are several projects, such as those at Cibola High Levee Pond and the Imperial Ponds Conservation Area, dedicated to habitat creation, backwater disconnection, manipulation, and conservation efforts, for and on behalf of the LCR MSCP fish species in this reach (LCR MSCP 2024).

The AZGFD Region IV Aquatics Program is responsible for managing the area corresponding to the LCR MSCP Reach 4–5. The nonnative fishery primarily consists of striped bass, channel catfish, smallmouth bass, largemouth bass, sunfishes (*Lepomis* spp.), common carp, red shiner, fathead minnow, crappie (*Pomoxis* spp.), shad (*Dorosoma* spp.), goldfish, bullhead (*Ameiurus* spp.), and blue tilapia (*Oreochromis aureus*) (Renner and Day 2022; Ham 2023a, 2023b; Ramey and Ham 2024). Flathead catfish have been found in the Lower Basin since at least the 1960s, and the most recent surveys reported their presence, a particular concern for native fishes due to their predatory nature (**Table TA 8-2**) (FWS 2019b; Rasset and Love-Chezem 2024).

There are no natural, extant populations of desert pupfish (*Cyprinodon macularius*) currently present in or along the Lower Colorado River. Historically, the species occurred in the Lower Colorado River and its floodplain downstream of Lake Mead. More recently, desert pupfish in the Lower Colorado River region occurred only in managed refugia populations maintained in artificial ponds at national wildlife refuges. Two small human-made ponds were constructed at Cibola and Imperial National Wildlife Refuges to support refugia populations derived from captive stock originally sourced from Mexico. The refugia pond at Cibola is located adjacent to the refuge headquarters on higher ground outside the historical floodplain and is supplied by the refuge's potable water system, which diverts water from the Colorado River using a pump. Desert pupfish are currently present only at the Cibola pond; individuals were temporarily moved there from the Imperial pond while repairs are completed at the refuge, and fish may be returned in the future. In all cases of pupfish presence in the Lower Basin, these ponds were established with the intent to provide outreach and educational opportunities, as well as to provide replicates for the El Doctor/Santa Clara Slough lineage of desert pupfish and a source for stockings and augmentations of additional sites. In the construct of the 1993 pupfish recovery plan (FWS 1993) and the 2019 amendment to the recovery plan (FWS 2019a), these highly managed artificial ponds are considered to be tier 3 replicates that contribute to the required number of replicates (by pupfish lineage) necessary for desert pupfish to be downlisted or delisted. As such, these ponds are an important conservation tool that contributes to recovery (FWS 2012). Because these populations occur in isolated, managed refugia outside the river channel and historical floodplain, they do not represent extant wild populations within the Lower Colorado River system. Management of the refugia ponds occurs separately from Lower Colorado River water management activities addressed under the LCR MSCP, and desert pupfish are therefore not associated with riverine habitats in the LCR action area.

Crayfish are invasive freshwater crustaceans originally introduced as fishing bait and biological control for aquatic vegetation (Renner and Day 2022; AZFG 2024b). Mueller et al. (2005) observed red swamp crayfish (*Procambarus clarkii*) predating on bonytail and razorback sucker eggs in Cibola High Levee Ponds. Additionally, quagga mussels and Malaysian trumpet snail, which are known

from locations within and downstream of Lake Mead, are also found in Reaches 4–5 (Renner and Day 2022; CDFW 2024; USGS 2025).

LCR MSCP Reaches 6 and 7– Imperial Dam to the SIB
Due to the overall low numbers of native and ESA-listed fishes and their low survival, coupled with current LCR MSCP fish sampling efforts being allocated primarily down through Reaches 4–5 (J. Stolberg, LCR MSCP, personal communication 2025; LCR MSCP 2024), we present information from Reaches 4–5 as the lowest-most combined reach routinely sampled (from Parker Dam [RM 192.3] to Imperial Dam [RM 49.2]). We will not present data for Reaches 6–7 of the LCR MSCP. We note that historical literature provides at least some semblance of species present in this reach (**Table TA 8-2**).

TA 8.2 Environmental Consequences

TA 8.2.1 Methodology

Decision Making Under Deep Uncertainty Modeling
To assess future alternatives and management strategies, a modeling analysis known as Decision Making under Deep Uncertainty (DMDU; see **Section 3.2.6**, Decision Making Under Deep Uncertainty and **Appendix E**, DMDU Overview and Approach, for additional details) was applied to systematically evaluate potential system responses across a wide range of plausible futures. The analysis incorporated five alternative scenarios (No Action, Basic Coordination, Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven Alternatives [both LB Priority and LB Pro Rata approaches]) and one Representative Preferred Alternative, which represents various flow conditions and the continuation of current flow management strategies from Lake Powell (Continued Current Strategies [CCS] Comparative Baseline). The modeling originally included three initial conditions (Dry, Mid, and Wet) across 400 hydrologic traces, resulting in 1,200 modeled futures. For the Final EIS, the Wet and Mid initial conditions and all associated modeled futures were removed. Only the Dry initial condition and its associated futures are retained. The Representative Preferred Alternative will focus on the analysis of the first 10 years of impacts, given its 10-year implementation period, which will begin with low reservoir elevations in 2027 and relatively poor initial decade performance in many threshold analyses.

These modeled scenarios are designed to span a broad spectrum of uncertainty, allowing examination of the impacts on aquatic habitats and resources under several alternatives and baseline conditions. By evaluating outcomes across these alternative futures, DMDU offers a rigorous approach to quantifying changes in habitat extent for both lake and riverine environments. This method enables detailed interpretation of data, such as lake elevations and flow conditions under each scenario, to assess the impacts on spawning and habitat availability relative to historic conditions. If an alternative achieves a robustness score of 90 percent or higher, it can be considered truly robust with respect to a particular resource. When the difference in robustness between alternatives exceeds 10 percent, one alternative can be considered more robust than another. If the difference is less than 10 percent, the alternatives are considered similarly robust. Models were considered based on a multiagency cooperation of resource impacts.

DMDU figures are presented to provide comprehensive and reliable information about potential system outcomes under each alternative, regardless of future uncertainties. By intentionally disconnecting the analysis from probabilistic interpretation, these figures focus attention on key resource concerns and improve our understanding of how each alternative performs across a range of hydrologic conditions, and are presented to provide comprehensive and reliable information about potential system outcomes under each alternative, regardless of future uncertainties.

Conditional Box Plots

The conditional boxplots serve as a visual tool to summarize the range of potential resource impacts for each alternative under varying hydrologic conditions, categorized by the 3-year average Lees Ferry natural flow preceding each simulated year. This averaging period balances capturing both persistent moderate hydrology and annual extremes, with five flow categories chosen to reflect historic conditions and stakeholder perspectives. The boxplots illustrate how each alternative responds to these hydrologic scenarios, especially under challenging conditions like drought, enabling direct comparison of resource impacts. By highlighting the variability and distribution of responses, the figures allow readers to infer connections between system history and outcomes. Because resource data points within each category are determined by hydrology rather than modeling outcomes, readers can compare relationships between different resources across conditional boxplots, and, where relevant, multiple variables may be displayed together to further illuminate system responses under different alternatives.

Robustness Heat Maps

Robustness heat maps evaluate how each alternative performs across a wide range of future scenarios over extended modeling periods, such as decades or the entire simulation horizon (2027–2060). Unlike conditional boxplots, which assess each year independently, heatmaps aggregate results based on resource-specific definitions of "acceptability," using thresholds and frequencies to classify scenarios as successful or unsuccessful. Each alternative is assigned a robustness score, indicating the percentage of futures in which the performance criteria are met, with higher scores indicating greater robustness. The heatmaps display multiple levels of performance, from the most challenging criteria at the top to less stringent criteria downstream of and use a highlighted row to emphasize key acceptability thresholds or significant comparison points. This color-coded format distills complex modeling results into an accessible, comparative framework, enabling readers to quickly compare alternatives, understand their relative robustness, and make informed decisions.

Vulnerability Bar Plots

Vulnerability bar plots display, for each alternative, the hydrologic conditions, based on a 10-year Lees Ferry natural flow statistic, under which threshold outcomes are classified as preferred minimum performance (blue) or undesirable (red), such as during the worst 10-year drought. This visual division highlights the specific scenarios that lead to vulnerability, with larger blue regions indicating greater robustness. Accompanying boxplots provide context by relating these vulnerability thresholds to recent observations and a wide range of plausible future scenarios. The primary purpose of the vulnerability bar plot is to clarify the conditions under which an alternative is likely to fail and to determine whether those conditions fall within what can reasonably be anticipated, thereby informing decision-makers about each alternative's limits and resilience.

Lake Powell

To assess the impacts of reservoir elevations in Lake Powell on fish populations and aquatic habitats—including critical habitats for the Colorado pikeminnow and razorback sucker—we drew on multiple data sources, combining monitoring, reporting, and spatial analysis methods. Annual catch data for sportfish, collected from various monitoring programs, were analyzed alongside other datasets to track changes in lake habitat quality and quantity as water levels declined. Monitoring and distribution data for endangered Colorado pikeminnow and razorback sucker, including abundance and expansion into newly formed riverine inflows, are sourced from the Utah Division of Wildlife Resources and the Upper Colorado River Basin and San Juan River Basin Recovery Implementation Programs. These programs also provide information on spawning habitat locations and the abundance of razorback sucker larvae, which are monitored to detect shifts in spawning sites and potential bathymetric tipping points that could limit habitat availability. Stage-to-habitat descriptions and relationships derived from scientific literature were used to evaluate habitat and fish species abundance. Stage-to-habitat descriptions link stage height (e.g., water surface elevation) to the amount and type of habitat available to fish. Surface area and longitudinal analyses were used to quantify changes in habitat extent for both lake and riverine environments, with data interpretation (e.g., lake elevation by alternative) using DMDU analysis. Additionally, the smallmouth bass model (Eppehimer et al. 2025; Eppehimer and Yackulic 2026) was used to determine entrainment of smallmouth bass at Glen Canyon Dam and the probability of entrainment based on Lake Powell elevation. The smallmouth bass model was developed by the U.S. Geological Survey (USGS) in collaboration with partners, including the Reclamation and AZGFD, as part of the Glen Canyon Dam Adaptive Management Program. The model was developed to evaluate how variables, such as water elevation, temperature, and velocity, affect smallmouth bass population dynamics. Entrainment refers to fish being drawn into and carried through water management structures such as dam intakes, pumps, or turbines, often resulting in injury, death, or unintended movement into new habitats. Together, these methodologies enable a comprehensive assessment of how reduced reservoir elevations impact sportfish, endangered native fish, and their critical habitats in Lake Powell and its inflows.

Glen Canyon Dam to Lake Mead

To assess the impacts of modified releases from Glen Canyon Dam down the Colorado River to Lake Mead, a multi-faceted methodology was employed. Habitat availability and species abundance for threatened and endangered native fishes, including humpback chub and razorback sucker, as well as other native species (e.g., flannelmouth sucker, bluehead sucker) and nonnative species (rainbow trout, brown trout, smallmouth bass) were evaluated using stage-to-habitat descriptions and relationships derived from the scientific literature. These descriptions explain how changes in flow or water level (stage) create or reduce habitats, including backwaters, side channels, riffles, or shorelines that different species need for spawning, rearing, or feeding. Monitoring data and reports from agencies such as the Grand Canyon Monitoring and Research Center, the FWS, AZGFD, and the NPS provided empirical evidence on changes in habitat and fish abundance by life stage, particularly in the Lees Ferry sub-reach. Predictive modeling tools included the smallmouth bass model, applied to predict escapement from Lake Powell, entrainment through Glen Canyon Dam, and subsequent survival downstream Eppehimer et al. 2025; Eppehimer and Yackulic 2026). Additionally, the conservation measures for humpback chub outlined in the LTEMP BO, including

the specific triggers that require management action, were incorporated to guide management decisions and evaluate the effectiveness of mitigation efforts. Together, these methods and the DMDU approach described in **Section 3.2.6**, Decision Making under Deep Uncertainty, enabled a comprehensive assessment of how flow modifications impact fish communities and habitats from Glen Canyon Dam to Lake Mead.

Lake Mead to SIB

To assess the impacts of reservoir elevations from Lake Mead downstream to the SIB on fish, other aquatic species, and their habitats, a comprehensive methodology was employed, integrating agency monitoring, habitat analysis, and species-specific evaluations. Annual and seasonal reports, along with monitoring data from agencies, including Reclamation, the LCR MSCP, AZGFD, NDOW, and Grand Canyon Monitoring and Research Center, were used to track changes in habitat quantity and quality for lake, wetland, and riverine environments. These data sources provided information on the distribution and abundance of sportfish, ESA-listed, and other native species (humpback chub, razorback sucker, bonytail, flannelmouth sucker, and desert pupfish) across newly expanded inflow zones and affected sub-reaches. The methodology included the analysis of Colorado River Simulation System (CRSS) data to identify changes in Lake Mead shoreline area (spawning and nursery habitats) and longitudinal habitat assessments to quantify habitat expansion or contraction throughout the Lower Colorado River system. CRSS is a long-term planning model developed and maintained by Reclamation, used to simulate how water moves through the Colorado River system under different inflow, demand, and management scenarios (for additional details see **Section 3.2,** Analysis Methods and **Appendix A**). Particular focus was placed on known spawning sites and critical habitats, as well as how changes in water quantity, release timing, temperature, and quality from Hoover Dam affect downstream riverine habitats.

The alternative analysis approach for Lower Basin fishes was based on the observation that native and nonnative fish populations have persisted through the interim guideline operational period (2008 to present), with ongoing multi-year drought, declining reservoir storage, and revised Colorado River management strategies (Reclamation 2007). Flow and water quality data from this period were thoroughly documented and analyzed (see **TA 3**, Hydrologic Resources and **TA 6**, Water Quality). The guiding principle for fisheries analysis assumed that populations capable of surviving under these historic conditions would likely persist under similar future scenarios. Using the DMDU approach, the analysis evaluated whether the Final EIS alternatives could produce future conditions, such as flows, lake elevations, and habitat availability, outside the historical range observed from 2008 to 2025. All relevant data were assessed using established DMDU procedures and CRSS modeling (see **TA 3**, Hydrologic Resources for details). This integrated, historically informed approach enabled a robust evaluation of how changing reservoir conditions could affect fish populations and aquatic habitats across the analysis area.

Impact Analysis Area

The impact analysis area includes the Colorado River corridor from the full-pool elevation of Lake Powell to the SIB as described in **Sections 3.2**, Analysis Methods. The issues analyzed under this section are specific to defined boundaries within the larger study area, as delineated in **Table TA 8-2**.

Assumptions

- There will be modifications in quantity, timing, temperature, and quality of water released from Glen Canyon Dam and Hoover Dam through the Lower Colorado River. Fish habitats, distributions, and abundances are likely influenced by changes in flows, with reduced flows and variations in dam releases potentially altering available habitat and population numbers.
- Backwaters and riverine native fish habitats are likely affected by reduced flows.
- Known spawning sites of razorback sucker may be affected by reduced flows. Analyses involving models (CRSS and smallmouth bass) will be conducted in collaboration with model developers and users from various cooperating agencies.
- Lake Powell reservoir elevations lower than 3,570 feet are likely to increase entrainment of smallmouth bass and other nonnative fish that would likely result in negative effects on humpback chub and other native fish in the action area.
- LCR MSCP reaches may be combined for analysis due to the lack of special status species, habitat, operations, and management.
- Ongoing fisheries management practices conducted by the various agencies in the Colorado River Basin would be similar and ongoing into the future.

Impact Indicators

- Abundance and location of razorback sucker larvae throughout the project area.
- Elevation where spawning habitat may become limited (if available) throughout the project area.
- Changes in annual monitoring of catches of sportfish throughout the project area.
- Changes in available habitat and abundances of native fish species by life stage throughout the project area.
- Changes in backwater areas at flow stages in the Lower Colorado River Basin (Lower Basin).
- Changes in distribution and abundance of Colorado pikeminnow and razorback sucker with expanded inflows in Lake Powell.
- Changes in distribution and abundance of humpback chub with expanded inflow habitats in Grand Canyon.
- Changes in electrofishing monitoring catch rates and angler catch rates of rainbow trout and brown trout in Lees Ferry sub-reach.
- Changes in fish habitat and/or fish distribution and numbers based on dam releases and flows throughout the project area.
- Changes in razorback sucker spawning site areas and suitability at flow stages in the Lower Basin.
- Reduction in Colorado pikeminnow and razorback sucker critical habitat in the Colorado River and San Juan River inflows to Lake Powell with increased elevation of Lake Powell.
- Changes to razorback sucker critical habitat, which is the full pool of Lake Mead.
- Increased numbers of smallmouth bass escaping through Glen Canyon Dam and increased distribution and numbers of smallmouth bass downstream.
- Changes in salinity concentration in the Lower Basin.

- Lower reservoir elevation changes to shoreline spawning and nursery habitat for razorback sucker throughout the project area.
- Lake Powell elevation below 3,666.5 feet to sustain Piute Farms Waterfall as a nonnative fish barrier.
- Lake Mead elevation below 1,090 feet to sustain Pearce Ferry Rapid as a nonnative fish barrier, but above 1,000 feet to protect the power pool.
- Reduced abundance and distribution of desert pupfish in the Lower Basin.
- Reduced abundance and distribution of tilapia and other fish species in the Lower Basin.
- Reduced water quality from nitrates and selenium, resulting in algal blooms and fish die-offs in the Lower Basin.
- Reduced wetland area and river inflow habitat in the Lower Basin.

TA 8.2.2 Issue 1: Lower Lake Powell reservoir elevations have reduced lake habitat and extended the inflows of the Colorado River and San Juan River by approximately 35 miles each. How will changes in flow impact the quantity and quality of lake, wetland, and riverine inflow habitats?

The most important threats to ESA-listed native fish associated with Lake Powell operations relate to the establishment and spread of nonnative fish-eating (piscivorous) fish, particularly smallmouth bass. Reservoir elevation plays an important role in these risks. Lower lake elevations increase the likelihood that smallmouth bass are entrained through Glen Canyon Dam and establish downstream populations, where they may increase predation and competition pressures on native fish, including humpback chub and other species targeted for recovery in the Colorado River Basin. Lake elevation also determines whether Piute Farms Waterfall on the San Juan River functions as a barrier preventing nonnative fish from moving upstream from Lake Powell into riverine habitats.

Consistent with these processes, the most important Impact Indicators for Lake Powell, in order of importance, are: (1) increased numbers of smallmouth bass escaping through Glen Canyon Dam and expanded distribution and abundance of smallmouth bass downstream, (2) maintaining Lake Powell elevation below 3,666.5 feet to sustain Piute Farms Waterfall as a nonnative fish barrier, (3) reduction in Colorado pikeminnow and razorback sucker riverine (lotic) critical habitat in the Colorado River and San Juan River inflows to Lake Powell with increased reservoir elevation, and (4) increase in shoreline habitat of rock cliffs and rock falls that favor spawning, growth, and recruitment of smallmouth bass in Lake Powell. The first two indicators represent the primary threats to native fish populations because they directly influence the potential growth, spread, and invasion of nonnative piscivorous fish upstream and downstream.

Lower reservoir elevations also reduce lake habitat for sportfish, which may negatively affect recreational fisheries but can shift habitat conditions in ways that favor smallmouth bass and increase predation pressure on native fish. Impact indicators associated with these processes include rates of smallmouth bass entrainment at Glen Canyon Dam, changes in the distribution and abundance of smallmouth bass downstream, alterations in upstream passage at Piute Farms Waterfall, variations in the distribution and abundance of Colorado pikeminnow and razorback sucker in river inflow areas, and changes in annual sportfish catches.

Piute Farms Waterfall serves as a barrier to the upstream movement of nonnative fish from Lake Powell into the San Juan River, reducing predators and competitors in upstream habitats used by native fish. However, the waterfall also prevents razorback sucker and Colorado pikeminnow that move or are transported downstream of the falls from returning upstream to historic and designated critical habitat. Reservoir elevation, therefore, influences both the effectiveness of this barrier and the connectivity between Lake Powell and upstream river habitats.

Reservoir elevation also affects the extent of riverine inflow habitat in the Colorado and San Juan Rivers upstream of Lake Powell. Lower lake levels expose longer segments of riverine habitat, including designated critical habitat for Colorado pikeminnow and razorback sucker, while higher elevations inundate portions of these reaches and convert them to reservoir conditions. Changes in the length of available riverine habitat represent a habitat effect that would primarily occur if Lake Powell refills and is evaluated separately from the risks associated with nonnative fish establishment and the loss of the Piute Farms Waterfall barrier.

Several key elevation thresholds are considered in this analysis. These include the elevation associated with increased risk of smallmouth bass entrainment at Glen Canyon Dam (3,570 feet; see smallmouth bass model in Eppehimer et al. 2025; Eppehimer and Yackulic 2026, **TA 8.2.3**), the elevation at which Piute Farms Waterfall becomes inundated and fish passage becomes possible (3,666.5 feet; Paul Grams, USGS/GCMRC, personal communication), the elevations at which designated critical habitat for Colorado pikeminnow and razorback sucker begins to inundate in the Colorado River inflow (3,598 feet) and San Juan River inflow (3,600 feet), and the elevation below which water can only be released through the river outlet works (3,490 feet). These thresholds help evaluate how reservoir operations may influence native fish persistence in Lake Powell and downstream of Glen Canyon Dam.

A relationship was developed linking the riverine lengths of the Colorado and San Juan Rivers and their inflows into Lake Powell to lake elevation (**Table TA 8-3**, **Table TA 8-4**). This analysis focuses on the designated critical habitat for Colorado pikeminnow and razorback sucker. Critical habitat for humpback chub and bonytail does not occur in these inflow areas. Critical habitat for Colorado pikeminnow and razorback sucker extends 33.5 miles of the Colorado River inflow from Rapid 25 (RM 201.5, full-pool elevation of Lake Powell at 3,700 feet) downstream to North Wash (RM 168, elevation of 3,598 feet). When Lake Powell rises above 3,598 feet, it begins to inundate designated critical habitat for Colorado pikeminnow and razorback sucker, converting lotic, riverine habitat to more lentic, lake habitat. A similar relationship was developed for critical habitat on the San Juan River inflow that extends 39 miles from upstream of the Clay Hills boat ramp (RM 63.5, full-pool elevation) downstream to Neskahai Canyon (RM 24.5) (**Table TA 8-4**). These species, especially the Colorado pikeminnow, prefer riverine habitats when available (FWS 2018, 2022), and extending riverine inflow benefits the species.

In **TA 3**, Hydrologic Resources, **Figure TA 3-6** analyzed water year minimum Lake Powell elevations for each alternative and the CCS Comparative Baseline under varying hydrologic categories. The categories are defined by the preceding 3-year average Lees Ferry natural flow and show how elevations change due to hydrologic conditions. Below, the modeled elevations are compared to critical elevations related to habitat and passage.

Table TA 8-3
Estimated Linear Miles of Colorado Pikeminnow and Razorback Sucker Critical Habitat at Varying Lake Powell Elevations (in feet) in the Colorado River Inflow

Colorado River Inflow	River Mile	Elevation	Critical Habitat Inundated (River Miles)
Rapid 25	201.5	3,700	33.5
Imperial Canyon	200	3,690	32
Gypsum Canyon	196.6	3,680	28.6
Clearwater Canyon	192	3,660	24
Bowdie Canyon	190.6	3,658	22.6
Cove Canyon	186	3,640	18
Dark Canyon	183	3,625	15
Sheep Canyon	177	3,610	9
Narrow Canyon	173	3,604	5
Dirty Devil River	169.5	3,602	1.5
North Wash	168	3,598	0

Note: River miles of critical habitat are computed from the relationship y= 0.3178x - 972.22 (R2 = 0.97), where x = lake elevation, y = river mile. River miles are measured upstream of Lees Ferry.

Table TA 8-4
Estimated Linear Miles of Colorado Pikeminnow and Razorback Sucker Critical Habitat at Varying Lake Powell Elevations (in feet) in the San Juan River Inflow

San Juan River Inflow	River Mile	Elevation	Critical Habitat Inundated (River Miles)
5.5 miles upstream of Clay Hills Boat Ramp	63.5	3,700	39
Clay Hills Boat Ramp	58	3,690	33.5
Piute Falls Waterfall-top	54.5	3,666	30
Piute Falls Waterfall-bottom	53.5	3,638	29
Mikes Canyon	50.5	3,632	26
Copper Canyon	45	3,627	20.5
Nokai Creek	42	3,626	17.5
Great Bend	29.5	3,605	5
Neskahai Wash	24.5	3,600	0

River miles of critical habitat are computed from the relationship y=0.3363x - 1177.8.22 (R2=0.81), where x = lake elevation, y = river mile. River miles are measured upstream from the historic confluence of the San Juan and Colorado Rivers.

In the Average Flow Category, only the Enhanced Coordination and Maximum Operational Flexibility Alternatives yield median elevations above 3,598 feet, at 3,613 feet and 3,604 feet, respectively. This indicates that these two alternatives result in the Colorado River inflow being partially inundated greater than 50 percent of the time in the Average Flow Category. For the remaining alternatives and the CCS Comparative Baseline, only the 75th or higher percentile elevations exceed 3,598 feet, indicating that, in the Average Flow Category, inundation of the Colorado River inflow does occur but less frequently than in the Enhanced Coordination and Maximum Operational Flexibility Alternatives.

In the Critically Dry Flow Category, the 90th percentile elevations are below 3,598 feet for all alternatives and the CCS Comparative Baseline, ranging from 3,509 feet (Supply Driven Alternative [both LB Priority and LB Pro Rata approaches]) to 3,595 feet (Enhanced Coordination Alternative). This indicates that the Colorado River inflow is not inundated in at least 90 percent of years in the Critically Dry Flow Category.

The results are practically the same when considering critical habitat in the San Juan River inflow, which is only 2 feet higher at 3,600 feet.

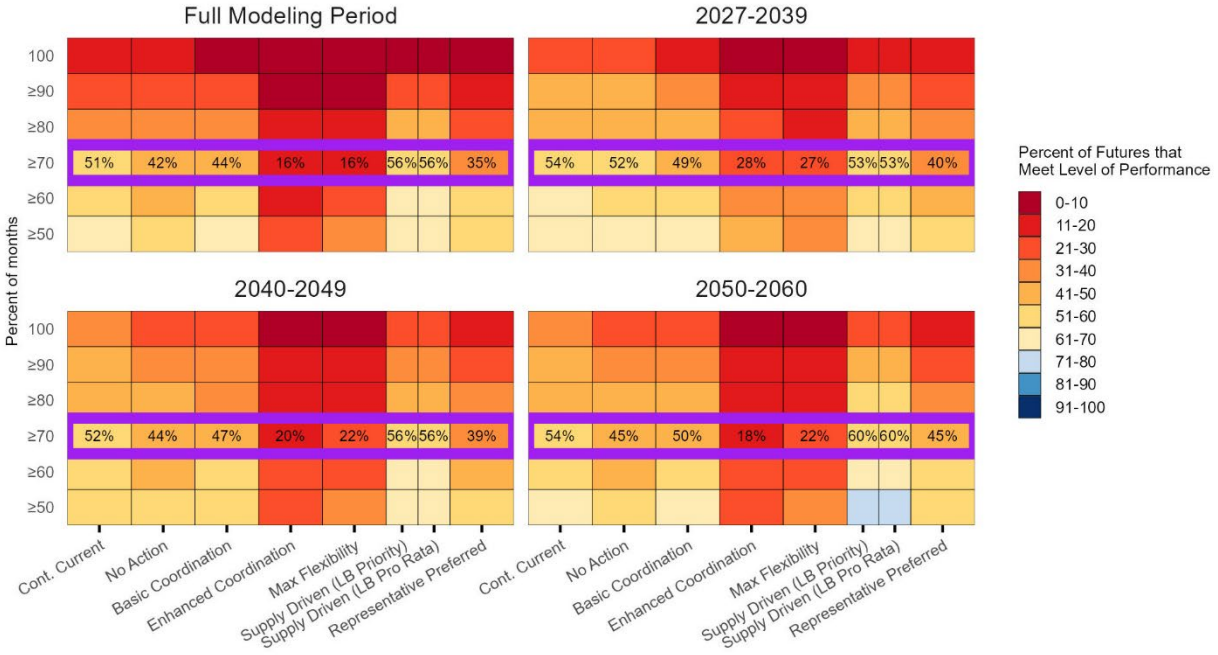

Figure TA 8-1 below depicts the ability of each alternative (columns) to maintain Lake Powell elevations below 3,598 feet in the specified percent of months (rows). Four modeling periods are shown to capture the full modeling period: 2027–2039, 2040–2049, and 2050–2060. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative keeps elevations below 3,598 feet at least 70 percent of months. 70 percent serves as a historical benchmark, as Lake Powell's elevation was below 3,598 feet in 66.7 percent of months in the recent decade (October 2015 to March 2026).

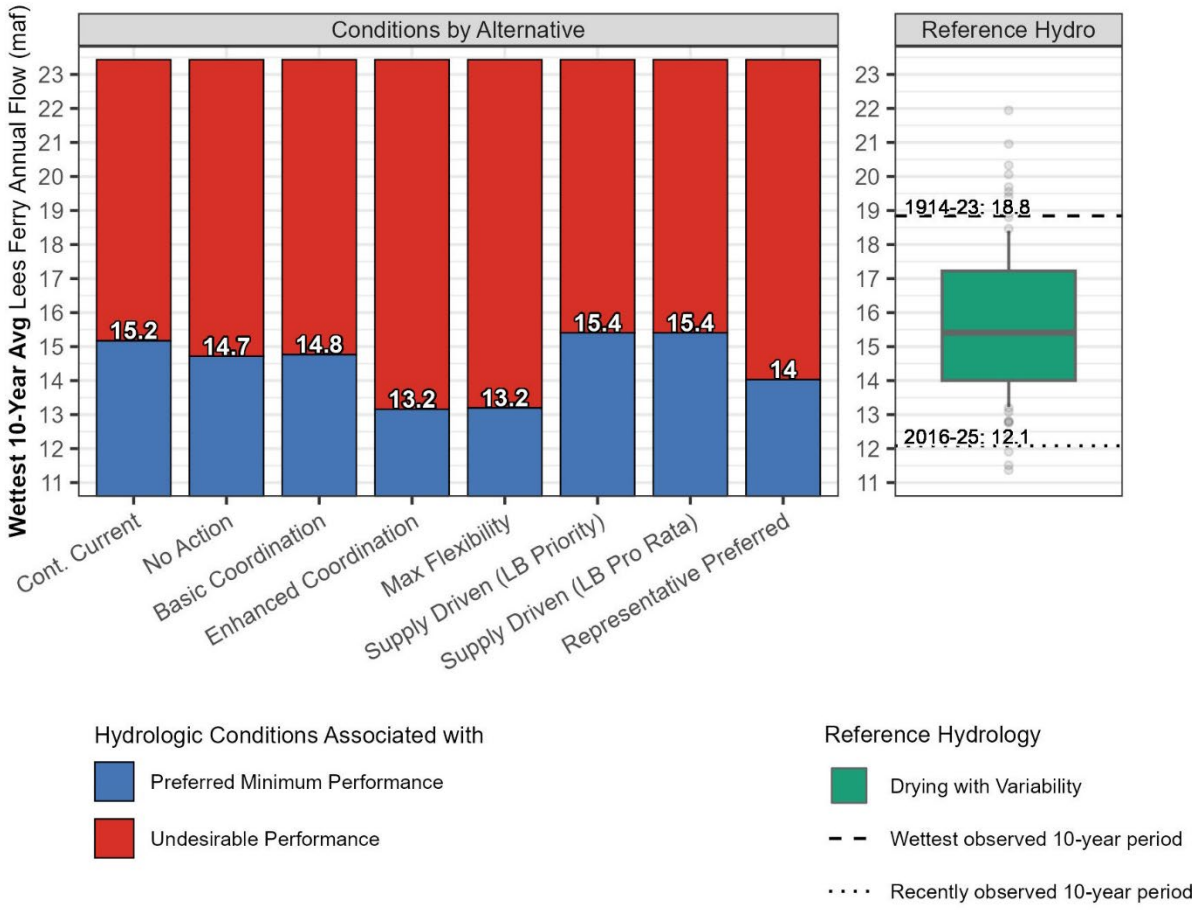
Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at protecting critical habitat for Colorado pikeminnow and razorback sucker in the Colorado River inflow. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard.

Over the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the least robust, satisfying the preferred minimum performance level in only 16 percent of modeled futures. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust, meeting the preferred minimum performance level in 56 percent of futures. Notably, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the only option that outperforms the CCS Comparative Baseline, which meets the preferred minimum performance level in 51 percent of futures. With respect to decadal results, the Enhanced Coordination and Maximum Operational Flexibility Alternatives continue to be the least robust over the three decadal periods. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) continues to be the most robust in all three decadal periods and meets the highest performance level of 60 percent in the last decade (2050–2060).

The Representative Preferred Alternative meets the preferred minimum level of 3,598 feet in 35 percent of modeled futures in the full modeling period. Based on the planned length of this decision,

Figure TA 8-1
Inundation of Critical Habitat of Colorado Pikeminnow and Razorback Sucker by Colorado River Inflow: Robustness.
Percentage of futures in which the Lake Powell elevation is below 3,598 feet in the percentage of months specified by each row



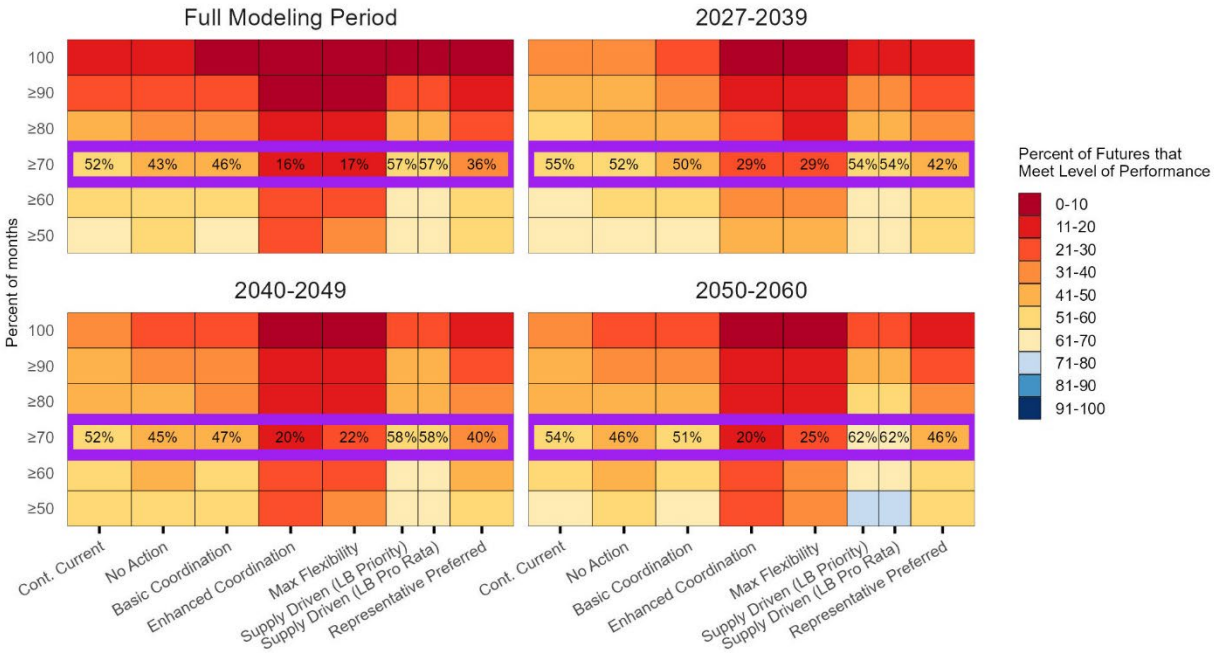
it is important to compare robustness in the 2027-2039 modeling period. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are similarly robust, meeting the preferred minimum performance in 49-54 percent of futures. The Representative Preferred Alternative is in the middle at 40 percent of futures, and the Enhanced Coordination (28 percent) and Maximum Operational Flexibility (27 percent) Alternatives are the least robust.

Figure TA 8-2 below shows what flow conditions are likely to result in Lake Powell elevations above 3,598 feet more than 30 percent of months. This definition of undesirable performance is based on the highlighted row in **Figure TA 8-1** above, which defined a future as successful when an alternative maintained elevations below 3,598 feet at least 70 percent of months.

For this vulnerability analysis, the wettest 10-year average Lees Ferry natural flow was a skillful predictor of undesirable performance. The vulnerability threshold for each alternative is described and compared with the reference hydrology ensemble using this streamflow summary statistic. The reference hydrology panel shows the range of median 10-year average flows represented in the Drying with Variability ensemble, which represents how hydrologic conditions may change in a warmer future, along with the most recent observed 10-year period. The median value of the Drying with Variability ensemble is approximately 15.5 maf, and the most recent 10-year average Lees Ferry annual flow (12.1 maf) is shown as a dotted line for comparison.

Figure TA 8-2
Inundation of Critical Habitat of Colorado Pikeminnow and Razorback Sucker by Colorado River Inflow: Vulnerability.
Conditions that could cause Lake Powell to go above 3,598 feet in more than 30 percent of months

Modeling results indicate that the Enhanced Coordination and Maximum Operational Flexibility Alternatives are likely to meet the preferred minimum performance level when the median 10-year average flow is less than 13.2 maf per year. Because nearly 90 percent of traces in the Drying with Variability ensemble exceed these values, these alternatives are expected to produce Lake Powell elevations above 3,598 feet in more than 30 percent of months unless future conditions are substantially drier than recent history.



The remaining action alternatives have thresholds between about 15.4 and 14.7 maf. Lake Powell elevations would be more likely to achieve the preferred minimum performance if flows like the recently observed 10-year period (12.1 maf) continue, thus helping maintain critical habitat for Colorado pikeminnow and razorback sucker in the Colorado River inflow. This represents a potential reduction in available riverine habitat if Lake Powell refills; however, it is distinct from the more immediate population-level risks associated with the establishment of nonnative piscivorous fish.

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to Lake Powell elevation above 3,598 feet more than 30 percent of the time if the wettest 10-year average Lees Ferry annual flow is greater than 14.0 maf. This alternative may or may not be vulnerable in the next 10 years because of the conflict in different aspects of the reference hydrology panel. Considering the Drying with Variability ensemble, greater than 50 percent of traces are greater than 14.0 maf, suggesting this alternative is reasonably likely to be vulnerable. However, the recently observed 10-year period is below 14.0 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.

Figure TA 8-3 below depicts the ability of each alternative to maintain Lake Powell elevations below 3,600 feet in the specified percent of months. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative keeps elevations below 3,600 feet at least 70 percent of months. 70 percent serves as a historical benchmark, as Lake Powell's elevation was below 3,600 feet in 68.3 percent of months in the recent decade (October 2015 to March 2026).

Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at protecting critical habitat for Colorado pikeminnow and razorback sucker in the San Juan River inflow. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard.

Figure TA 8-3
Inundation of Critical Habitat of Colorado Pikeminnow and Razorback Sucker by San Juan River Inflow: Robustness.
Percentage of futures in which the Lake Powell elevation is below 3,600 feet in the percentage of months specified by each row

Over the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the least robust, satisfying the preferred minimum performance level in only 16 percent and 17 percent of modeled futures, respectively. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust, meeting the preferred minimum performance level in 57 percent of futures. Notably, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the only option that outperforms the CCS Comparative Baseline, which meets the preferred minimum performance level in 52 percent of futures. The decadal results show similar performance and ranking of alternatives.

The Representative Preferred Alternative meets the preferred minimum performance level in 36 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are similarly robust, meeting the preferred minimum performance in 50-55 percent of futures. The Representative Preferred Alternative is in the middle at 42 percent of futures, and the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the least robust (both 29 percent).

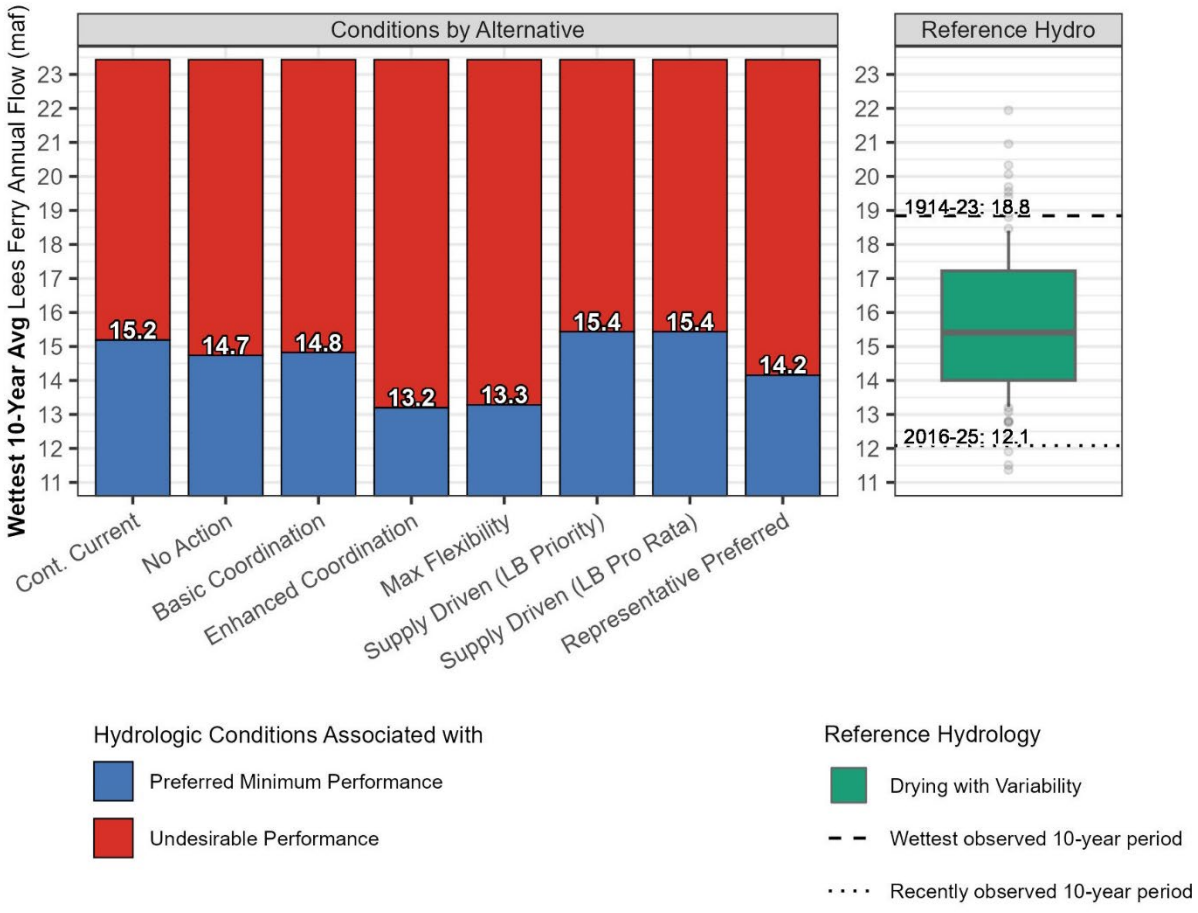


Figure TA 8-4 shows what flow conditions are likely to result in Lake Powell elevations above 3,600 feet more than 30 percent of months. This definition of undesirable performance is based on the highlighted row in **Figure TA 8-3** above, which defines a future as successful when an alternative maintains elevations below 3,600 feet at least 70 percent of months. Elevations above this threshold inundate critical habitat for Colorado pikeminnow and razorback sucker in the San Juan River inflow.

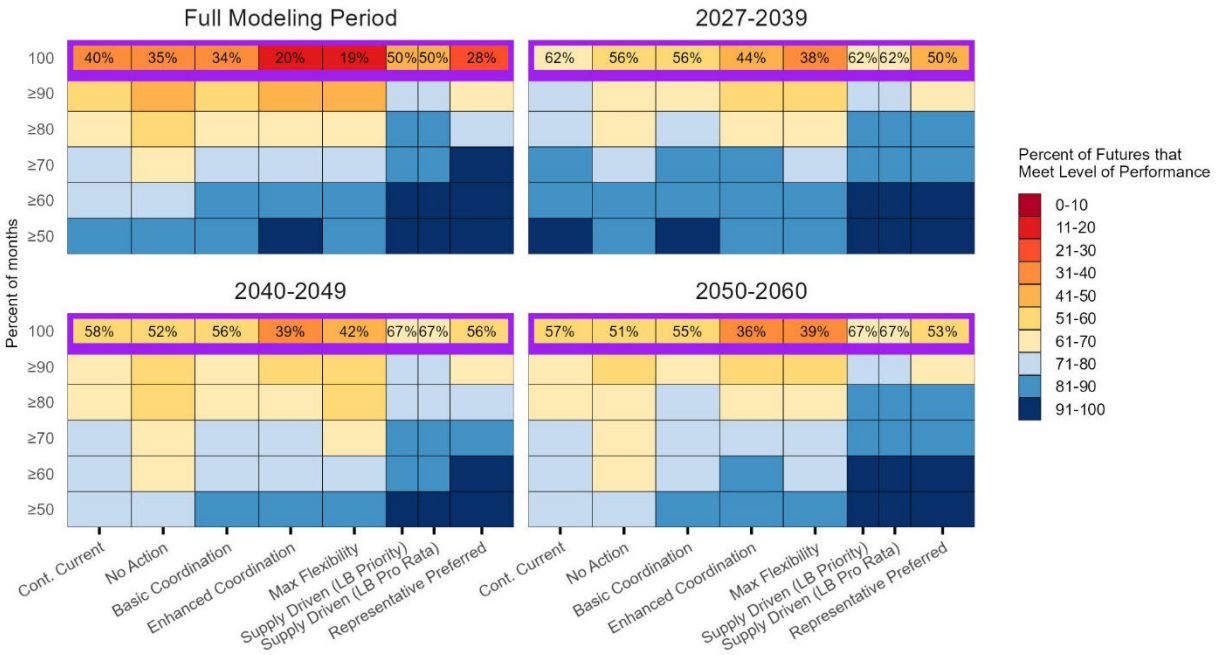
For this vulnerability analysis, the wettest 10-year average Lees Ferry natural flow was a skillful predictor of undesirable performance. The median value of the Drying with Variability ensemble, which represents how hydrologic conditions may change in a warmer future, is approximately 15.4 maf. The most recent 10-year average Lees Ferry annual flow (12.1 maf) is shown as a dotted line for comparison.

If the future has a wettest 10-year average flow greater than 13.2 maf, Enhanced Coordination Alternative modeling results indicate undesirable performance. If the future has a wettest 10-year average flow greater than 13.3 maf, the Maximum Operational Flexibility Alternative modeling results indicate undesirable performance. Unless future hydrology is similar to or drier than the most recent 10-year average, these alternatives are expected to result in Lake Powell elevations above 3,600 feet in approximately 30 percent of months.

Modeling results indicate that the Enhanced Coordination and Maximum Operational Flexibility Alternatives are likely to meet the preferred minimum performance level when the median 10-year average flow is less than 13.2 maf and 13.3 maf per year, respectively. Because nearly 90 percent of traces in the Drying with Variability ensemble exceed these values, these alternatives are expected to produce Lake Powell elevations above 3,600 feet in more than 30 percent of months unless future conditions are substantially drier than recent history.

Figure TA 8-4
Inundation of Critical Habitat of Colorado Pikeminnow and Razorback Sucker by San Juan River Inflow: Vulnerability.
Conditions that could cause Lake Powell to go above 3,600 feet in more than 30 percent of months



The remaining action alternatives have thresholds between about 15.4 and 14.7 maf. Between 25 and 75 percent of traces in the Drying with Variability ensemble have a median 10-year average above these values. Lake Powell elevations would be more likely to achieve the preferred minimum performance if flows like those observed during the recent 10-year period (12.1 maf) continue, thereby helping maintain critical habitat for Colorado pikeminnow and razorback sucker in the San Juan River inflow. Inundation of this habitat reduces its suitability and may decrease fish abundance, survival, and reproductive potential.

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to Lake Powell elevation above 3,600 feet more than 30 percent of the time if the wettest 10-year average Lees Ferry annual flow is greater than 14.2 maf. This alternative may or may not be vulnerable in the next 10 years because of the conflict in different aspects of the reference hydrology panel. Considering the Drying with Variability ensemble, greater than 50 percent of traces are greater than 14.2 maf, suggesting this alternative is reasonably likely to be vulnerable. However, the recently

observed 10-year period is below 14.2 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.

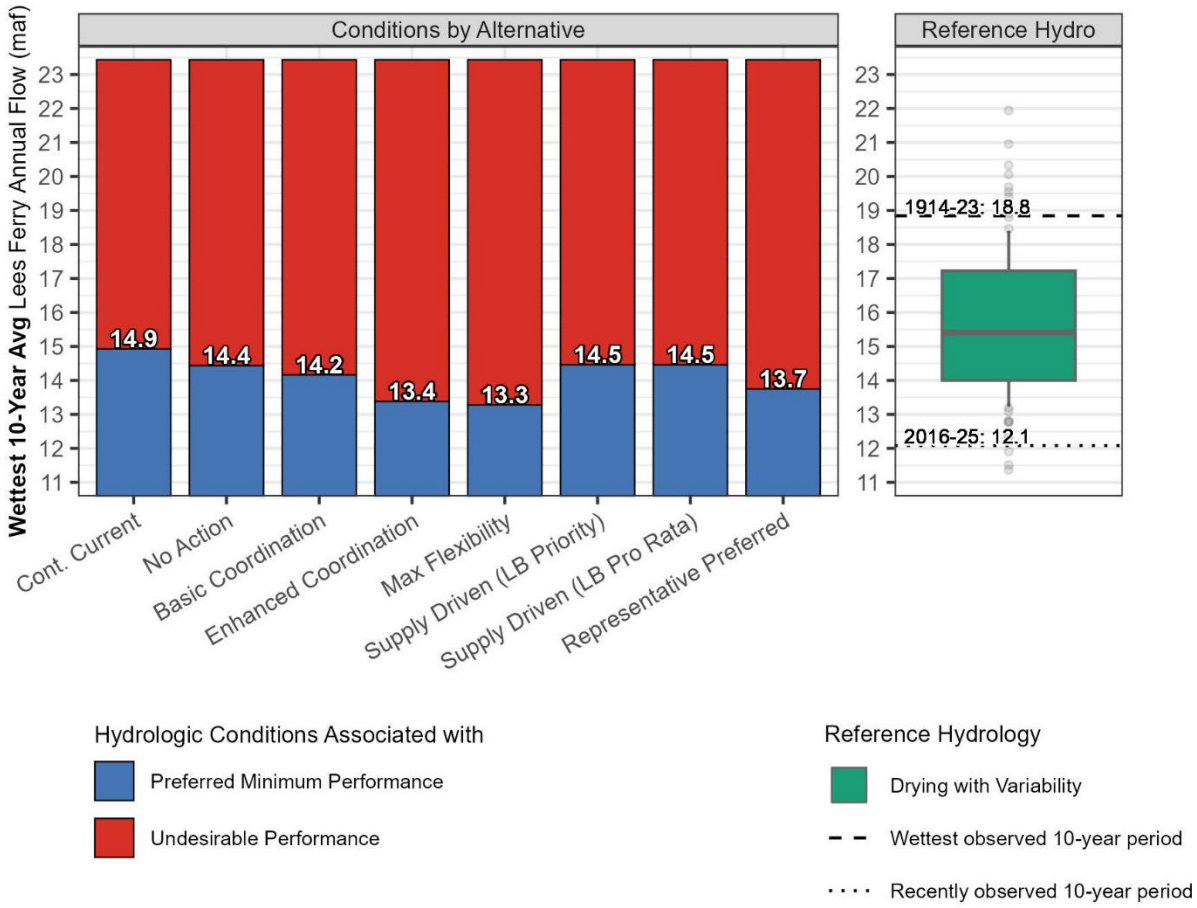
Below, **Figure TA 8-5** evaluates the robustness of each alternative with respect to Paiute Farms Waterfall continuing to function as a barrier. The figure reports the percentage of modeled futures for each alternative in which Lake Powell elevation is below 3,666.5 feet in the percentage of months specified by each row. The highlighted row identifies the preferred minimum performance level: that Lake Powell elevation remains below 3,666.5 feet in 100 percent of months within each modeled future. Staying below this elevation ensures that Piute Farms Waterfall continues to function as a barrier, preventing both native and nonnative fish from moving upstream from the reservoir into the San Juan River's historical riverine habitat. Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at maintaining this barrier and preventing upstream fish movement. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard.

Figure TA 8-5
Piute Farms Waterfall remains a barrier to upstream fish passage: Robustness. Percentage of futures in which the Lake Powell elevation is below 3,666.5 feet in the percentage of months specified by each row

Over the full modeling period, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs the best, satisfying the preferred minimum performance level in 50 percent of modeled futures. This is higher than the CCS Comparative Baseline, which meets the preferred minimum performance level in 40 percent of futures. The results indicate that maintaining Lake Powell's elevation below 3,666.5 feet in every month over the next 34 years may be difficult. If the performance level is relaxed to require elevations below 3,666.5 feet in at least 90 percent of months,

performance improves substantially. Under this condition, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and the CCS Comparative Baseline meet the performance level in more than 71 percent and 51 percent of futures, respectively. Similar alternative rankings are observed when analyzed by decade, with improved performance across all alternatives.

The Representative Preferred Alternative meets the preferred maximum level of 3,666.5 feet in 28 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are similarly robust, meeting the preferred minimum performance in 56-62 percent of futures. The Representative Preferred Alternative is in the middle at 50 percent of futures, and the Enhanced Coordination (44 percent) and Maximum Operational Flexibility (38 percent) Alternatives are the least robust.



When the elevation of Lake Powell is above 3,666.5 feet, the Piute Farms Waterfall on the San Juan River becomes inundated, allowing fish to move above the waterfall from Lake Powell into the San Juan River. This would allow native fish to access historical riverine habitat, which could benefit their populations. But these same conditions would also allow nonnative fish to access the river as potential predators and competitors of native fish.

Figure TA 8-6 shows which flow conditions are likely to result in one or more instances of Lake Powell exceeding 3,666.5 feet. This definition of undesirable performance is based on the highlighted row in **Figure TA 8-5** above, which defines a future as successful when an alternative maintains elevations below 3,666.5 feet 100 percent of the time since elevations above this threshold can inundate the Piute Farms Waterfall.

The wettest 10-year average Lees Ferry natural flow was identified as a skillful predictor of undesirable performance. The reference hydrology panel shows the range of the wettest 10-year average flows represented in the Drying with Variability ensemble, along with the most recent observed 10-year period. The Drying with Variability median value is approximately 15.4 maf, and the most recent 10-year average Lees Ferry annual flow (12.1 maf for 2016–2025) is shown as a dotted line for comparison.

The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most vulnerable, with futures that experience a 10-year average greater than 13.4 and 13.3 maf expected to result in at least one occurrence of elevation above 3,66.5 feet. 10-year averages above these values have occurred historically, and about 90 percent of traces in the Drying with Variability ensemble experience a 10-year average wetter than these thresholds. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), Basic Coordination Alternative, No Action Alternative, and the CCS Comparative Baseline are less vulnerable, with 10-year averages of 14.2–14.9 maf or wetter expected to result in undesirable performance. Between 50 and 75 percent of traces in the Drying with Variability ensemble experience a 10-year average wetter than these thresholds.

Figure TA 8-6
Piute Farms Waterfall remains a barrier to upstream fish passage: Vulnerability. Conditions that could cause Lake Powell elevation to go above 3,666.5 feet in 1 or more Months

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to one or more occurrences of Lake Powell elevation above 3,666.5 feet if the wettest 10-year average Lees Ferry annual flow is greater than 13.7 maf. This alternative may or may not be vulnerable in the next 10 years because of the conflict in different aspects of the reference hydrology panel. Considering the Drying with Variability ensemble, about 75 percent of traces are greater than 13.7 maf, suggesting this alternative is reasonably likely to be vulnerable. However, the recently observed 10-year period is below 13.72 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.

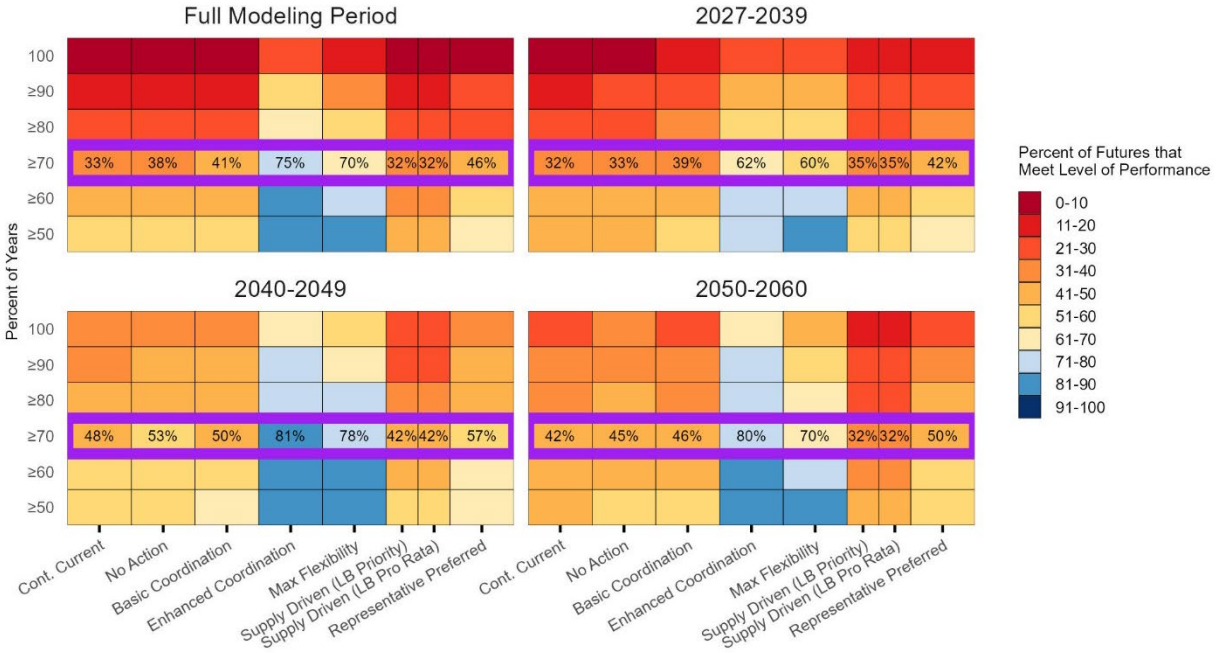
While maintaining the Piute Farms Waterfall as a fish barrier could reduce the effectiveness of river population augmentation efforts (e.g., entrainment of native fish over the waterfall into Lake Powell) and may influence long-term genetic diversity of native fish, it is still considered a net benefit for native fish recovery. Preventing upstream movement of predatory nonnative species, such as striped bass, largemouth bass, and walleye, is critical to protecting recovery efforts. To mitigate impacts on native species, the San Juan River Basin Recovery Implementation Program currently funds manual

translocation of native fish from below the falls to above them and is working to secure funding for a selective fish passage structure that would support native fish movement at this site in the future.

Table TA 8-5 shows the area of inundated shoreline habitat (in acres) at different elevations of Lake Powell, based on the relationship from Root and Jones (2022). The analysis quantifies how changes in lake elevation influence the availability of nearshore habitat. At higher lake elevations, the shoreline typically consists of cobble/gravel benches and shallow, vegetated areas. At lower elevations, the shoreline is primarily steep cliff faces and rock falls. Higher lake levels tend to favor popular sportfish, like largemouth bass, bluegill, and crappie, whereas lower levels favor smallmouth bass (Gustaveson 2018). Expansion of these nonnative sportfishes will likely add predation pressure to native fishes, with the smallmouth bass likely having the highest impact (Eppehimer et al. 2025).

Table TA 8-5
Estimated Acres of Shoreline Habitat at Varying Lake Powell Elevations

Elevation of Lake Powell (Feet)	Inundated Shoreline Habitat (Acres)	Available Shoreline Habitat (Acres)
3,700	160,784	0
3,680	145,647	13,900
3,660	130,899	27,110
3,640	118,054	39,880
3,620	105,929	51,700
3,600	95,387	62,920
3,580	85,667	73,240
3,560	75,981	82,580
3,540	67,206	91,690
3,520	59,476	99,640
3,500	52,386	106,600
3,490	44,883	109,790



Source: Root and Jones 2022
Note: Acres of habitat are computed from the relationship $y=0.00113145734416358*X^3+(-0.9757039*X^2) + (35570.7021*X) + (-38508306.3)$ ($R^2 = 0.9998$), where x=lake elevation, y=acres of inundated shoreline (relationship from Root and Jones [2022]).

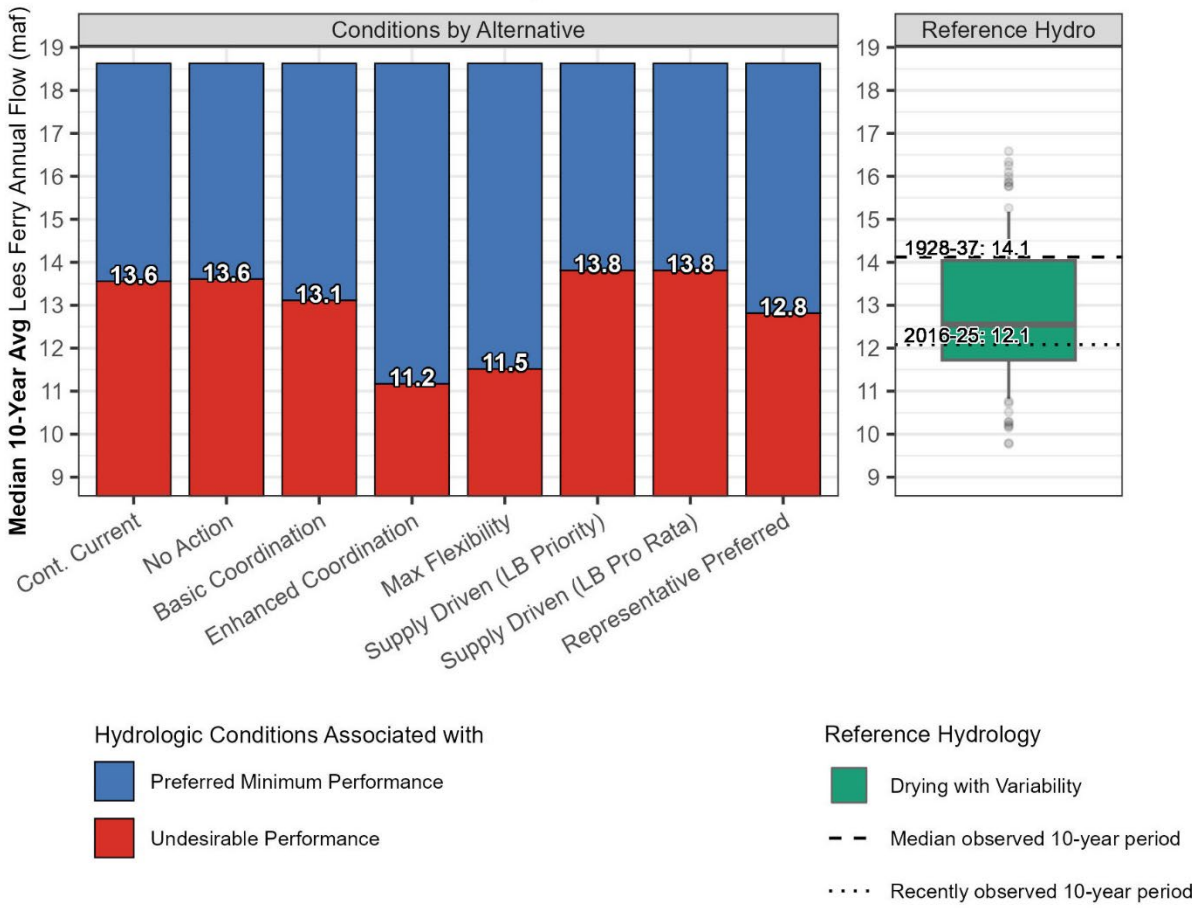
In the Average Flow Category for water year maximums, 90 percent, and 75 percent interquartile ranges for all alternatives other than the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), are projected to increase inundation of shoreline habitat around Lake Powell (see **Figure TA 3-6**, Water Year Minimum and End of Water Year (EOWY) Elevations and Storage Volumes of Lake Powell, in **TA 3**, Hydrologic Resources). The increase or decrease (-) in shoreline habitat (acres) for each alternative, compared to the CSS Comparative Baseline, is the No Action Alternative (7,484), the Basic Coordination Alternative (-9,286), the Enhanced Coordination Alternative (-2,187), the Maximum Operational Flexibility Alternative (-732), and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches; -18,740). Lower reservoir elevations for all alternatives will result in shorelines with steep cliffs and rockfalls that favor smallmouth bass reproduction and recruitment, thereby increasing the population and the risk of entrainment and

additional predation pressures on humpback chub and other native fish downstream of Glen Canyon Dam.

Figure TA 8-7 below shows the ability of each alternative to maintain October 1 Lake Powell elevation above 3,570 feet in the percentage of years specified by each row. The highlighted row identifies the preferred minimum performance level: that the October 1 Lake Powell elevation remains above 3,570 feet in at least 70 percent of years within each modeled future. This threshold reflects recent historical conditions, as the October 1 elevation was above 3,570 feet in seven of ten years from 2016 to 2025, or 70 percent of years.

Figure TA 8-7
Smallmouth Bass Entrainment: Robustness.
Percentage of futures for each alternative in which the October 1st Lake Powell elevation is above 3,570 feet in percent of years specified by each row

Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at reducing the risk of entraining smallmouth bass from the Glen Canyon Dam forebay and allowing them to escape into the Colorado River downstream of the dam. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective and could increase the likelihood that smallmouth bass become more abundant in the Lees Ferry sub-reach and potentially further downstream, increasing predation and competition pressures on native fish, particularly the threatened humpback chub.



Over the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust, satisfying the preferred minimum performance level in 75 percent and 70 percent of futures, respectively. The remaining alternatives and the CCS Comparative Baseline perform substantially worse, meeting the preferred minimum performance level in only 32

to 41 percent of futures. Similar alternative rankings are observed when analyzed by decade, with improved performance across all alternatives.

The Representative Preferred Alternative meets the preferred minimum performance level in 46 percent of futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Enhanced Coordination (62 percent) and Maximum Operational Flexibility (60 percent) Alternatives are the most robust, followed by the Representative Preferred Alternative (42 percent). The remaining alternatives are less robust, meeting the preferred minimum performance level in 32-39 percent of futures.

Figure TA 8-8 below shows what flow conditions are likely to result in October 1st Lake Powell elevation falling below 3,570 feet more than 30 percent of years. This definition of undesirable performance is based on the highlighted row in **Figure TA 8-7** above, which defines a future as successful when an alternative maintains elevations above 3,570 feet at least 70 percent of the time to reduce the risk of entraining smallmouth bass through Glen Canyon Dam.

Figure TA 8-8
Smallmouth Bass Entrainment: Vulnerability.
Conditions that could cause the October 1 Lake Powell Elevation to go below 3,570 feet in more than 30 percent of years

For this vulnerability analysis, the median 10-year average Lees Ferry natural flow was a skillful predictor of undesirable performance. The median value of the Drying with Variability ensemble, which represents how hydrologic conditions may change in a warmer future, is approximately 12.5 maf. The most recent median 10-year average Lees Ferry annual flow (12.1 maf) is shown as a dotted line for comparison.

The Enhanced Coordination and Maximum Operational Flexibility Alternatives are vulnerable to median 10-year averages of 11.2 and 11.5 maf, which are significantly lower than the other alternatives. Less than 25 percent of the Drying with Variability traces have a median 10-year average this dry, so it is reasonably unlikely these alternatives will result in October 1st elevations below 3,570 feet more than 30 percent of the time. The remaining action alternatives and CCS Comparative Baseline are vulnerable to undesirable performance for median 10-year averages between 13.1 and 13.8 maf. Greater than 50 percent of traces in the Drying with Variability ensemble exhibit flows drier than this, indicating these alternatives are reasonably likely to result in October 1st elevation below 3,570 feet more than 30 percent of the time. In other words, they could produce October 1 elevations below 3,570 feet more frequently than observed in recent decades, increasing the likelihood that smallmouth bass could move through Glen Canyon Dam into the Colorado River. Increased presence of smallmouth bass in the Lees Ferry sub-reach and potentially farther downstream could elevate predation and competition pressures on native fish, including the threatened humpback chub.

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to October 1st Powell elevation below 3,570 feet more than 30 percent of years under a median 10-year average of 12.8 maf. This alternative is reasonably likely to be vulnerable in the next 10 years because these conditions occur in more than 50 percent of the traces in the Drying with Variability ensemble, which represents a drier future.

TA 8.2.3 Issue 2: Changes in water quantity, release timing, temperature, and quality from Glen Canyon Dam downstream through the Grand Canyon to Pearce Ferry.

The reach of the Colorado River from Glen Canyon Dam to Lake Mead has undergone ecological changes due to modifications in water quantity, timing, temperature, and quality resulting from dam operations. These changes have affected the habitats and populations of both native and nonnative fish species throughout the Grand Canyon. Of particular concern are the threatened humpback chub and endangered razorback sucker, whose survival and abundance are closely tied to flow regimes and habitat availability. Other native species, such as flannelmouth sucker and bluehead sucker, as well as sportfish such as rainbow trout, are similarly affected by altered river conditions. As the elevation of Lake Powell decreases, the epilimnion, the warm, well-mixed surface water where most fish reside, aligns more closely with the dam's penstocks. The reduction in water elevation increases the likelihood that nonnative fish, such as smallmouth bass, will be entrained, pass through the dam, and enter the Colorado River downstream. Results from entrainment modeling (Eppehimer et al. 2025) suggest that propagule pressure increases dramatically when elevations are below 3,530. If reservoir elevations fall below 3,510 feet, the risk persists as long as water continues to be released through the penstocks (3,490 feet). Once below 3,490 feet, the risk of invasion declines as water is released through the river outlet works. Under current dam

operations, the model predicts that maintaining reservoir elevations above 3,570 feet at the start of the year would substantially reduce the risk of entraining smallmouth bass and other undesirable nonnative species (Eppehimer et al. 2025). Additionally, as Lake Powell's water level declines, warmer water from the epilimnion is released through the dam, resulting in higher downstream water temperatures. These warmer water conditions are likely to facilitate the reproduction and establishment of warmwater nonnative fish that pose a major threat to ESA-listed fish species and other native and sportfish living downstream of Glen Canyon Dam. If highly predatory smallmouth bass were to establish themselves downstream of the dam, removal efforts would be difficult and expensive, with potentially limited success.

To analyze these issues, a suite of biological and ecological indicators and metrics was used. Results of the hydrologic CRSS model were used to evaluate the effects of flows on aquatic resources. Preliminary quantitative models integrating information on smallmouth bass population dynamics, potential entrainment rates, water temperature, and other variables to assess invasion risk and potential management options for smallmouth bass were also used. Key indicators include changes in available habitat and species abundance by life stage, shifts in catch rates for rainbow trout and brown trout in the Lees Ferry sub-reach, and the capture of smallmouth bass downstream of Glen Canyon Dam.

A key metric for this analysis is water temperature thresholds at Lees Ferry, the Little Colorado River confluence, the Havasu Creek confluence, and Pearce Ferry along the river's longitudinal extent between Glen Canyon Dam and Lake Mead. For humpback chub, temperatures below 12 °C (53.6 °F) limit or inhibit growth while temperatures above 16 °C (60.8 °F) allow for mainstream spawning (Valdez and Speas 2007). For smallmouth bass, 16 °C (60.8 °F) was analyzed as temperatures near or exceeding 16 °C (60.8 °F) promote successful spawning (Bestgen and Hill 2016). For trout species, 20 °C (68 °F) was used as the thermal threshold at which trout exhibit stress and mortality, with brown trout more tolerant than rainbow trout at temperatures above 20 °C (68 °F; Valdez and Speas 2007).

The smallmouth bass model was used to predict both propagule pressure, defined as the number of smallmouth bass entrained or passing through Glen Canyon Dam, and downstream lambda (λ, [population growth rate]) based on factors such as Lake Powell elevation, temperature, inflow volumes, and outflows (Yackulic et al. 2024; Eppehimer et al. 2025; Eppehimer and Yackulic 2026). The model provides predictions for propagule pressure estimated at Glen Canyon Dam and lambda at specific river miles, including RM 15, RM 61 at the Little Colorado River confluence, RM 156 at the Havasu Creek confluence, and RM 281 at Pearce Ferry, which can help assess the potential impacts of different management alternatives on smallmouth bass populations. Lambda indicates whether the population is increasing (values greater than 1) or declining (values less than 1). It serves as an important metric for evaluating the reproduction and survival success of smallmouth bass downstream of Glen Canyon Dam. A lambda threshold of less than 1 was chosen for the analysis.

The smallmouth bass model estimates the number of fish that become entrained and survive passage through the dam to determine how dam operations and environmental conditions might influence smallmouth bass population dynamics. When entrainment rates are relatively high (mean estimate of greater than or equal to 100 adult smallmouth bass per year), controlling the invasion

could be challenging due to continued propagule pressure (Eppehimer et al. 2025). However, lower entrainment rates could be a management concern during the early stages of the invasion, as is the case in the Colorado River below Glen Canyon Dam. The mean estimated abundance of adult smallmouth bass in the Glen Canyon Dam tailwater in 2022 and 2023 ranged from approximately 40-50 individuals, with 50 percent credible intervals ranging from approximately 25-55 individuals (Eppehimer et al. 2025). Propagule pressure from reservoirs is an important consideration for smallmouth bass population and invasion dynamics. In the Yampa and Green Rivers of the Upper Colorado River Basin (Breton et al. 2015), 2003–2009 mean estimates of propagule pressure from Elkhead Reservoir into the Yampa River by tagged, translocated smallmouth bass ranged from 21 to 522 individuals per year (Breton et al. 2013). Assuming a theoretical, constant reservoir elevation throughout a year, Lake Powell elevations of 3,536 feet and 3,520 feet correspond to estimated mean annual entrainment and survival rates of approximately 50 and 100 adult smallmouth bass, respectively (Eppehimer et al. 2025; Eppehimer and Yackulic 2026). Therefore, an estimated entrainment rate of greater than or equal to 50 adult smallmouth bass per year could represent more than a doubling of the population of reproductively capable fish. Entrainment of less than 50 individuals was chosen as the analysis threshold below for alternative comparison rather than a desirable condition.

River Flows

River flows for each alternative are reported under **TA 3**, Hydrologic Resources, and are referenced as appropriate within this issue analysis as a baseline for flow conditions that may impact water quality and quantity as they relate to native fish, trout species, and smallmouth bass.

Since 1996, Reclamation has conducted high-flow experiment (HFE) releases from Glen Canyon Dam to manage sediment and maintain or increase sandbar size. These releases are much larger than typical base flows and are specifically designed to enhance sediment deposition. HFE releases are the only current method for generating river stages high enough to build significant sandbars. While HFEs can be as low as 31,500 cubic feet per second, flows of 37,000 cubic feet per second or higher are needed for effective sandbar formation. Most HFEs are of relatively short duration and do not use enough water to significantly impact Lake Powell's elevation or long-term flow conditions. HFEs are primarily sediment management tools and have no direct effect on fish populations in Lake Powell. The only notable biological impact is on fish in the Grand Canyon, especially in the Lees Ferry sub-reach, due to the use of both penstocks and river outlet works that release colder water during HFEs. Please refer to **TA 5**, Geomorphology and Sediment Resources, for a description and analysis of the effects of HFEs downstream of Glen Canyon Dam.

Water Quality

Dissolved oxygen is a critical factor for fish health. Research on dissolved oxygen thresholds for both warmwater and cold-water fish species shows that salmonids are particularly vulnerable to mortality when exposed to low dissolved oxygen concentrations compared to warmwater species (Saari et al. 2017). Sustained dissolved oxygen levels below 3 milligrams per liter (mg/L) can significantly reduce survival rates and feeding efficiency, whereas concentrations in the range of 6–9 mg/L are considered optimal for growth and survival across all life stages (EPA 1986).

Analysis of minimum annual dissolved oxygen concentrations released from Glen Canyon Dam (**Figure TA 6-11**, in **TA 6,** Water Quality) shows that, in the Average Flow Category, all management alternatives result in median dissolved oxygen levels between 4 and 7 mg/L. As flow categories become drier (10.0–12.0 maf) the median dissolved oxygen concentrations decrease and interquartile ranges increase, with more variability among alternatives. In the Critically Dry Flow Category, the Enhanced Coordination and Maximum Operational Flexibility Alternatives generally result in lower minimum annual dissolved oxygen concentrations than other alternatives because they are more effective at maintaining elevations above 3,490 feet (see **Figure TA 3-6**, in **TA 3** Hydrologic Resources, and **Figure TA 15-9**, in **TA 15**, Dams and Electrical Power Resources). The remaining alternatives tend to result in elevations below 3,490 feet in the Critically Dry Category, meaning water is released from the river outlet works and modeled dissolved oxygen increases to 8 mg/L. The robustness and vulnerability analyses in this technical appendix evaluate the ability of each alternative to maintain preferred minimum dissolved oxygen concentrations and keep Lake Powell elevation above 3,490 feet.

Robustness analysis (see **Figure TA 6-12** in **TA 6.2.4**, Issue 3) demonstrates that the Enhanced Coordination and Maximum Operational Flexibility Alternatives have the highest percentage of futures in which minimum annual dissolved oxygen concentrations exceed the hypoxic threshold of 2 mg/L in at least 90 percent of years across the full modeling period. In contrast, the CCS Comparative Baseline and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) have the fewest futures that meet this criterion. When considering operational constraints—specifically, Lake Powell elevations below 3,490 feet and the use of river outlet works (with a conservative minimum dissolved oxygen assumption of 8 mg/L)—the Enhanced Coordination and Maximum Operational Flexibility Alternatives remain the most robust (see **Figure TA 6-13** in **TA 6.2.4**, Issue 3). These alternatives are the only ones to maintain dissolved oxygen concentrations above 2 mg/L in at least 90 percent of years in a majority of futures. Similar alternative rankings occur at higher thresholds (e.g., greater than 5 mg/L) with reduced probabilities.

Vulnerability analysis (see **Figure TA 6-14** in **TA 6.2.4**, Issue 3) indicates that the CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are reasonably likely to result in undesirable performance (dissolved oxygen below 2 mg/L or Lake Powell below 3,490 feet) because they are vulnerable under hydrologic conditions that have occurred historically and in about 75 percent of traces in the Drying with Variability ensemble, which represents how hydrology could change in a drier future. By contrast, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are reasonably unlikely to result in undesirable performance because they are vulnerable under much drier conditions, which have not been observed historically and occur in only about 10 percent of the Drying with Variability ensemble. The Representative Preferred Alternative is reasonably likely to result in undesirable performance because it is vulnerable under hydrologic conditions that have occurred historically and in about 75 percent of traces in the Drying with Variability ensemble.

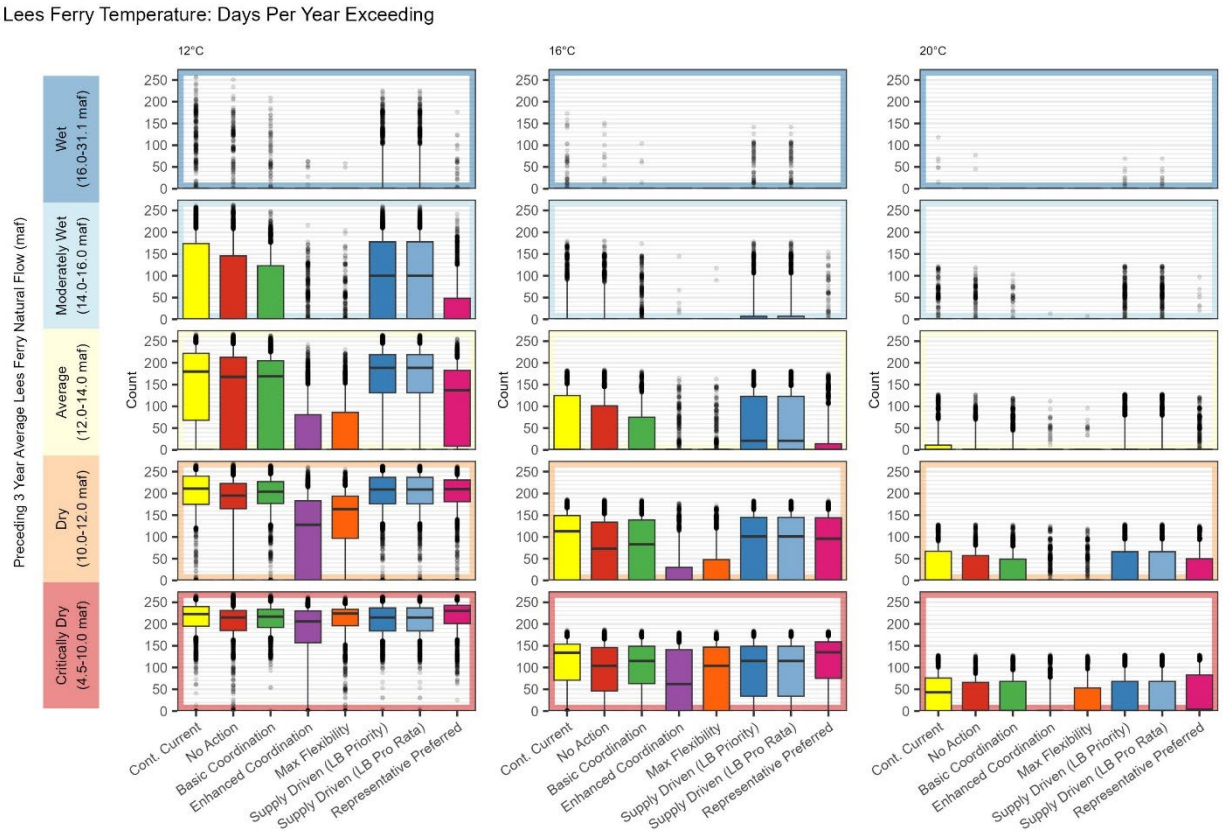
While all alternatives perform similarly under wet conditions, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are more resilient to low dissolved oxygen and reservoir elevations during droughts. The general performance comparisons across alternatives would hold true at higher thresholds required to maintain fish health.

Water Temperature

Water temperature conditions relevant to native fish habitat were evaluated using historical temperature records and scenario analysis outputs. Hourly water temperature data were obtained from the GCMRC GCDAMP database for two monitoring stations: Colorado River above the Little Colorado River (USGS station 09383100) and Colorado River above Diamond Creek (USGS station 09404200). The analysis used data from water years 2008–2025.

Hourly temperature records were aggregated to daily mean temperatures. For each water year, the number of days with mean daily temperature exceeding biologically relevant thresholds of 12°C (53.6 °F) and 16 °C (60.8 °F) was calculated. Temperature data from the station above the Little Colorado River were used to evaluate the 12 °C (53.6 °F) threshold, while data from the station above Diamond Creek were used to evaluate the 16 °C (60.8 °F) threshold. These thresholds represent temperature conditions associated with suitable growth and habitat use for humpback chub and other native fishes.

The two locations were selected to reflect differences in spawning and habitat use along the river. Humpback chub populations near the Little Colorado River primarily rely on the tributary for spawning; therefore, the 12 °C (53.6 °F) threshold evaluated at this location reflects conditions supporting growth and seasonal habitat suitability in the mainstream river near the confluence. In contrast, Diamond Creek was used to evaluate the 16 °C (60.8 °F) threshold because it is more representative of warmer mainstream conditions downstream, where humpback chub spawning has been observed. For each year in the analysis period, the total number of days exceeding each temperature threshold was tabulated to characterize the duration of thermally suitable conditions.



Historical exceedance patterns were used to establish a representative temperature-duration benchmark for subsequent decision-scaling and scenario analyses. Examination of the Diamond Creek record showed that approximately 90 percent of years (16 of 18 water years from 2008–2025) experienced at least 110 days with mean daily temperatures above 16 °C (60.8 °F). Based on this historical relationship, a criterion of at least 110 days above the selected temperature threshold, occurring in at least 90 percent of years, was adopted as a benchmark for sustained thermally suitable conditions.

This benchmark was then applied within the DMDU framework to evaluate projected temperature outcomes under alternative management and hydrologic scenarios. Model outputs were summarized using heatmaps showing the frequency with which the temperature-duration criteria were achieved across scenarios at multiple river locations, including the Colorado River above the Little Colorado River, Havasu Creek, and Pearce Ferry. These analyses were used to evaluate the robustness of management alternatives and to identify hydrologic conditions associated with achieving biologically meaningful temperature targets. This approach highlights longitudinal warming patterns as the river flows downstream from Glen Canyon Dam and provides a basis for comparing projected temperature outcomes across assessed futures. By displaying results in this format, we can evaluate how Lake Powell water temperatures, dam operations, and hydrology may influence thermal regimes.

Lees Ferry

Figure TA 8-9 shows the number of days that modeled water temperatures at Lees Ferry exceed thresholds of 12 °C (53.6 °F), 16 °C (60.8 °F), and 20 °C (68 °F) under each alternative. Exceeding 12 °C (53.6 °F) improves humpback chub growth rates and is considered a desirable response, whereas exceeding 16 °C (60.8 °F) promotes smallmouth bass reproduction and exceeding 20 °C (68 °F) reduces rainbow trout survival; both are considered undesirable responses. Because humpback chub do not typically inhabit the Lees Ferry sub-reach, 12 °C (53.6 °F) is not critical in this analysis but is retained for consistency with subsequent analysis. Thus, fewer days above 16 °C (60.8 °F) would help to limit smallmouth bass spawning without limiting humpback chub. Results are evaluated based on the preceding 3-year average natural flow at Lees Ferry, and the boxplots show the distribution of exceedance days across alternatives and flow regimes.

Figure TA 8-9
Water Temperature at Lees Ferry Based on 3-year Preceding Average River Temperatures at Lees Ferry Exceeding 12° C, 16 °C, and 20 °C Under Each Alternative

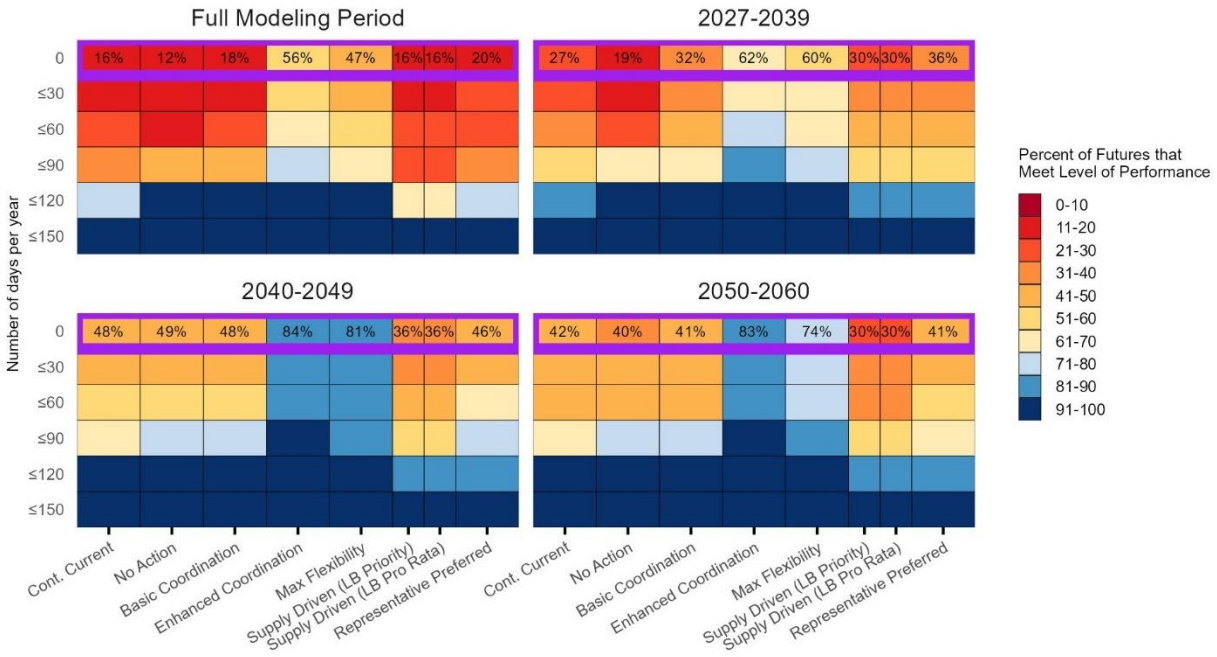
For the 12 °C (53.6 °F) threshold, in the Average Flow Category, the No Action and Basic Coordination Alternatives have similar 25th to 75th percentiles, spanning from 0 to just over 200 days, with similar medians of 168 and 169 days, respectively. The CCS Comparative Baseline has a higher median (180 days), with similar 25th–75th percentiles (68–222 days). The Enhanced Coordination and Maximum Operational Flexibility Alternatives exceed 12 °C (53.6 °F) less frequently than the other alternatives and the CCS Comparative Baseline, with 25th–75th percentiles

from 0 days up to 81 and 86 days, respectively. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has the highest median (188 days) and a narrower interquartile range (25th and 75th percentiles of 131 and 219 days) than the other alternatives and the CCS Comparative Baseline.

As hydrologic conditions become drier (10.0–12.0 maf and 4.5–10.0 maf), patterns remain similar to those observed in the Average Flow Category, with higher medians and smaller interquartile ranges across alternatives. Under the driest conditions (4.5–10.0 maf), temperatures exceed 12 °C (53.6 °F) more frequently across all alternatives, with the Enhanced Coordination Alternative showing the greatest interquartile range (25th and 75th percentiles of 157 and 230 days).

For the 16 °C (60.8 °F) threshold in the Average Flow Category, the median number of days exceeding 16 °C is 0 days across all alternatives except for the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches). At these flows, the Enhanced Coordination and Maximum Operational Flexibility Alternatives have about 90 percent of years with 0 days above 16 °C (60.8 °F). As hydrologic conditions become drier, the overall pattern remains similar, although the median number of days exceeding 16 °C (60.8 °F) increases among all alternatives and the CCS Comparative Baseline.

For the 20 °C (68 °F) threshold, variability remains generally similar across alternatives. Under Moderately Wet and Wet Flow Categories, all alternatives and the CCS Comparative Baseline result in 90 percent or more years with zero days exceeding 20 °C (68 °F). Under Dry and Critically Dry Flow Categories, the percentage of years with days exceeding 20 °C (68 °F) marginally increases, but is less than 50 percent of years for all alternatives except the CCS Comparative Baseline in the Critically Dry Flow Category.



The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the 12 °C (53.6 °F) threshold, the 25th and 75th percentiles range from 181–231 days with a median of 210 days. At 16 °C (60.8 °F), the number of days decreases between the 25th and 75th percentile (0–144 days), with a lower median of 96 days. At 20 °C (68 °F), the median is 0 days with a 75th percentile of only 50 days. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the 12 °C (53.6 °F) threshold, the 25th and 75th percentiles range from 201–243 days with a median of 230 days. At 16 °C (60.8 °F), the number of days decreases between the 25th and 75th percentile (75–159 days), with a lower median of 135 days. At 20 °C (68 °F), the median is 3 days with a 25th and 75th percentile range of 0–83 days.

Overall, as hydrologic conditions become drier, the number of days exceeding each temperature threshold generally increases across alternatives.

Each alternative was evaluated based on its ability to prevent temperatures at Lees Ferry from exceeding 20 °C (68 °F). According to the life histories of rainbow trout and native Grand Canyon fishes, temperatures above 20 °C (68 °F) are likely to decrease rainbow trout survival while creating conditions more favorable for the growth of native fish and smallmouth bass. Additionally, warmer water temperatures may increase brown trout's competitive advantage, as this species is more tolerant of elevated temperatures.

In **Figure TA 8-10**, the percentage of modeled futures for each alternative in which water temperatures remain below 20 °C (68 °F) is evaluated according to the number of days specified by each row. The highlighted row identifies the preferred minimum performance level: that water temperatures remain below 20 °C (68 °F) on all days during the analysis period. Maintaining temperatures below this threshold reduces the risk of rainbow trout mortality due to thermal exposure.

Figure TA 8-10
Rainbow Trout and Native Grand Canyon Fishes Survival: Robustness. Percentage of futures in which the number of days exceeding 20 °C at Lees Ferry is less than the number of days specified by each row

Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at maintaining water temperatures that reduce thermal stress on rainbow trout. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard. Rows toward the top of the figure represent conditions that allow fewer days below 20 °C (68 °F) and are more difficult to achieve, while rows toward the bottom represent conditions that allow more days above 20 °C (68 °F) and are easier to achieve.

Over the full modeling period, the Enhanced Coordination Alternative is the most robust, meeting the preferred minimum performance level in 56 percent of futures. The Maximum Operational Flexibility Alternative performs lower than the Enhanced Coordination Alternative at 47 percent but still performs substantially better than the remaining alternatives. The No Action and Supply Driven Alternatives, including both the LB Priority and LB Pro Rata approaches, perform similarly and are the least robust, meeting the preferred minimum performance level in 12 to 18 percent of futures and performing similarly to the CCS Comparative Baseline. Decadal comparisons of robustness reveal similar rankings among the alternatives. Robustness scores tend to be lowest in 2027 due to

the low initial reservoir conditions in 2027. Robustness is highest after 2040, with the best-performing alternatives—the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative—nearing or exceeding 80 percent in meeting the preferred minimum performance threshold.

The Representative Preferred Alternative meets the preferred minimum performance level in 20 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Enhanced Coordination (62 percent) and Maximum Operational Flexibility (60 percent) Alternatives are the most robust. The remaining action alternatives (including the Representative Preferred Alternative) and the CCS Comparative Baseline are similarly less robust (27-36 percent). The No Action Alternative is the least robust (19 percent).

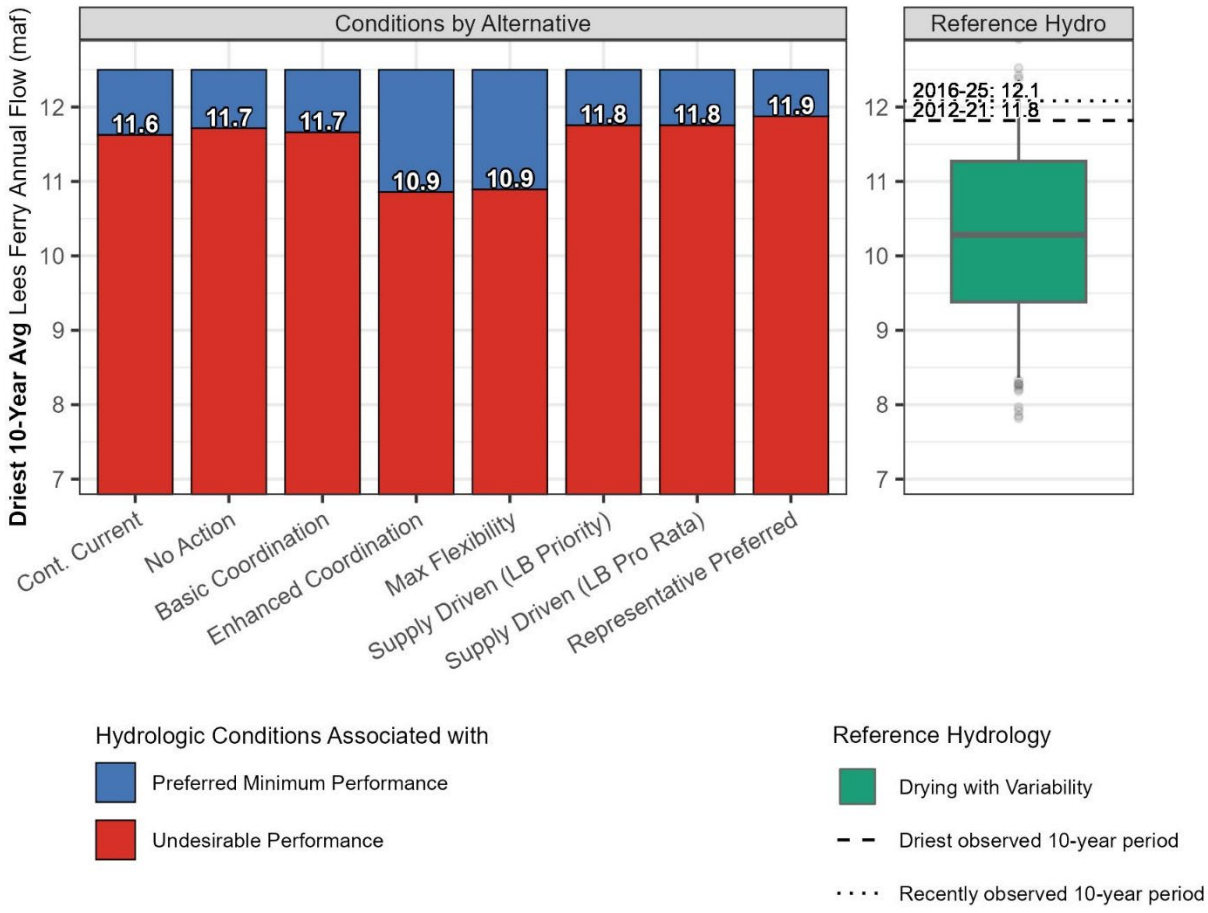


Figure TA 8-11 below shows what flow conditions are likely to result in at least one day with temperature at Lees Ferry exceeding 20 °C (68 °F). This definition of undesirable performance is based on the highlighted row in **Figure TA 8-10** above, which defined a future as successful when an alternative always maintained temperatures below 20 °C (68 °F).

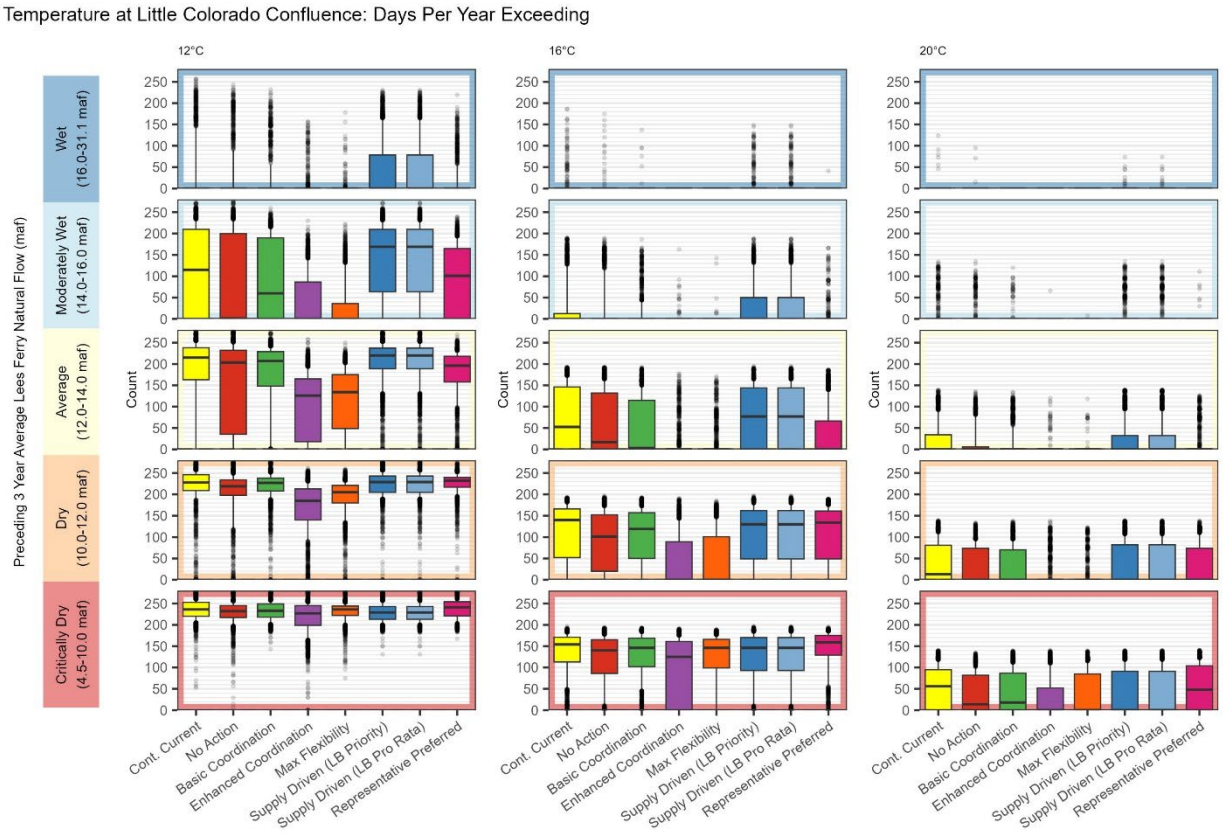
The driest 10-year average Lees Ferry natural flow was identified as a skillful predictor of undesirable performance. The reference hydrology panel shows the range of driest 10-year average flows represented in the Drying with Variability ensemble, which represents how hydrology could change in a drier future. The most recent and driest observed historical 10-year periods are also shown as dotted and dashed lines. The Drying with Variability ensemble's median value is approximately 10.3 maf. The most recent 10-year average Lees Ferry annual flow is 12.1 maf (2016–2025), and the driest 10-year period in the observed record is 11.8 maf (2012–2021).

The CCS Comparative Baseline and No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are vulnerable to temperatures exceeding 20 °C (68 °F) under similar conditions: 10-year average flows between 11.6 and 11.8 maf or lower. These alternatives are reasonably likely to result in undesirable performance because flows similar to this have occurred in the past, and about 90 percent of traces in the Drying with Variability ensemble exhibit these conditions. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are less vulnerable, becoming susceptible to undesirable performance under flows of 10.9 maf. Although these conditions have not occurred historically, about 75 percent of traces in the Drying with Variability ensemble exhibit these conditions

Overall, the Enhanced Coordination Alternative is the most robust for maintaining cooler temperatures at Lees Ferry, followed closely by the Maximum Operational Flexibility Alternative. Cooler conditions support rainbow trout survival and limit smallmouth bass reproduction, but may constrain the growth of some native fishes. Alternatives that maintain higher Lake Powell elevations and cooler release temperatures generally perform better than the No Action Alternative and CCS Comparative Baseline. However, during extended droughts, all alternatives become more vulnerable to warming, which can alter fish habitat and species composition by increasing the presence of native fish and smallmouth bass and potentially favoring brown trout over rainbow trout.

Figure TA 8-11
Rainbow Trout and Native Grand Canyon Fishes Survival: Vulnerability. Conditions that could cause the temperature at Lees Ferry to exceed 20°C in one or more days



The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 11.9 maf or less. Compared to the historical periods shown in the reference hydrology panel, this flow has occurred before. Compared to the Drying with Variability ensemble that represents potential future hydrologic conditions, approximately 90 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

Little Colorado River Confluence

Figure TA 8-12 shows the number of days that modeled water temperatures at the Little Colorado River confluence exceed thresholds of 12 °C (53.6 °F), 16 °C (60.8 °F), and 20 °C (68 °F) under each alternative. Results are evaluated based on the preceding 3-year average natural flow at Lees Ferry, and the boxplots show the distribution of exceedance days across alternatives and flow regimes.

Figure TA 8-12
Water Temperature at the Little Colorado River Confluence Based on 3-year Preceding Average River Temperatures at Lees Ferry Exceeding 12 °C, 16 °C, and 20 °C Under Each Alternative

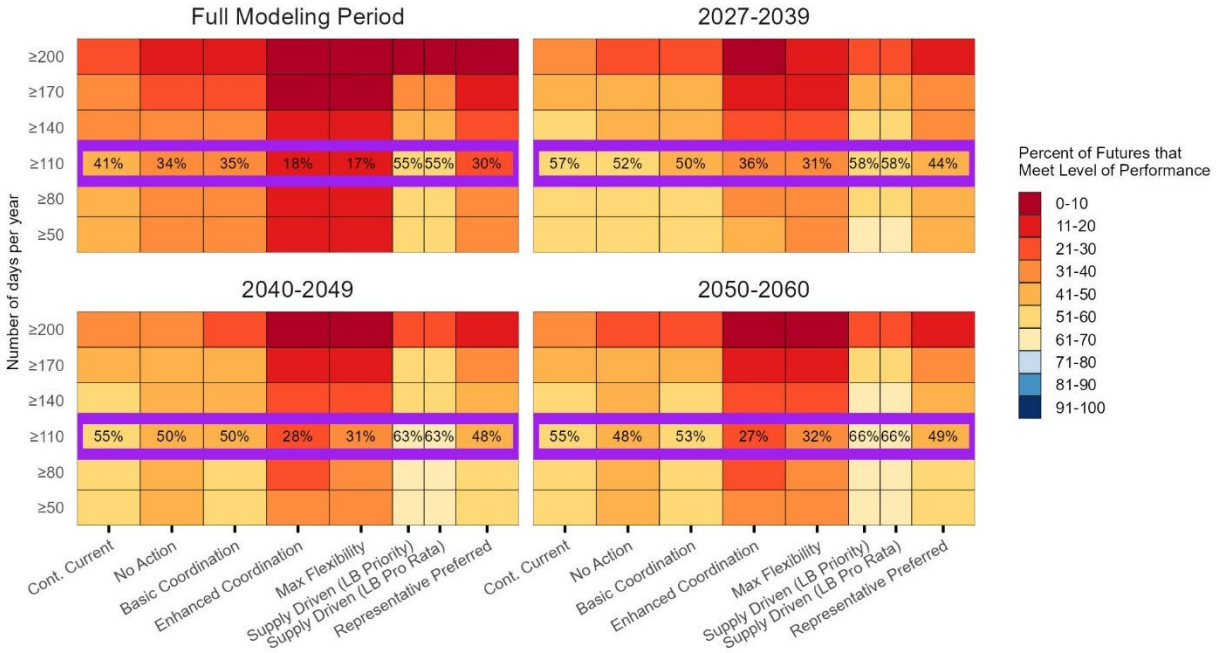
For the 12 °C (53.6 °F) threshold in the Average Flow Category, the Basic Coordination Alternative and CCS Comparative Baseline have similar 25th to 75th percentiles spanning from 148 to approximately 238 days, but different medians (207 and 215 days, respectively). The No Action Alternative has a median similar to those of the Basic Coordination Alternative and the CCS Comparative Baseline, but with greater variability (25th and 75th percentiles of 36 and 232 days). The Enhanced Coordination and Maximum Operational Flexibility Alternatives exceed 12 °C (53.6 °F) less frequently than the other alternatives and the CCS Comparative Baseline, with 25th and 75th percentiles of 18 and 165 days and 49 and 175 days, respectively. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has a higher median (220 days) and a narrower interquartile range (25th and 75th percentiles of 189 and 237 days) compared to the other alternatives and the CCS Comparative Baseline.

In the Dry and Critically Dry Flow Categories, the median number of days above 12 °C (53.6 °F) tends to increase while variability decreases. Comparisons between alternatives remain similar to those observed in the Average Flow Category. In the Critically Dry Flow Category, temperatures exceed 12 °C (53.6 °F) with higher frequency across all alternatives, with the Enhanced

Coordination Alternative showing the most variability (25th and 75th percentiles of 199 and 245 days).

For the 16 °C (60.8 °F) threshold, the median number of days exceeding 16 °C (60.8 °F) is considerably lower than the 12 °C (53.6 °F) threshold, and even 0 days for the Enhanced Coordination and Maximum Operational Flexibility Alternatives in all but the Critically Dry Flow Category. In Wet to Dry Flow Categories, the Enhanced Coordination and Maximum Operational Flexibility Alternatives have relatively few years with days above 16 °C (60.8 °F). As hydrologic conditions become drier, the overall pattern remains similar, although the median number of days exceeding 16 °C (60.8 °F) increases among all alternatives and the CCS Comparative Baseline.

For the 20 °C (68 °F) threshold, under Wet to Average Flow Categories, there are few years with days exceeding 20 °C (68 °F). The percentage of years exceeding 20 °C (68 °F) increases for all alternatives in the Dry and Critically Dry Flow Categories.



The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the 12 °C (53.6 °F) threshold, the 25th and 75th percentiles range from 217–240 days with a median of 232 days. At 16 °C (60.8 °F), the number of days decreases between the 25th and 75th percentile (49–161 days), with a lower median of 134 days. At 20 °C (68 °F), the median is 0 days with a 75th percentile of only 74 days. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the 12 °C (53.6 °F) threshold, the 25th and 75th percentiles range from 221–254 days with a median of 241 days. At 16 °C (60.8 °F), the number of days decreases between the 25th and 75th percentile (129–175 days), with a lower median of 159 days. At 20 °C (68 °F), the median is 48 days with a 25th and 75th percentile range of 0–104 days.

Overall, as hydrologic conditions become drier, the number of days exceeding each temperature threshold generally increases. Enhanced Coordination and Maximum Operational Flexibility tend to result in fewer days above the temperature thresholds than the other alternatives, and the differences among the other alternatives is relatively small.

Each alternative was analyzed based on the number of days per year water temperatures exceed 12 °C (53.6 °F) and 16 °C (60.8 °F). Based on native Grand Canyon fishes' and smallmouth bass life histories, temperatures above 12 °C (53.6 °F) would be conducive to humpback chub growth. Water temperatures exceeding 16 °C (60.8 °F) promote spawning in humpback chub and smallmouth bass. Although warmer water temperatures are beneficial to native fish, such as humpback chub, maintaining cooler water temperatures may limit smallmouth population growth within critical humpback chub habitats.

Figure TA 8-13 reports the percent of modeled futures in which water temperatures at the Little Colorado River confluence exceed 12 °C (53.6 °F) in the number of days per year specified by each row, in at least 90 percent or more of the years. The highlighted row identifies the preferred minimum performance level: that water temperatures exceed 12 °C (53.6 °F) for at least 110 days per year, in at least 90 percent of years. This threshold was selected based on a historical analysis that found that during water years 2008–2025, all but one year had at least 110 days with average daily temperatures above 12 °C (53.6 °F) at the Little Colorado River confluence.

Figure TA 8-13
Humpback Chub Growth at the Little Colorado River Confluence: Robustness. Percentage of modeled futures in which water temperature at the Little Colorado River confluence exceeds 12 °C for at least the number of days per year specified in each row in 90 percent or more of years.

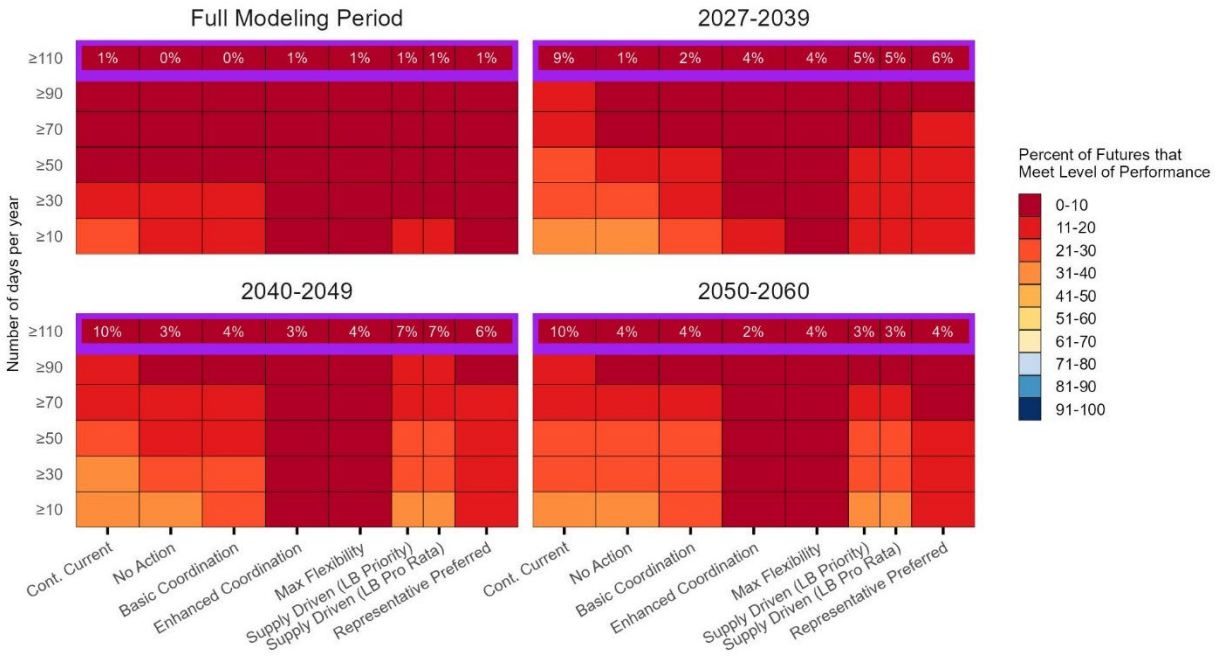
Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at providing water temperatures that promote humpback chub growth. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard. Higher rows represent conditions in which temperatures exceed 12 °C (53.6 °F) for a greater number of days and are more difficult to achieve, while lower rows represent fewer days above 12 °C (53.6 °F) and are easier to achieve.

Over the full modeling period, the Basic Coordination Alternative performs similarly to the No Action Alternative and the CCS Comparative Baseline, meeting the preferred minimum performance level in 34 to 41 percent of futures. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform substantially worse, only meeting the preferred minimum performance level in 18 percent and 17 percent of futures, respectively. The best-performing alternatives (Supply Driven [LB Priority and LB Pro Rata]) are substantially more robust than the Enhanced Coordination and Maximum Flexibility Alternatives, and to a lesser degree, more robust than the Basic Coordination and No Action Alternatives, as well as the CCS Comparative Baseline. As the number of days increases (higher rows in the figure), robustness declines across all alternatives. The same pattern is revealed with the decadal breakout of robustness. Years that maintain higher Lake Powell elevations and greater flow from Glen Canyon Dam create conditions that allow for cooler water temperatures at the Little Colorado River confluence. Overall, alternatives that limit the number of days exceeding 12 °C (53.6 °F), particularly the Enhanced

Coordination and Maximum Operational Flexibility Alternatives, reduce the likelihood of thermal conditions that support humpback chub growth.

The Representative Preferred Alternative meets the preferred minimum performance level in 30 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are similar and the most robust, meeting the preferred minimum performance 50-58 percent of futures. The Representative Preferred Alternative is in the middle (44 percent), and the Enhanced Coordination (36 percent) and Maximum Operational Flexibility (31 percent) Alternatives are the least robust.

Figure TA 8-14 reports the percentage of modeled futures in which water temperatures at the Little Colorado River confluence exceed 16 °C (60.8 °F) in the number of days per year specified by each row, in at least 90 percent or more of the years. The highlighted row identifies the preferred minimum performance level: water temperatures exceeding 16 °C (60.8 °F) for greater than 110 days in at least 90 percent of years during the analysis period. This threshold was selected based on a historical analysis that found that during water years 2008–2025, all but one year had at least 110 days with average daily temperatures above 16 °C (60.8 °F) at the Diamond Creek Confluence. Temperatures at Diamond Creek were used to inform the threshold in this analysis of temperatures at the Little Colorado River confluence because of known humpback chub mainstream spawning throughout the western Grand Canyon.



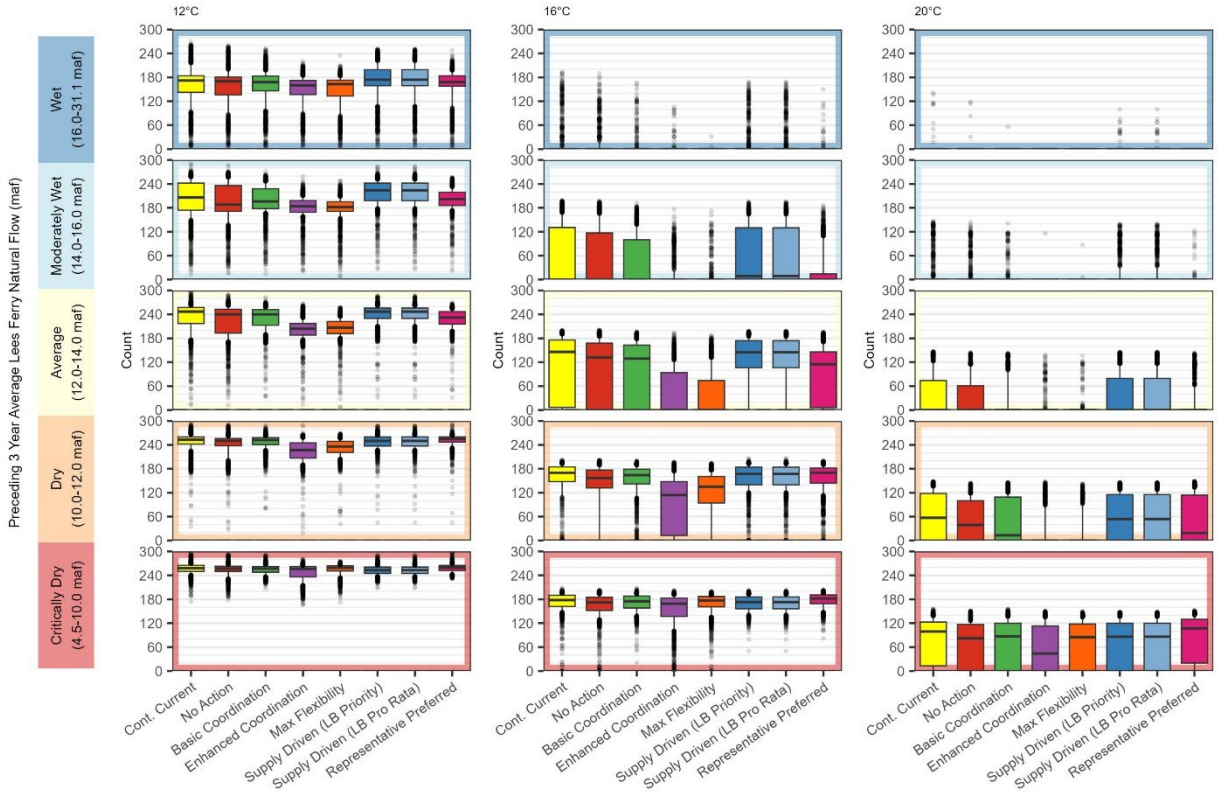
Alternatives that achieve this preferred minimum performance level in a higher percentage of futures better promote humpback chub spawning. Simultaneously, the same conditions could also promote smallmouth bass spawning. Lower rows require fewer days per year above 16 °C (60.8 °F) and are easier to achieve.

Over the full modeling period, all alternatives perform poorly, meeting the preferred minimum performance level in 0 or 1 percent of modeled futures. As the number of days required decreases (lower rows), robustness increases across all alternatives but with relatively low scores. Similar results are observed when broken out by decade.

These results indicate it is difficult to achieve temperatures at the Little Colorado River confluence that support mainstream spawning of humpback chub. However, in this area of the river, humpback chub utilize the Little Colorado River proper for spawning and may not be as dependent on mainstream water temperatures in this area of the Grand Canyon. Although the alternatives perform poorly at promoting humpback chub spawning in the mainstream river, this also indicates poor conditions for smallmouth bass spawning.

The Representative Preferred Alternative meets the preferred minimum performance level in 1 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. All alternatives and the CCS Comparative Baseline perform poorly, meeting the preferred minimum performance in 1-9 percent of futures. The Representative Preferred Alternative meets the preferred minimum performance in 6 percent of futures.

Figure TA 8-14
Humpback Chub Spawning at the Little Colorado River Confluence: Robustness. Percentage of futures in which the temperature at the Little Colorado River confluence exceeds 16 °C in the days per year specified by each row in 90 percent or more of years.



Havasu Creek Confluence

Figure TA 8-15 shows the number of days per year that modeled water temperatures at the Havasu Creek confluence exceed thresholds of 12 °C (53.6 °F), 16 °C (60.8 °F), and 20 °C (68 °F) under each alternative. Results are evaluated based on the preceding 3-year average natural flow at Lees Ferry, and the boxplots show the distribution of exceedance days across alternatives and flow regimes.

For the 12 °C (53.6 °F) threshold, in the Average Flow Category, the Basic Coordination, No Action, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives and the CCS Comparative Baseline result in similar median values, ranging from 240 to 247 days. These alternatives differ in terms of variability and 25th percentiles, with the No Action Alternative having the most variability and the lowest 25th percentile (193 days) and Supply Driven (both LB Priority and LB Pro Rata approaches) being the least variable and having the highest 25th percentile (230 days) among these alternatives. The Enhanced Coordination and Maximum Operational Flexibility Alternatives have notably lower median values of 204 and 207 days, meaning they exceed 12 °C (53.6 °F) less frequently.

Figure TA 8-15
Water Temperature at the Havasu Creek Confluence Based on 3-year Preceding Average River Temperatures at Lees Ferry Exceeding 12 °C, 16 °C, and 20 °C Under Each Alternative

In the Dry and Critically Dry Flow Categories, patterns remain similar to those observed in the Average Flow Category, but with higher medians and smaller interquartile ranges across alternatives. In the Critically Dry Flow Category, temperatures exceed 12 °C (53.6 °F) at similar frequencies across alternatives, although the Enhanced Coordination Alternative shows the largest interquartile range (25th and 75th percentiles of 236 and 262 days).

For the 16 °C (60.8 °F) threshold, variability increases compared to the 12 °C (53.6 °F) results due to a higher frequency of years that result in zero or only a small number of days that exceed 16 °C (60.8 °F). Across all alternatives, median values are lower. In the Average Flow Category, all alternatives except Enhanced Coordination and Maximum Operational Flexibility have similar medians between 129 and 146 days. Enhanced Coordination and Maximum Operational Flexibility tend to have fewer days above 16 °C (60.8 °F), with median values of 0 days. Median values tend to increase, and variability decreases in the Dry and Critically Dry Flow Categories.

For the 20 °C (68 °F) threshold, the frequency of exceeding 20 °C (68 °F) is low in the Wet to Average Flow Categories, demonstrated by all alternatives having median values of 0. The frequency of days above 20 °C (68 °F) increases under drier conditions, with median values ranging from 44

days (Enhanced Coordination Alternative) to 99 days (CCS Comparative Baseline) in the Critically Dry Flow Category. The Enhanced Coordination Alternative has the lowest median value (44 days).

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the 12 °C (53.6 °F) threshold, the 25th and 75th percentiles range from 247–260 days with a median of 255 days. At 16 °C (60.8 °F), the number of days decreases between the 25th and 75th percentile (144–182 days), with a lower median of 170 days. At 20 °C (68 °F), the median is 19 days with a 25th and 75th percentile range of 0–114 days. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the 12 °C (53.6 °F) threshold, the 25th and 75th percentiles range from 252–265 days with a median of 260 days. At 16 °C (60.8 °F), the number of days decreases between the 25th and 75th percentile (169–191 days), with a lower median of 182 days. At 20 °C (68 °F), the median is 107 days with a 25th and 75th percentile range of 20–130 days.

Overall, as hydrologic conditions become drier, the number of days exceeding each temperature threshold generally increases. Most alternatives are relatively similar except Enhanced Coordination and Maximum Operational Flexibility, which tend to result in fewer days per year exceeding the temperature thresholds.

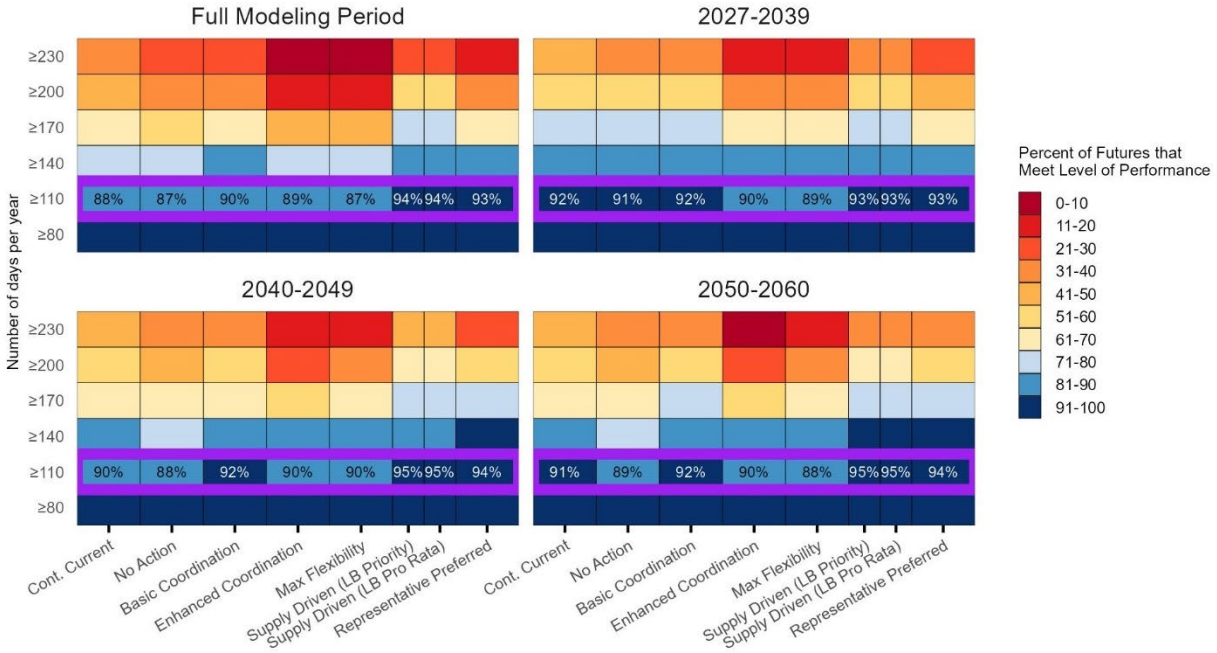
Figure TA 8-16 reports the percentage of modeled futures in which water temperatures at the Havasu Creek confluence exceed 12 °C (53.6 °F) in the number of days per year specified by each row, in at least 90 percent or more of the years. The highlighted row identifies the preferred minimum performance level: water temperatures exceeding 12 °C (53.6 °F) for at least 110 days in at least 90 percent of years during the analysis period. This threshold was selected based on the computed daily average temperature and the analysis of the number of days per water year (2008–2025) with average daily temperatures above 12 °C (53.6 °F) at the Little Colorado River.

Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at providing water temperatures that promote humpback chub growth. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard. Higher rows represent conditions in which temperatures exceed 12 °C (53.6 °F) for a greater number of days and are more difficult to achieve, while lower rows represent fewer days above 12 °C (53.6 °F) and are easier to achieve.

Over the full modeling period, all alternatives performed well at the greater than 110-day threshold (87 percent or higher of futures). The Supply Driven Alternative, including both the LB Priority and LB Pro Rata approaches, and the Basic Coordination Alternative, all show robustness greater than or equal to 90 percent of futures. Similar performance is observed in each decade.

The Representative Preferred Alternative meets the preferred minimum performance level in 93 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. All alternatives are robust, meeting the preferred minimum performance in 89-93 percent of futures. Specifically, the Representative Preferred Alternative meets the preferred minimum performance in 93 percent of futures.

Figure TA 8-16
Humpback Chub Growth at the Havasu Creek Confluence: Robustness. Percentage of futures in which the temperature at the Havasu Creek confluence exceeds 12 °C in the days specified by each row in 90 percent or more of years.



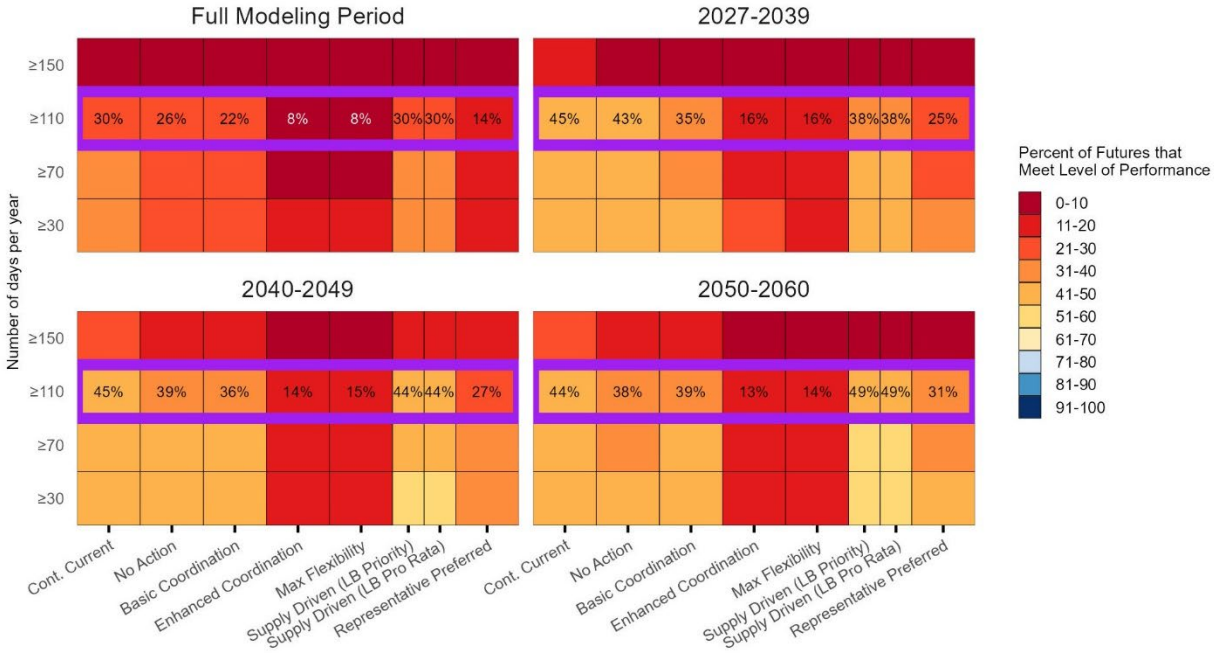


Figure TA 8-17 reports the percentage of modeled futures in which water temperatures at the Havasu Creek confluence exceed 16 °C (60.8 °F) in the number of days per year specified by each row, in at least 90 percent of years. The highlighted row identifies the preferred minimum performance level: water temperatures exceeding 16 °C (60.8 °F) for at least 110 days in at least 90 percent of years during the analysis period. This threshold was selected based on a historical analysis that found that during water years 2008–2025, all but one year had at least 110 days with average daily temperatures above 16 °C (60.8 °F) at the Diamond Creek Confluence. Temperatures at Diamond Creek were used to inform the threshold in this analysis of temperatures at the Havasu Creek Confluence because of known humpback chub mainstream spawning throughout the western Grand Canyon.

Alternatives that achieve this preferred minimum performance level in a higher percentage of futures better promote thermal conditions conducive to humpback chub spawning. Conversely, alternatives that achieve this preferred minimum performance level in a lower percentage of futures are more effective at limiting thermal conditions that support smallmouth bass spawning. Higher rows represent conditions with more days exceeding 16 °C (60.8 °F) and are more difficult to achieve, while lower rows represent fewer days above 16 °C (60.8 °F) and are easier to achieve.

Figure TA 8-17
Humpback Chub Spawning at the Havasu Creek Confluence: Robustness. Percentage of futures in which the temperature at the Havasu Creek confluence exceeds 16 °C in the days specified by each row in 90 percent or more of years.

Over the full modeling period, the Basic Coordination Alternative and the Supply Driven Alternative, including both the LB Priority and LB Pro Rata approaches, perform similarly to the No Action Alternative and the CCS Comparative Baseline, meeting the preferred minimum performance level in 22 to 30 percent of futures. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform worse, only meeting the preferred minimum performance level in 8 percent of futures. Considering the results by decade, the comparison between alternatives remains generally the same, although robustness increases slightly for each alternative. As the required number of days decreases (lower rows in the figure), robustness increases slightly across all alternatives.

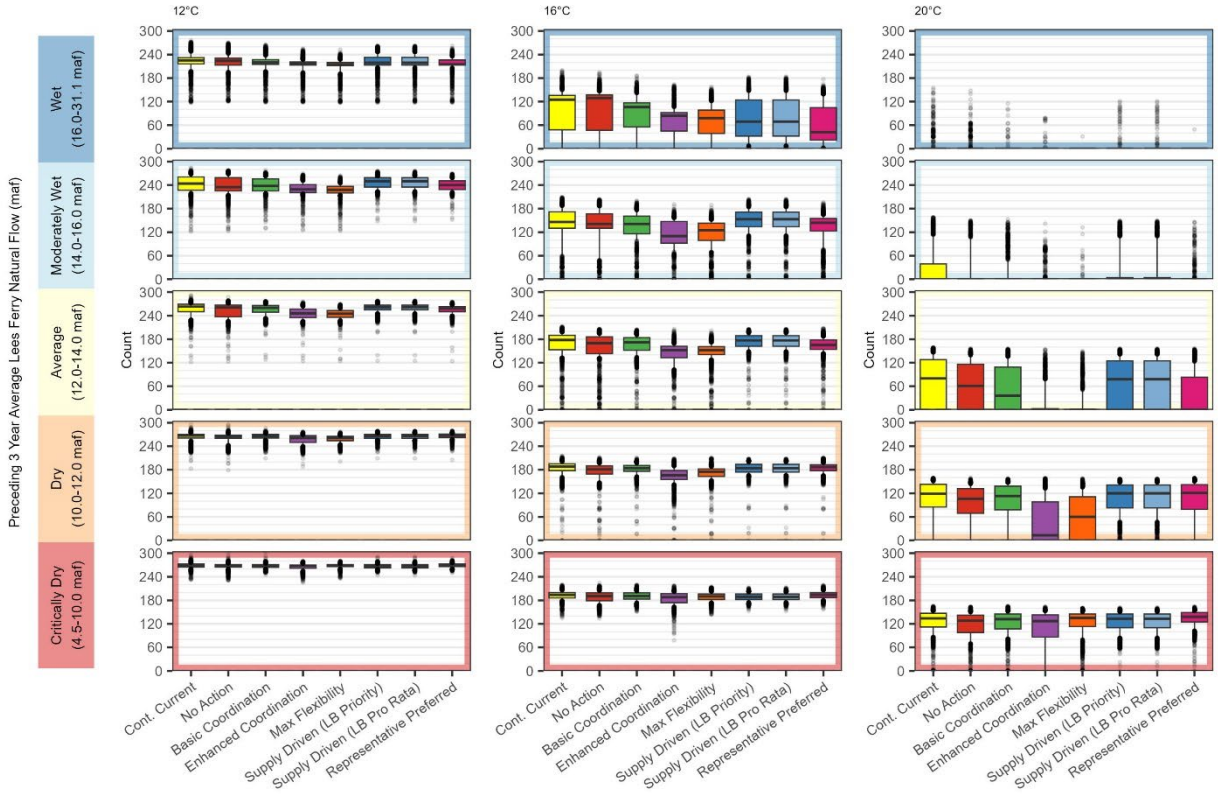
Overall, the Enhanced Coordination and Maximum Operational Flexibility Alternatives result in fewer days exceeding 16 °C (60.8 °F) compared to the other alternatives and the CCS Comparative Baseline, which is less conducive to humpback chub spawning. However, Enhanced Coordination and Maximum Operational Flexibility Alternatives result in temperatures less conducive for smallmouth bass spawning.

The Representative Preferred Alternative meets the preferred minimum performance level in 14 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are the most robust, meeting the preferred minimum performance in

35-45 percent of futures. The Representative Preferred Alternative is in the middle (25 percent), and the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the least robust (both 16 percent).

As with the Little Colorado River, exceeding the 12 °C (53.6 °F) threshold creates thermal conditions that support mainstream humpback chub growth. While these warmer temperatures can benefit native humpback chub by enhancing growth and recruitment, temperatures exceeding 16 °C (60.8 °F) also favor smallmouth bass, which may increase predation and competition pressures on native fish populations. The comparative analysis of alternatives at the 12 °C (53.6 °F) and 16 °C (60.8 °F) thresholds is critical for identifying management scenarios that balance the needs of native and nonnative species. Alternatives that limit the number of days above these temperature thresholds (Enhanced Coordination and Maximum Operational Flexibility Alternatives) may help reduce smallmouth bass population growth but could also restrict opportunities for humpback chub reproduction.

Pearce Ferry



Water temperature analysis at Pearce Ferry allows comparison of variability among alternatives, providing insight into the likelihood of exceeding thresholds that affect humpback chub and smallmouth bass population growth. Although water temperatures at Pearce Ferry can be influenced by Glen Canyon Dam release temperatures, the location is also more influenced by ambient air temperatures relative to upstream reaches. In the fall, when dam releases can be at their warmest, when the lake naturally turns over, and the warmer water is more aligned with the penstock, mainstream water temperatures may cool as they move downstream over 280 river miles. During warmer months, cooler releases from the dam result in cooler water moving downstream (Valdez et al. 2013). This can create a scenario in which average and maximum temperatures are more similar across alternatives at this location.

Figure TA 8-18 shows the number of days that modeled water temperatures at Pearce Ferry exceed thresholds of 12 °C (53.6 °F), 16 °C (60.8 °F), and 20 °C (68 °F) under each alternative. Results are evaluated based on the preceding 3-year average natural flow at Lees Ferry. The boxplots display the range of outcomes for each alternative across different flow regimes. Each row represents a flow category, and the distributions show the number of days temperatures exceed the specified threshold under each alternative.

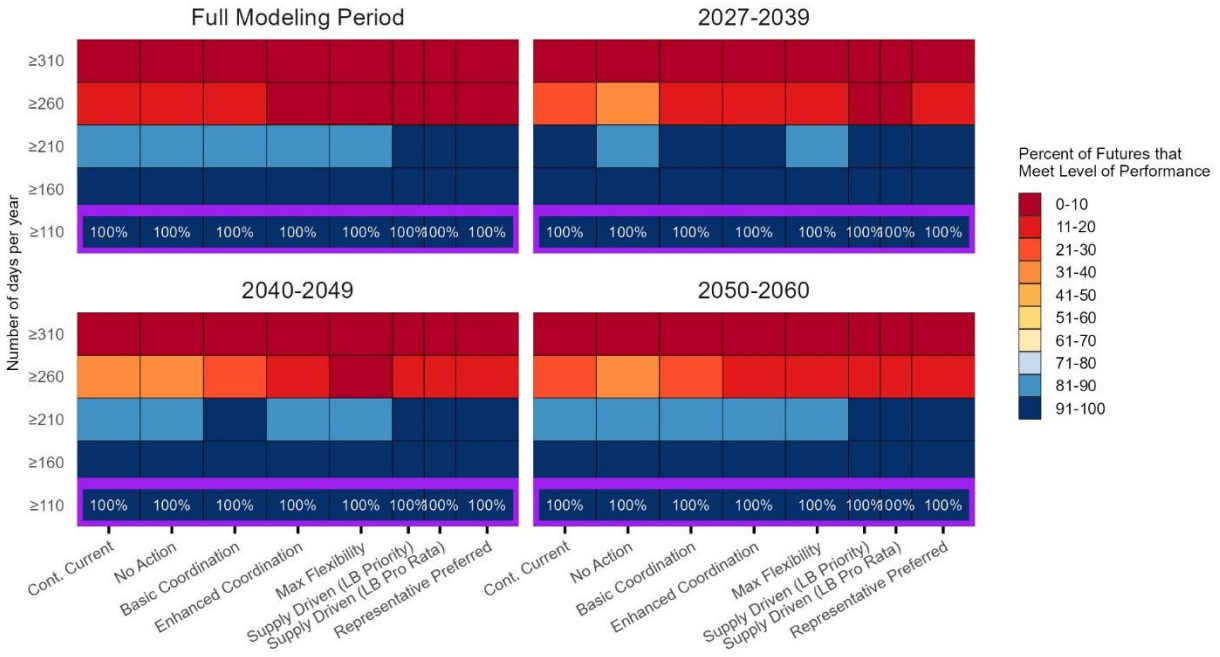
For the 12 °C (53.6 °F) threshold, in the Average Flow Category, the Enhanced Coordination and Maximum Operational Flexibility Alternatives have lower medians of 246 and 245 days, respectively, while the remaining alternatives and CCS Comparative Baseline have median values between 260 and 263 days. No Action exhibits greater variability, caused by a low 25th percentile of 237 days (similar to Enhanced Coordination and Maximum Operational Flexibility) whereas the other alternatives have 25th percentiles between 249 and 255 days.

In the Dry and Critically Dry Flow Categories, median values increase for all alternatives and variability decreases. Under the Critically Dry Flow Category, median values are similar for all alternatives and the CCS Comparative Baseline, between 267 and 269 days.

Figure TA 8-18
Water Temperature at Pearce Ferry Based on 3-year Preceding Average River Temperatures at Lees Ferry Exceeding 12 °C, 16 °C, and 20 °C Under Each Alternative

For the 16 °C (60.8 °F) threshold, median values are lower and interquartile ranges are larger across all alternatives and the CCS Comparative Baseline under each flow category. As conditions become drier, interquartile ranges tend to decrease among alternatives and the CCS Comparative Baseline.

For the 20 °C (68 °F) threshold, in the Very Wet and Wet Flow Categories, the frequency of exceeding 20 °C (68 °F) is low for all alternatives. However, in the Average, Dry, and Critically Dry Flow Categories, the frequency of exceeding 20 °C (68 °F) increases. In the Critically Dry Flow Category, the median number of days above 20 °C (68 °F) ranges between 127 and 135 days.



The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the 12 °C (53.6 °F) threshold, the 25th and 75th percentiles range from 262–271 days with a median of 267 days. At 16 °C (60.8 °F), the number of days decreases between the 25th and 75th percentile (178–193 days), with a lower median of 187 days. At 20 °C (68 °F), the median is 121 days with a 25th and 75th percentile range of 79–142 days. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the 12 °C (53.6 °F) threshold, the 25th and 75th percentiles range from 266–273 days with a median of 270 days. At 16 °C (60.8 °F), the number of days decreases between the 25th and 75th percentile (187–200 days), with a lower median of 194 days. At 20 °C (68 °F), the median is 138 days with a 25th and 75th percentile range of 125–149 days.

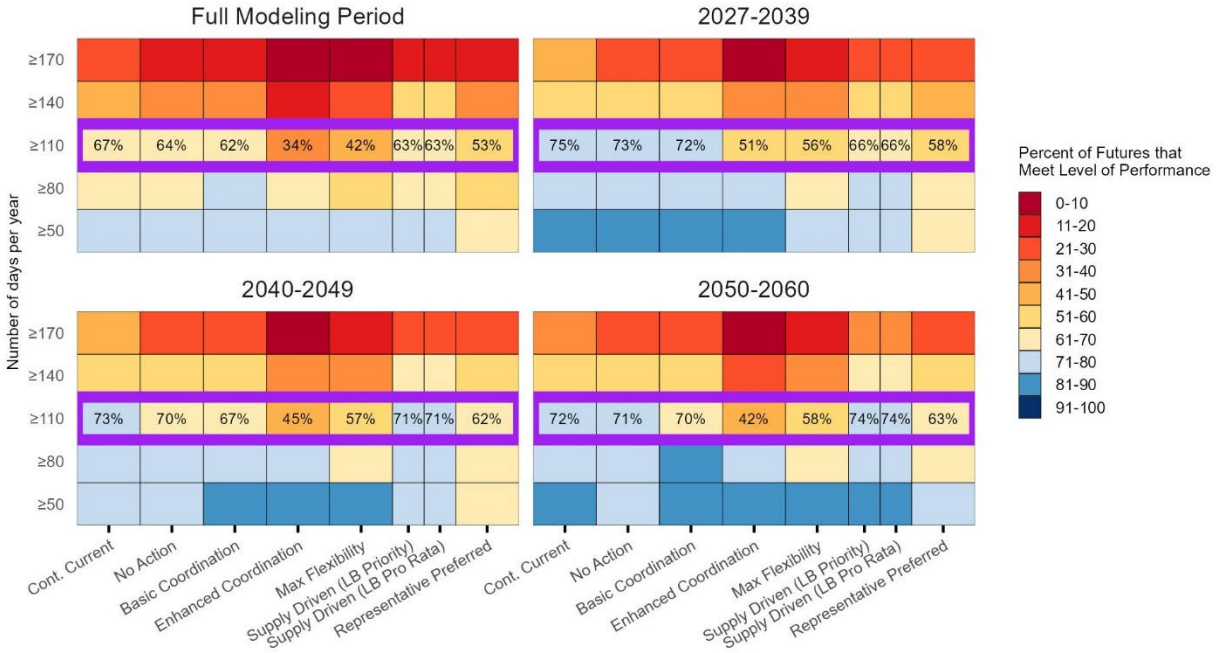
Overall, as hydrologic conditions become drier, the number of days exceeding each temperature threshold generally increases. The differences between alternatives are relatively small except for the Enhanced Coordination and Maximum Operational Flexibility Alternatives, which can result in fewer days exceeding each temperature threshold.

Figure TA 8-19 reports the percentage of modeled futures in which water temperatures at Pearce Ferry exceed 12 °C (53.6 °F) is in the number of days specified by each row in at least 90 percent of years. The highlighted row identifies the preferred minimum performance level: water temperatures exceeding 12 °C (53.6 °F) for at least 110 days in at least 90 percent of years during the analysis period. This threshold was selected based on the computed daily average temperature and the analysis of the number of days per water year (2008–2025) with average daily temperatures above 12 °C (53.6 °F) at the Little Colorado River.

Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at providing water temperatures that promote humpback chub growth. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard. Higher rows represent conditions in which temperatures exceed 12 °C (53.6 °F) for a greater number of days and are more difficult to achieve, while lower rows represent fewer days above 12 °C (53.6 °F) and are easier to achieve.

Figure TA 8-19
Humpback Chub Growth at Pearce Ferry: Robustness.
Percentage of futures in which the temperature at Pearce Ferry exceeds 12 °C in the days specified by each row in 90 percent or more of years

Over the full modeling period and within each decade, all alternatives meet the preferred minimum performance (at least 110 days above 12 °C [53.6 °F] in 90 percent or more years) in 100 percent of the analyzed futures. Differences in performance are not revealed until the number of days per year exceeds 210. Alternatives that create higher elevations at Lake Powell and increase flow allow for cooler water temperatures at Pearce Ferry, even though ambient temperature plays an important role in water temperatures there.



The Representative Preferred Alternative meets the preferred minimum performance level in 100 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to note that it meets the preferred minimum performance level in 100 percent of futures in the first modeling period, as do the other alternatives and the CCS Comparative Baseline.

Figure TA 8-20 reports the percentage of modeled futures in which water temperatures at Pearce Ferry exceed 16 °C (60.8 °F) in the number of days specified by each row in at least 90 percent of years. The highlighted row identifies the preferred minimum performance level: water temperatures exceeding 16 °C (60.8 °F) for more than 110 days in at least 90 percent of years during the analysis period. This threshold was selected based on a historical analysis that found that during water years 2008–2025, all but one year had at least 110 days with average daily temperatures above 16 °C (60.8 °F) at the Diamond Creek Confluence. Temperatures at Diamond Creek were used to inform the threshold in this analysis of temperatures at the Havasu Creek Confluence because of known humpback chub mainstream spawning throughout the western Grand Canyon. Alternatives that achieve this preferred minimum performance level in a higher percentage of futures better promote thermal conditions conducive to humpback chub spawning. Conversely, alternatives that achieve this preferred minimum performance level in a lower percentage of futures are more effective at limiting thermal conditions that support smallmouth bass spawning. Higher rows represent conditions with more days exceeding 16 °C (60.8 °F) and are more difficult to achieve, while lower rows represent fewer days above 16 °C (60.8 °F) and are easier to achieve.

Over the full modeling period, the Basic Coordination Alternative and the Supply Driven Alternative, including both the LB Priority and LB Pro Rata approaches, perform similarly to the No Action Alternative and the CCS Comparative Baseline, meeting the preferred minimum performance level in 62 to 67 percent of futures. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform worse, meeting the preferred minimum performance level in 34 percent and 42 percent of futures, respectively. Performance is generally higher for all alternatives when compared by decade, but the same rankings among alternatives hold true through 2060. As the required number of days decreases (lower rows in the figure), robustness increases across all alternatives.

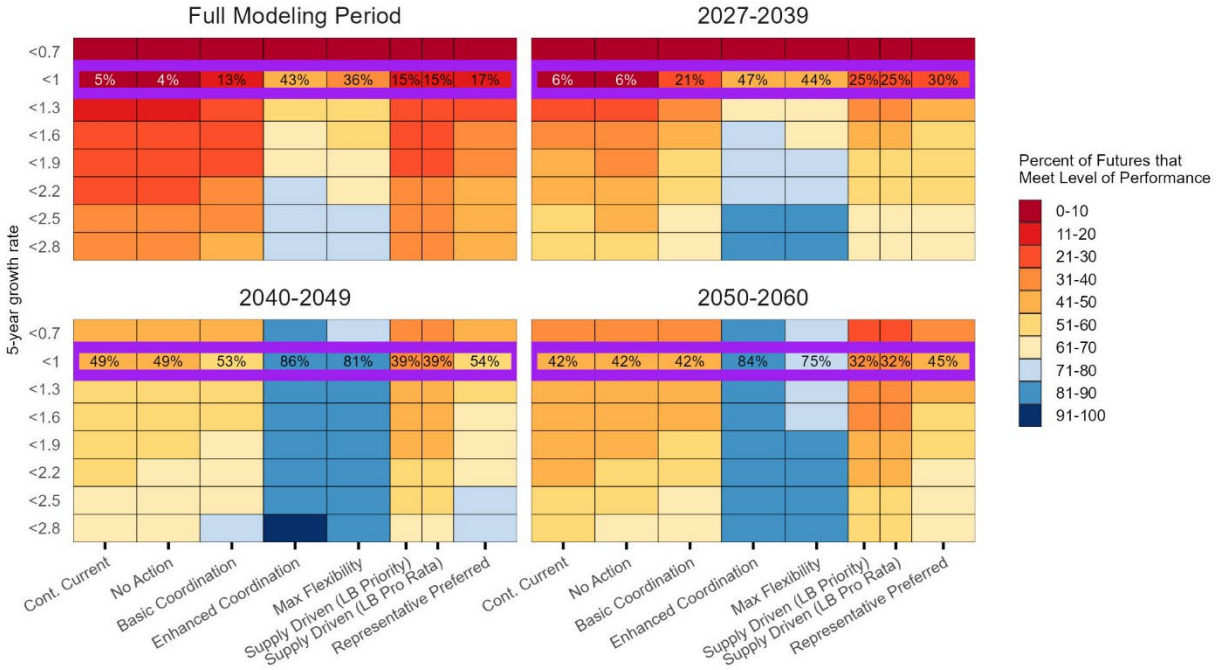
Overall, alternatives that limit the number of days exceeding 16 °C (60.8 °F), particularly the Enhanced Coordination and Maximum Operational Flexibility Alternatives, generally perform worse than the No Action Alternative and the CCS Comparative Baseline in maintaining temperatures beneficial for humpback chub spawning, but those same alternatives may limit smallmouth bass spawning.

Figure TA 8-20
Humpback Chub Spawning at Pearce Ferry: Robustness.
Percentage of futures in which the temperature at Pearce Ferry exceeds 16 °C in the days per year specified by each row in 90 percent or more of years.

The Representative Preferred Alternative meets the preferred minimum performance level in 53 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are the most robust, meeting the preferred minimum performance in 66-75 percent of futures. The Representative Preferred (58 percent), Maximum Operational Flexibility (56 percent), and Enhanced Coordination (51 percent) are slightly less robust.

As with the Little Colorado River and Havasu Creek, exceeding the 12 °C (53.6 °F) threshold creates thermal conditions that support mainstream humpback chub growth. While these warmer temperatures can benefit native humpback chub by enhancing growth and recruitment, temperatures exceeding 16 °C (60.8 °F) also favor smallmouth bass, which may increase predation and competition pressures on native fish populations. The comparative analysis of alternatives at the 12 °C (53.6 °F) and 16 °C (60.8 °F) thresholds is critical for identifying management scenarios that balance the needs of native and nonnative species. Alternatives that limit the number of days above these temperature thresholds (Enhanced Coordination and Maximum Operational Flexibility Alternatives) may help reduce smallmouth population growth but could also restrict opportunities for humpback chub reproduction.

Smallmouth Bass Population Growth



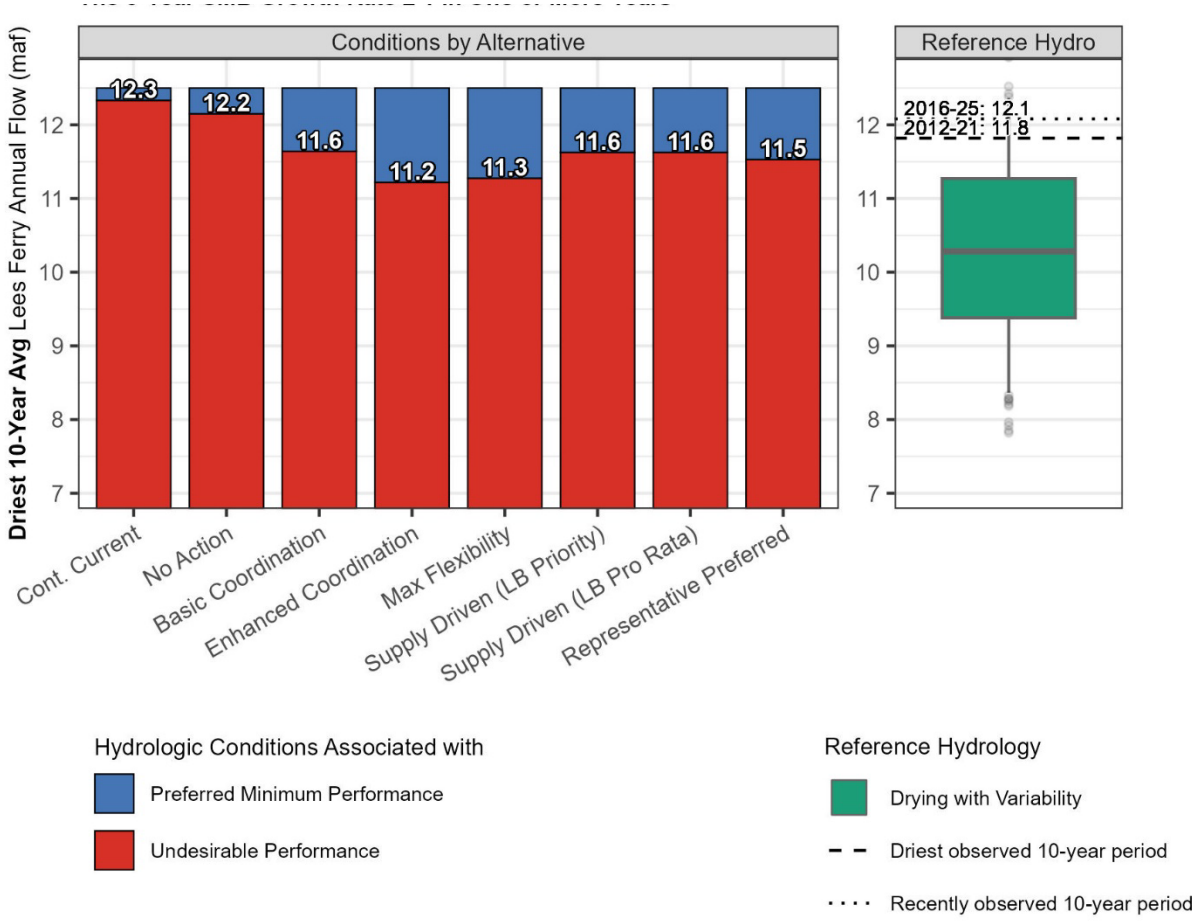
An analysis comparing the percentage of futures in which smallmouth bass lambdas are less than 1 was used to compare alternatives in controlling smallmouth bass survival and recruitment throughout the Grand Canyon. For each year and trace within an alternative, the predicted population growth rate, lambda, was calculated based on predicted water temperatures using the model described in Eppehimer et al. (2025). To keep the smallmouth bass population growth declining, lambda values would need to remain below 1.

The analysis below uses the 5-year product of lambda because it captures the cumulative effect of annual population growth rates and highlights conditions that could lead to sustained population expansion. Considering the 5-year lambda product means a single-year lambda could still exceed 1 but not necessarily result in positive or sustained population growth (Dibble et al. 2026; Pine et al. 2025; Eppehimer, D., GCMRC, personal communication). For consistency with previous analyses (i.e., Reclamation 2024), we use a threshold of less than 1 for analysis and comparison across alternatives.

Figure TA 8-21 reports the percentage of modeled futures in which the 5-year product of smallmouth bass population growth rate (lambda) at Lees Ferry always remains below the value specified in each row. The highlighted row identifies the preferred minimum performance level: 5-year lambda is always less than 1. Meeting the preferred minimum performance level means that, over any 5-year period, the population growth rate declined, decreasing the risk of smallmouth bass populations increasing and being established in the Grand Canyon. 5-year lambdas below 1 are favorable for native fish conservation, whereas values above 1 indicate the potential for increased predation and competition with native fishes. Higher rows represent lower 5-year lambda values that are more difficult to achieve, while lower rows represent higher values that are easier to achieve.

Over the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust, meeting the preferred minimum performance level in 43 percent and 36 percent of futures, respectively. The CCS Comparative Baseline and No Action Alternative perform similarly and perform substantially worse than all other alternatives, meeting the preferred minimum performance level in 5 and 4 percent of futures, respectively. The Basic Coordination and Supply Driven Alternatives, including both the LB Priority and LB Pro Rata approaches, perform similarly to each other with relatively low performance related to the threshold. Across the range of thresholds shown in the figure, alternatives perform similarly at slightly higher 5-year lambda values, which are easier to achieve. For all alternatives, robustness is lowest in 2027–2039 because every modeled future begins with low initial reservoir conditions in 2027. In the second and third decades, the Enhanced Coordination and Maximum Operational Flexibility Alternatives achieve high scores (75 to 86 percent of futures), indicating they are robust at maintaining 5-year lambda below 1. The other alternatives meet the preferred minimum performance level between 32 and 54 percent of futures.

Figure TA 8-21
5-Year Smallmouth Bass Growth Rate: Robustness.
Percentage of futures in which the 5-year product of Smallmouth Bass growth rate (lambda) at Lees Ferry is always less than the value specified by each row



The Representative Preferred Alternative meets the preferred minimum performance level in 17 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Enhanced Coordination (47 percent) and Maximum Operational Flexibility (44 percent) Alternatives are the most robust, followed by the Representative Preferred Alternative (30 percent). The Supply Driven (both LB Priority and LB Pro Rata approaches) (25 percent) and Basic Coordination (21 percent) Alternatives are less robust, while the CCS Comparative Baseline and No Action Alternative are the least robust (both 6 percent).

Figure TA 8-22 below shows what flow conditions are likely to result in at least one occurrence of the 5-year lambda at or above 1.0, indicating conditions that could allow smallmouth bass populations to increase. This definition of undesirable performance is based on the highlighted row in **Figure TA 8-21** above, which defined a future as successful when an alternative always kept the 5-year lambda below 1.0.

The driest 10-year average Lees Ferry natural flow was identified as a skillful predictor of undesirable performance. The reference hydrology panel shows the range of driest 10-year average flows, along with the most recent and driest observed 10-year periods. The reference hydrology's median value is approximately 10.3 maf. The most recent 10-year average Lees Ferry annual flow (12.1 maf from 2016–2025) is represented by a dotted line for comparison, and the driest observed 10-year period averaged about 11.8 maf.

Figure TA 8-22
5-Year Smallmouth Bass Growth Rate: Vulnerability.
Conditions that could cause the 5-year smallmouth bass population growth rate to be at least 1 in one or more years

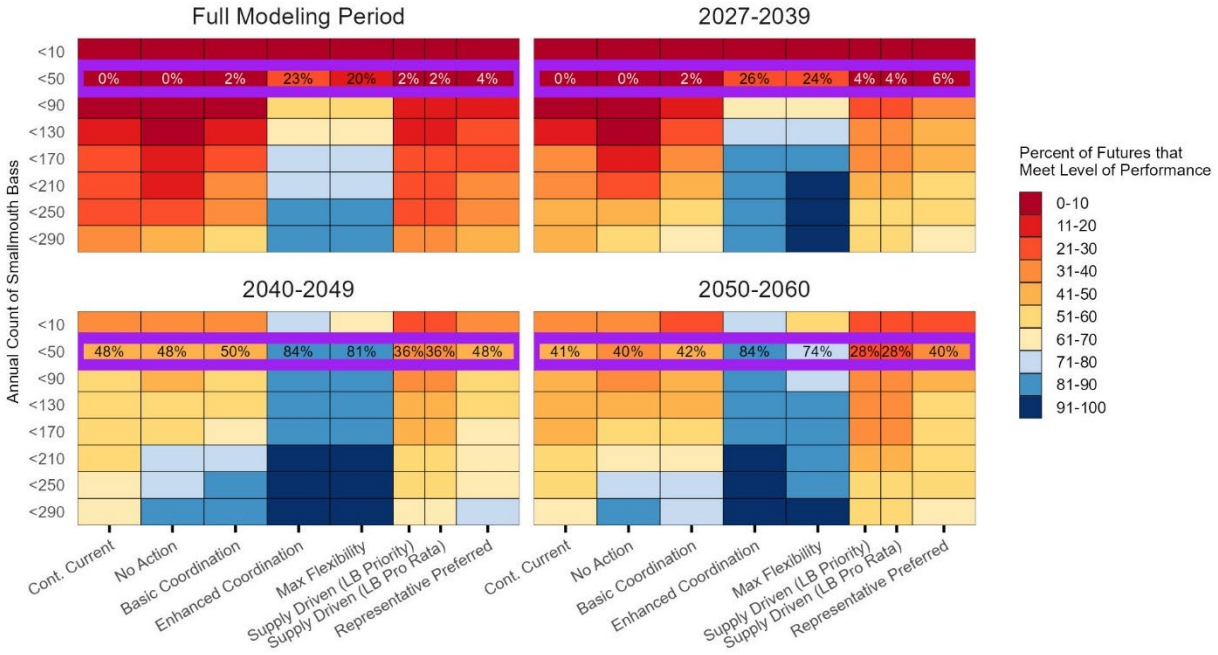
The CCS Comparative Baseline and No Action Alternative are the most vulnerable, being expected to result in undesirable performance under 10-year averages of 12.3 and 12.2 maf. The Basic Coordination and the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives can withstand slightly drier conditions, expecting undesirable performance under 10-year averages of 11.6 maf. These alternatives are reasonably likely to result in undesirable performance because these conditions are similar to the driest historical 10-year period (11.8 maf), and about 90 percent or more of the traces in the Drying with Variability ensemble, which represents how hydrology could change in a drier future, are drier. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform slightly better, with undesirable performance likely under 10-year average flows of 11.2 and 11.3 maf. Although these flows have not occurred historically, they are still reasonably likely to be vulnerable because more than 75 percent of traces in the Drying with Variability ensemble are drier than these thresholds.

The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 11.5 maf or less. Compared to the historical periods shown in the reference

hydrology panel, this flow has not occurred before. Compared to the Drying with Variability ensemble that represents potential future hydrologic conditions, greater than 75 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

Water temperature inputs into the smallmouth bass model drive the lambda results. Based on the analysis of water temperature at Lees Ferry (see **Figure TA 8-9**), the Enhanced Coordination and Maximum Operational Flexibility Alternatives result in fewer days exceeding temperature thresholds (i.e., lower water temperatures), which generally decreases lambda relative to the other alternatives.

Smallmouth Bass Entrainment



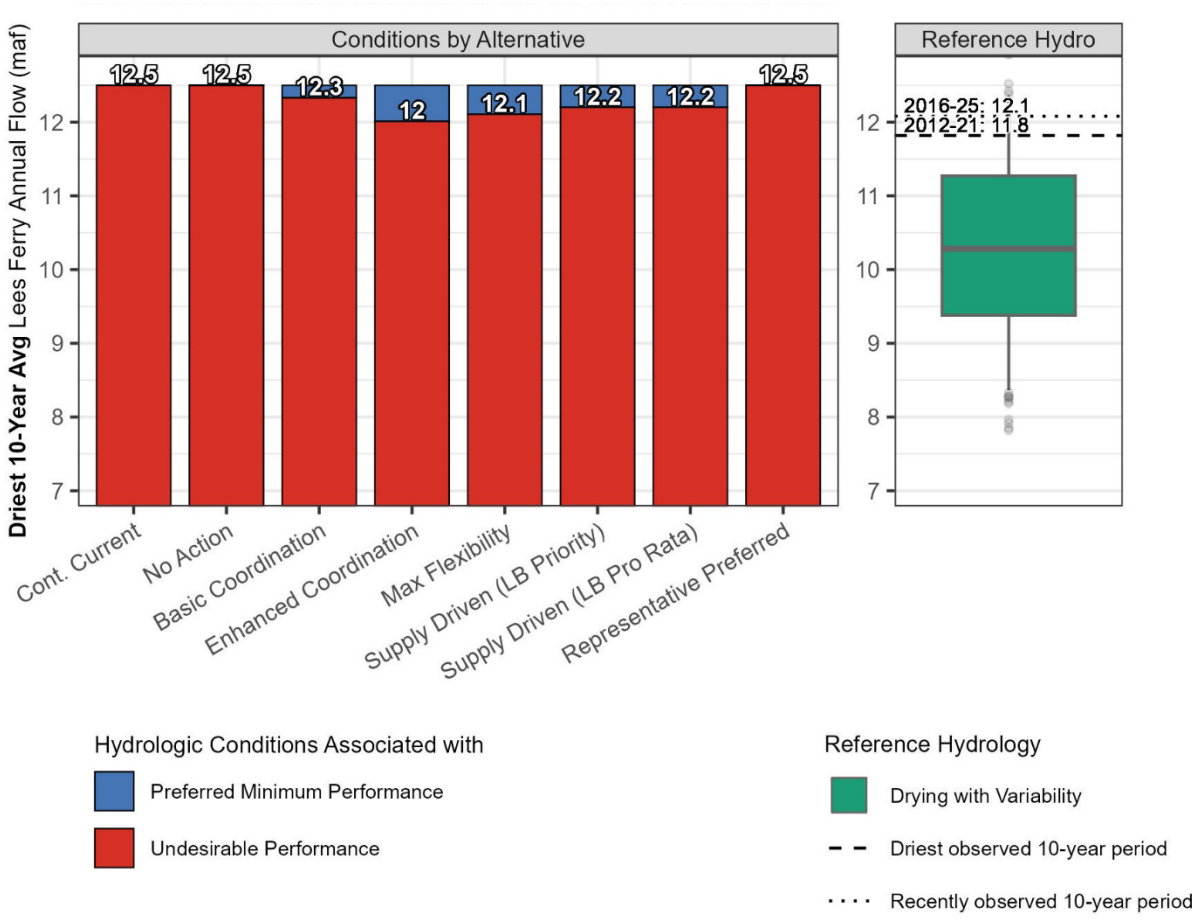
Entrainment of smallmouth bass through Glen Canyon Dam poses a threat to the native fish community, including humpback chub downstream. Data from the smallmouth bass model assess entrainment of adult smallmouth bass through Glen Canyon Dam. We use the annual elevation of Lake Powell to calculate the potential for entrainment and use a relative threshold of fewer than 50 adult individuals for assessment, as described in the methodology.

Figure TA 8-23 reports the percentage of modeled futures in which the annual number of adult smallmouth bass that are entrained through Glen Canyon Dam and survive remains below the number specified by each row. In addition to the 5-year product of smallmouth bass lambda, entrainment and survival are used to assess performance because they reflect the potential for repeated entrainment events to contribute to population establishment and growth in the Grand Canyon.

The highlighted row identifies the preferred minimum performance level: the annual number of adult smallmouth bass that are entrained and survive remains below 50 individuals in every year of each modeled future. This threshold was selected because 50 adults per year could represent more than a doubling of the population of reproductively capable fish, based on abundance estimates from 2022 and 2023 at the beginning of the invasion. This threshold was selected to compare alternative performance rather than assess a preferred entrainment threshold. Higher rows represent conditions allowing fewer adult fish to be entrained and are more difficult to achieve, while lower rows represent higher allowable counts and are easier to achieve.

Over the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust, meeting the preferred minimum performance level in 23 percent and 20 percent of futures, respectively. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven Alternatives, including both the LB Priority and LB Pro Rata approaches, perform similarly and substantially worse, meeting the preferred minimum performance level in approximately 0 to 2 percent of futures. Across thresholds shown in the figure, alternatives perform similarly relative to each other at higher annual counts that are easier to achieve, and slightly lower counts that are more difficult to achieve. Results also indicate that lower Lake Powell elevations increase the probability of entrainment because warmer water, where smallmouth bass typically reside, aligns more closely with the dam penstocks at elevations approaching 3,490 feet (see **Figure TA 8-7** for an analysis of entrainment related to Lake Powell elevation). The percent of

Figure TA 8-23
Smallmouth Bass Entrainment and Survival: Robustness.
Percentage of futures in which the annual count of adult smallmouth bass that are entrained and survive is always less than amount specified by each row



futures that meet the preferred minimum performance is lowest in the first decade because all modeled futures begin with Lake Powell elevation at 3,511 feet in 2027, which makes it difficult to maintain entrainment below 50 individuals. All alternatives perform better in the second and third decades, with Enhanced Coordination and Maximum Operational Flexibility performing the best, meeting the preferred minimum performance in 74 to 84 percent of futures.

The Representative Preferred Alternative meets the preferred minimum performance level in 4 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Enhanced Coordination (26 percent) and Maximum Operational Flexibility (24 percent) Alternatives are the most robust. The remaining alternatives perform poorly, meeting the preferred minimum performance in 0-6 percent of futures. Specifically, the Representative Preferred Alternative meets the preferred minimum performance in 6 percent of futures.

Figure TA 8-24 below shows which flow conditions are likely to result in one or more years with entrainment of 50 or more individuals. This definition of undesirable performance is based on the highlighted row in **Figure TA 8-23** above, which defined a future as successful when an alternative maintained entrainment below 50 individuals. Higher entrainment levels increase the risk of downstream transfer of nonnative fish through Glen Canyon Dam above the current levels and conditions.

Figure TA 8-24
Smallmouth Bass Entrainment and Survival: Vulnerability.
Conditions that could cause the count of smallmouth bass entrained and surviving in any year to be 50 individuals or more

The driest 10-year average Lees Ferry natural flow was identified as a skillful predictor of undesirable performance. The reference hydrology panel shows the range of driest 10-year average flows represented in the Drying with Variability ensemble, which represents how future hydrology could change in a drier future. In addition, the most recent and driest observed 10-year periods are shown with dotted and dashed lines. The reference hydrology's median value is approximately 10.3 maf. The most recent 10-year average Lees Ferry annual flow is 12.1 maf (from 2016–2025), and the driest observed 10-year period averaged about 11.8 maf (2012–2021).

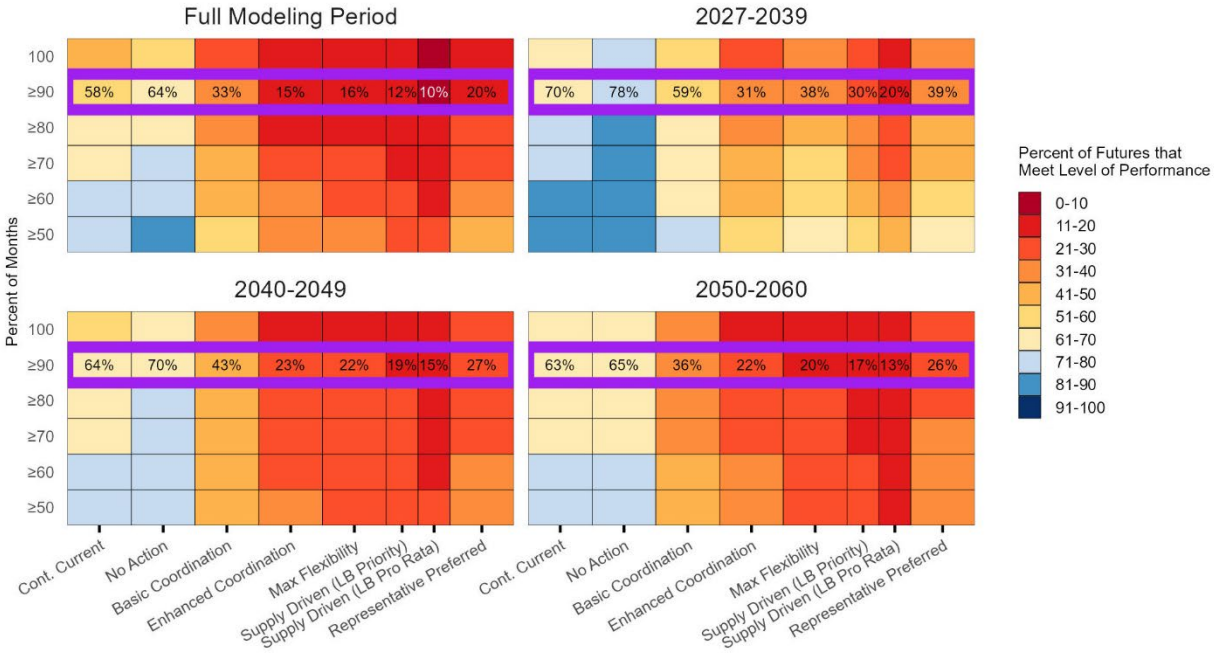
All alternatives and the CCS Comparative Baseline are likely to be vulnerable beginning at 10-year averages between 12 and 12.5 maf. All alternatives are reasonably likely to experience at least one year with 50 or more smallmouth bass entrained because similar conditions have occurred historically, and over 90 percent of traces in the Drying with Variability ensemble exhibit drier conditions. Although all alternatives are likely vulnerable over the full 34-year modeling period, recall that the Enhanced Coordination and Maximum Operational Flexibility Alternatives exhibit strong

robustness later in the modeling period, after having time to recover from low initial reservoir conditions in 2027 (see **Figure TA 8-23**, above).

The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 12.5 maf or less. Compared to the historical periods shown in the reference hydrology panel, this flow has occurred before. Compared to the Drying with Variability ensemble that represents potential future hydrologic conditions, approximately 90 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

TA 8.2.4 Issue 3: Lower reservoir elevations have reduced lake habitat and extended river inflows, including about 30 miles on the Colorado River and 20 miles on the Virgin River, with similar extensions observed at Las Vegas Bay, Echo Bay, and other locations in Lake Mead. How will these inflow changes affect the quantity and quality of Lake Mead, wetland, and riverine inflow habitats?

The Lower Basin from Lake Mead to the SIB has experienced ecological changes driven by fluctuations in reservoir elevations and tributary inflows. These changes affect the quantity and quality of aquatic habitats in both lake and inflow areas, with consequences for native, nonnative, and recreationally important fish species. Lower lake elevations reduce shoreline habitat for sportfish and razorback sucker, while simultaneously extending riverine inflow habitats on the Colorado River, Virgin River, and other tributaries. Such shifts may alter designated critical habitat for razorback sucker and influence the distribution of native species, including humpback chub and razorback sucker. Spawning and nursery habitats for razorback sucker may change with increases in elevation of Lake Mead and could become limited. Pearce Ferry Rapid functions as a natural barrier to fish movement (native and nonnative), but at elevations above 1,090 feet, the rapid no longer serves as a barrier. However, elevations below 1,000 feet compromise hydropower generation.



To evaluate these changes, indicators include monitoring data on sportfish catch, shifts in the distribution and abundance of native fish species, and the extent and quality of inflow and shoreline spawning habitats. Bathymetric analyses or lake elevation data provide critical insight into thresholds where razorback sucker spawning habitats become desiccated or reduced. Thresholds also include lake elevations outside the historical 2007 Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead period (2008–2025) (FWS 2007), which represent untested conditions for fish communities within Lake Mead. Assessment methods integrate monitoring data from AZGFD, NDOW, and the LCR MSCP, as well as DMDU analyses of lake elevation scenarios to evaluate differences in aquatic habitat and fish community response under alternative management strategies.

Thresholds used in the analysis include: (1) Lake Mead elevation above 1,090 feet, at which Pearce Ferry Rapid becomes inundated and no longer functions as a barrier to upstream fish passage, and (2) lake elevations at which razorback sucker spawning locations in the lake are desiccated or, more broadly, when elevations and habitats fall outside the historical range of lake elevations observed during 2015–2025. These thresholds are biologically significant because they may influence the distribution, survival, and reproduction of both native fish populations and sportfish in Lake Mead and represent conditions not previously experienced in recent decades. In all cases, an important

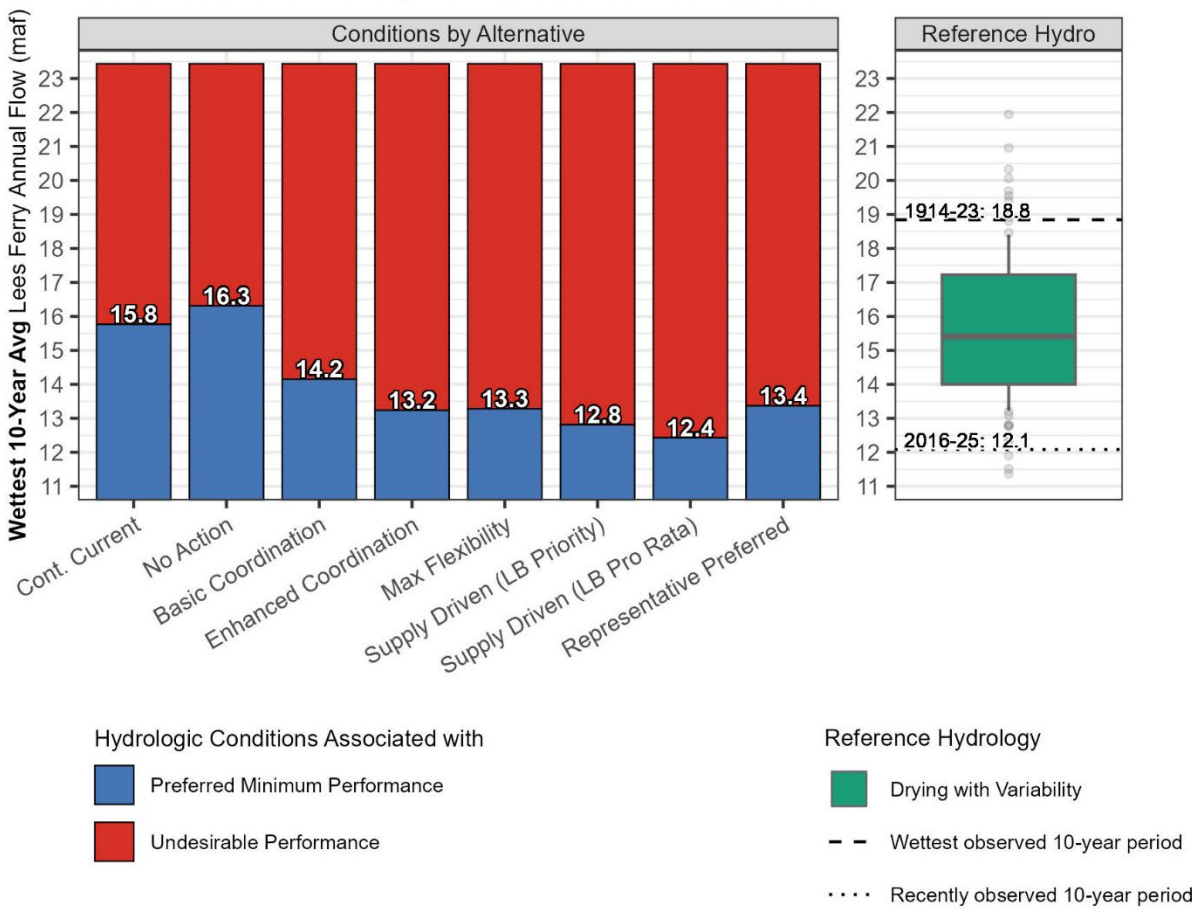
assumption is that fisheries management practices, such as stocking of listed fish species, would generally continue as they have during 2008–present.

We analyzed how each alternative affects the likelihood of sustaining Pearce Ferry Rapid as a natural deterrent to upstream movement. Based on current conditions and historic fish captures relative to lake elevation, it is thought that if Lake Mead remains below approximately 1,090 feet and follows the historical levels observed during the interim guideline period, the current species composition and population dynamics within the Grand Canyon and Lake Mead would remain similar. The analysis sheds light on upstream movement by native species, such as razorback sucker, while also allowing for upstream movement of nonnative fishes into the Grand Canyon. The last time Lake Mead elevation was above 1,090 feet was in May 2020 (Reclamation 2026). In **Figure TA 8-25**, the percentage of modeled futures for each alternative in which Lake Mead elevation remains below 1,090 feet is evaluated according to the percentage of months specified by each row. The highlighted row identifies the preferred minimum performance level, specifically, that Lake Mead elevation remains below 1,090 feet in at least 90 percent of months within each modeled future. This threshold reflects recent historical conditions, as Lake Mead elevation has been below 1,090 feet in approximately 94.3 percent of months from January 2016 to March 2026. This period was selected because it more accurately reflects recent conditions at Pearce Ferry Rapid.

Figure TA 8-25
Pearce Ferry Rapids as Nonnative Fish Barrier: Robustness.
Percentage of futures in which Lake Mead elevation stays below 1,090 feet in the percentage of months specified by each row

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at maintaining Pearce Ferry Rapid as a barrier that helps contain nonnative fish species and limit the Grand Canyon's exposure to additional nonnative fish pressure. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard. Higher rows represent conditions in which Lake Mead remains below 1,090 feet for a greater share of months and are more difficult to achieve, while lower rows represent less restrictive conditions that are easier to achieve.



Over the full modeling period, the No Action Alternative is the most robust, meeting the preferred minimum performance level in 64 percent of futures. The CCS Comparative Baseline performs similarly, meeting the threshold in 58 percent of futures. All other alternatives perform substantially worse, with differences exceeding 10 percent relative to the No Action Alternative and the CCS Comparative Baseline. Among the action alternatives, the Basic Coordination Alternative performs the best, meeting the preferred minimum performance level in 33 percent of futures. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven Alternatives, including both the LB Priority and LB Pro Rata approaches, are the least robust, meeting the preferred minimum performance level between 10 to 16 percent of futures.

Over the different decadal modeling periods, the No Action Alternative is the most robust, meeting the preferred minimum performance level between 65 and 78 percent of futures. The CCS Comparative Baseline performs similarly, meeting the threshold in 63 to 70 percent of futures. All other alternatives perform substantially worse, with differences exceeding 10 percent relative to the No Action Alternative and the CCS Comparative Baseline. Among the action alternatives, the Basic Coordination Alternative performs the best, meeting the preferred minimum performance level in 36 to 59 percent of futures.

The Representative Preferred Alternative meets the minimum performance level (at least 90 percent of months) in 20 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The No Action Alternative (78 percent), CCS Comparative Baseline (70 percent), and Basic Coordination Alternative (59 percent) are the most robust. The Representative Preferred (39 percent), Maximum Operational Flexibility (38 percent), Enhanced Coordination (31 percent), and Supply Driven (LB Priority Approach) (30 percent) Alternatives are less robust. The Supply Driven (LB Pro Rata approach) Alternative is the least robust (20 percent).

Figure TA 8-26 below shows what flow conditions are likely to result with Lake Mead elevations above 1,090 feet in more than 10 percent of months. This definition of undesirable performance is based on the highlighted row in **Figure TA 8-25** above, which defined a future as successful when an alternative maintained Lake Mead elevations below 1,090 feet at least 90 percent of the time.

Figure TA 8-26
Pearce Ferry Rapid remains a barrier to upstream fish passage: Vulnerability. Conditions that could cause Lake Mead elevation to go above 1,090 feet in more than 10 percent of months

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

The wettest 10-year average Lees Ferry natural flow was identified as a skillful and highly relevant predictor of vulnerability. The reference hydrology panel shows the range of wettest 10-year average flows represented in the Drying with Variability ensemble, along with the most recent and wettest observed 10-year periods. The reference hydrology's median value is approximately 15.4 maf, and the most recent 10-year average Lees Ferry annual flow (12.1 maf for 2016–2025) is shown as a dotted line for comparison. The wettest 10-year period in the observed record averaged about 18.8 maf (1914–1923) and is represented by a dashed line.

The Supply Driven (both LB Priority and LB Pro Rata approaches), Enhanced Coordination, and Maximum Operational Flexibility Alternatives are the most vulnerable, being vulnerable to elevations above 1,090 feet more than 10 percent of the time in 10-year average flows of 12.4 to 13.2

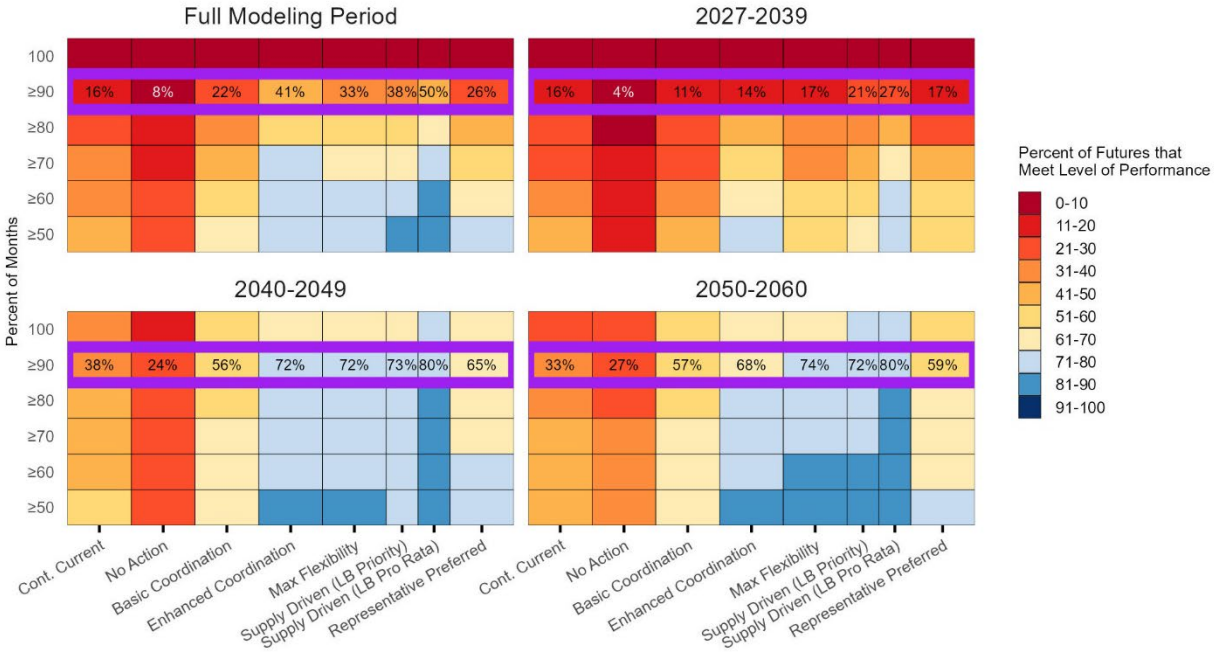
maf or wetter. About 90 percent or more of traces in the Drying with Variability ensemble exhibit these conditions.

The Basic Coordination and Representative Preferred Alternatives are slightly less vulnerable, being vulnerable under 10-year averages of 14.2 and 13.4 maf or wetter. About 75 percent of traces in the Drying with Variability ensemble exhibit these conditions.

The No Action Alternative and CCS Comparative Baseline are the least vulnerable, being vulnerable under 10-year averages of 16.3 and 15.8 maf or wetter. Less than 50 percent of traces in the Drying with Variability ensemble exhibit these conditions.

The wettest 10-year period in the observed record averaged about 18.8 maf, indicating that all alternatives are susceptible to conditions similar to those experienced in the early 1900s. However, all alternatives would be expected to satisfy the preferred minimum performance level if the wettest 10-year period is no wetter than the most recent observed 10-year average of 12.1 maf.

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to Lake Mead elevations exceeding 1,090 feet in at least 10 percent of months in a 10-year average flow of 13.4 maf or wetter. This alternative may or may not be vulnerable in the next 10 years because different aspects of the reference hydrology panel conflict. Considering the Drying with Variability ensemble, about 75 percent of traces are greater than 13.4 maf, suggesting this alternative is reasonably likely to be vulnerable. However, the recently observed 10-year period is below 13.4 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.



Alternatives that allow for more flow and Lake Mead storage perform worse than the No Action Alternative and CCS Comparative Baseline for native fishes such as razorback sucker, flannelmouth sucker, or even humpback chub that may wish to move from downstream to upstream and into the Grand Canyon. Thus, under a less robust scenario, native fish movement upstream out of Lake Mead would occur more frequently, which could allow for additional spawning and genetic mixing within the Colorado River in the Grand Canyon but would also allow for more competition from nonnative fish moving into the western Grand Canyon, where native fish abundance currently dominates the fish community.

To explore shoreline habitat availability in Lake Mead, we used the 2008–2026 lake elevation data as a proxy to determine whether there would be suitable littoral shoreline habitats for the fish community in Lake Mead. An important assumption is that, at any given lake elevation, the amount of littoral shoreline habitat available to fishes and other aquatic species is related to the elevations and shoreline habitats present from 2008 to March 2026. The lowest elevation observed in Lake Mead from 2008 to March 2026 was 1,040.92 feet in July 2022. Because it appears that the current fish and aquatic species assemblage within Lake Mead survived at that lake elevation, we presume the shoreline habitat at that elevation is suitable for the overall current fish community.

In **Figure TA 8-27**, the percentage of modeled futures for each alternative in which Lake Mead elevation remains above the historical minimum elevation of 1,040.92 feet is evaluated according to the percentage of months specified by each row. The highlighted row identifies the preferred minimum performance level, specifically, that Lake Mead elevation remains at or above 1,040.92 feet in at least 90 percent of months within each modeled future. Using the 90 percent threshold allows the analysis to reflect scenarios in which Lake Mead remains at or above the historical minimum elevation for most months during the full modeling period from 2027 to 2060.

Alternatives that achieve this preferred minimum performance level in a higher percentage of futures are more effective at maintaining Lake Mead above its historical minimum elevation. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard. Higher rows represent conditions in which Lake Mead remains above the threshold in a greater share of months and are more difficult to achieve, while lower rows represent less restrictive conditions that are easier to achieve.

Figure TA 8-27
Lake Mead Historical Minimum Shoreline Habitat: Robustness.
Percentage of futures in which Lake Mead elevation remains above the historical minimum elevation (1,040.92 feet) in the percentage of months specified by each row

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

Over the full modeling period, the No Action Alternative is the least robust, meeting the preferred minimum performance level in 8 percent of futures. The CCS Comparative Baseline improves performance to 16 percent of futures, while the Basic Coordination Alternative increases

performance to 22 percent of futures. The Enhanced Coordination Alternative, Maximum Operational Flexibility Alternative, Supply Driven (LB Priority) Alternative, and Supply Driven (LB Pro Rata) Alternative perform better, meeting the preferred minimum performance level in 41 percent, 33 percent, 38 percent, and 50 percent of futures, respectively. The Supply Driven Alternative under the LB Pro Rata approach performs the best, meeting the preferred minimum performance level in 50 percent of futures and showing the highest likelihood of maintaining Lake Mead at or above 1,040.92 feet. Alternative performance rankings remain similar in future decades, but tend to improve in robustness from 2040–2060. Futures and alternatives with more water, representing higher lake elevations, would likely yield more robust performance.

The Representative Preferred Alternative meets the minimum performance level (at least 90 percent of months) in 26 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Supply Driven Alternative is most robust, meeting the preferred minimum performance in 27 percent of futures under the LB Pro Rata approach and 21 percent of futures under the LB Priority Approach. No Action (4 percent) is the least robust alternative. The Representative Preferred Alternative (17 percent) performs in the middle, similar to the CCS Comparative Baseline (16 percent), and the Basic Coordination (11 percent), Enhanced Coordination (14 percent) and Maximum Operational Flexibility (17 percent) Alternatives.

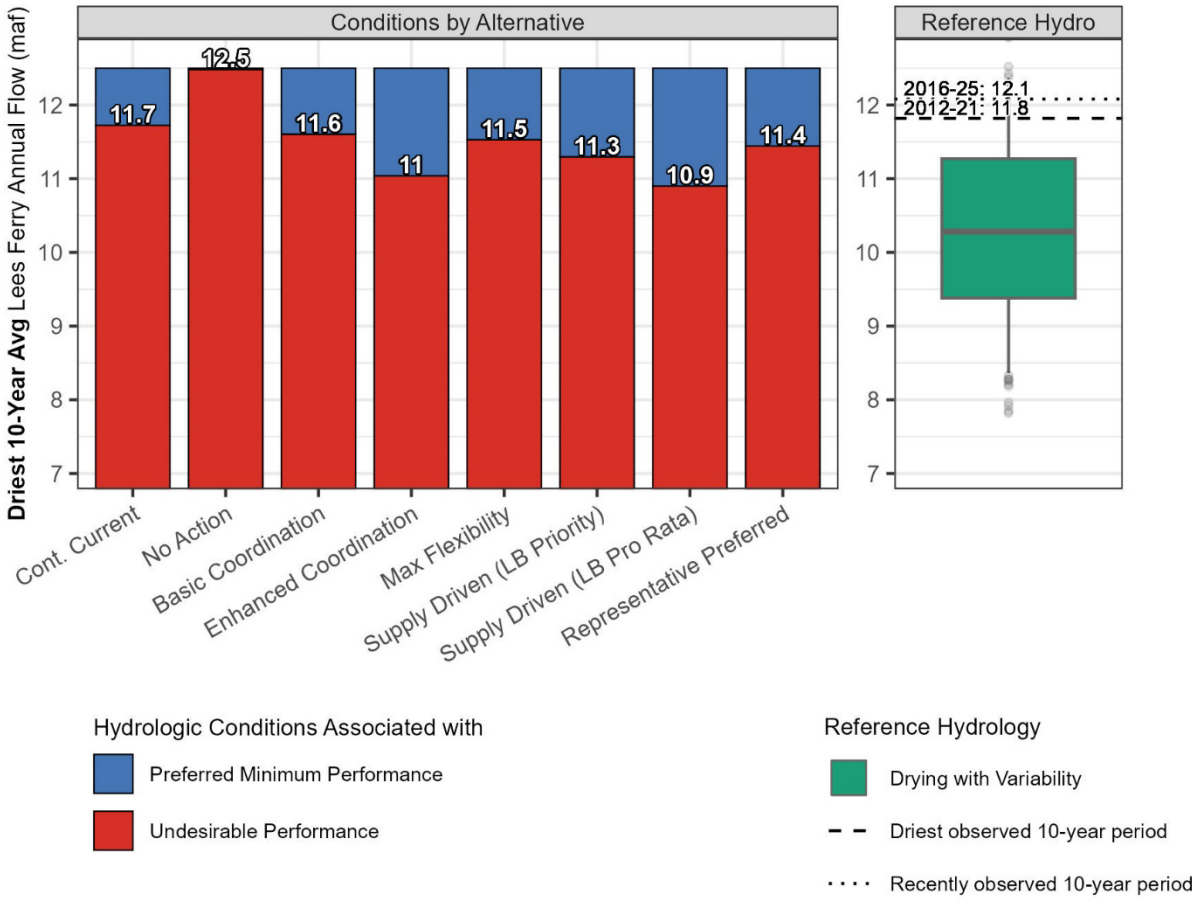


Figure TA 8-28 below shows what flow conditions are likely to result in Lake Mead elevation falling below 1,040.92 feet more than 10 percent of the time. This definition of undesirable performance is based on the highlighted row in **Figure TA 8-27** above, which defined a future as successful when an alternative maintained elevations above 1,040.92 feet at least 90 percent of the time.

The driest 10-year average Lees Ferry natural flow was identified as a skillful predictor of undesirable performance. The reference hydrology panel shows the range of driest 10-year average flows represented in the reference hydrology, along with the driest observed 10-year period in the historical record. The reference hydrology's median value is approximately 10.3 maf, and the driest 10-year average Lees Ferry annual flow observed in the historical record (11.8 maf from 2012–2021) is represented by a dashed line for comparison.

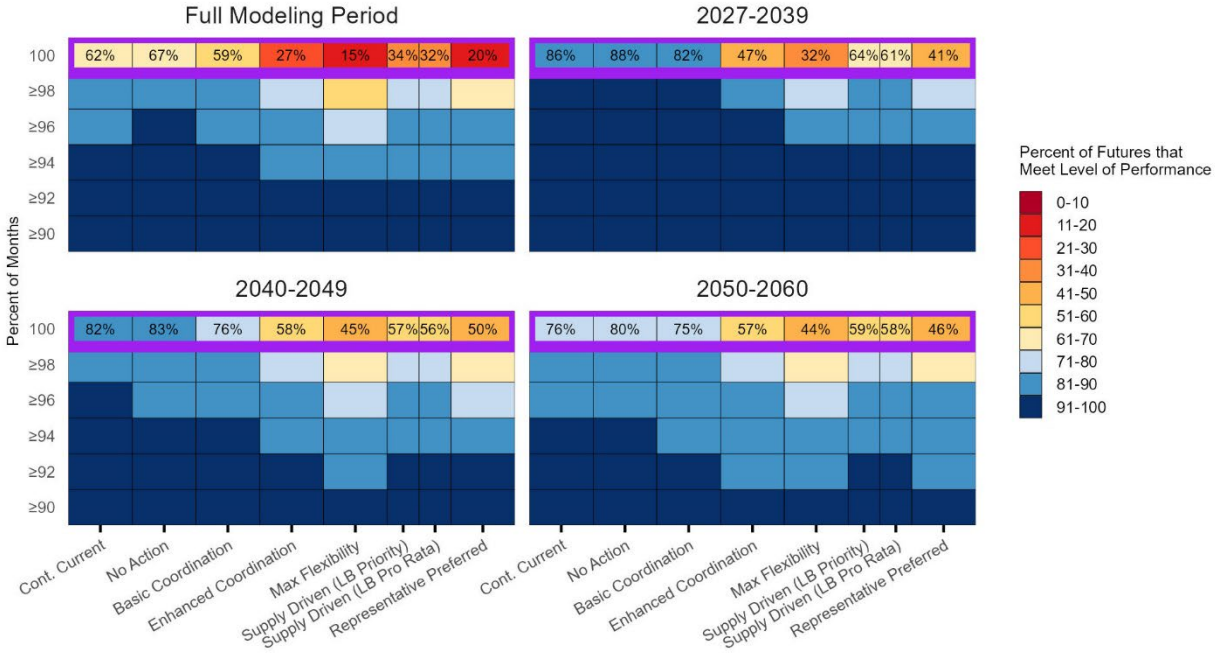
All action alternatives are vulnerable to Lake Mead elevation falling below the historical minimum (1,040.92 feet) more than 10 percent of months under flows between 10.9 maf (Supply Driven LB [Pro Rata], the least vulnerable) and 11.7 maf (CCS Comparative Baseline, more vulnerable) or drier. Similar but slightly wetter conditions have occurred historically (11.8 maf), and greater than 75 percent or more traces in the Drying with Variability ensemble exhibit drier conditions. The No Action Alternative is vulnerable under flows of 12.5 maf or drier, which has occurred historically and occurs in nearly all traces in the Drying with Variability ensemble.

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to 10 percent or more months falling below 1,040.92 feet under 10-year averages of 11.4 maf or drier. While these conditions have not yet been observed, absent additional action, this alternative is reasonably likely to be vulnerable in the next 10 years because these conditions occur in more than 75 percent of the traces in the Drying with Variability ensemble, which represents a drier future.

Figure TA 8-28
Lake Mead Historical Minimum Shoreline Habitat: Vulnerability. Conditions that could cause Lake Mead to fall below 1040.92 feet in more than 10 percent of months

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

The fish community in Lake Mead has adapted to fluctuating lake elevations for decades (Rogers et al. 2025a). If lake elevations remain within the historical range observed from 2008 to March 2026, the conditions that support current species composition and population dynamics are likely to persist. If the Lake Mead elevation remains relatively stable and within the historical elevations, the aquatic community would likely continue to find spawning and/or nursery habitats. However, prolonged low-elevation periods may increase the vulnerability of shoreline habitats used by aquatic species by reducing spawning and/or nursery habitat beyond what those species have routinely experienced in this system from 2008 to March 2026.



TA 8.2.5 Issue 4: How will modifications in water quantity, timing, temperature, and quality released from Hoover Dam affect the Lower Colorado River, including LCR MSCP Reaches 2 through 6 (Hoover Dam to Davis Dam and Lake Mohave; Davis Dam to Parker Dam and Lake Havasu; Parker Dam to Cibola Gage; Cibola Gage to Imperial Dam and Imperial Reservoir; and Imperial Dam to the Northerly International Boundary)?

Although mitigation measures are already in place through prior ESA consultation, the EIS analyzes river flows of Hoover Dam to assess how different operational alternatives may affect aquatic resources within the NEPA framework. If the alternatives stay within historical flow-release levels from Hoover Dam, the current fish species composition and population dynamics will likely remain unchanged. However, modified flows from Hoover Dam to Imperial Dam, along with associated effects of timing, temperature, and water quality, may influence the habitats and abundances of razorback sucker and bonytail, as well as the backwater and riverine habitats that support these endangered and other native fishes. Flow modifications may also impact known razorback sucker spawning sites, while flannelmouth sucker downstream of Davis Dam to Parker Dam could similarly be affected. In addition, desert pupfish inhabiting off-channel ponds in the Lower Colorado River may experience impacts from modified flows that could fall outside of historical 2008–2025 bounds, particularly if flooding of constructed refuge ponds occurred. Furthermore, the presence of flathead catfish downstream of the Cibola gage to Imperial Dam poses an additional concern, as reduced flows may allow this predator to access upper reaches, increasing risks to endangered and other native fish populations. Impact indicators include fish habitats, distributions, and the assumption that populations are influenced by dam releases and flow conditions, which also affect the extent and availability of backwater areas. In addition, the location, size, and overall suitability of razorback sucker spawning sites could vary across different flow regimes, highlighting the importance of flow management in maintaining critical life-history habitats. Assessment methods include reports and monitoring data from agencies such as AZGFD, NDOW, the California Department of Fish and Wildlife, Reclamation, LCR MSCP, and the FWS. In all cases, an important assumption is that fisheries management practices, such as stocking of listed and other fish species, would generally continue as they have from 2008 to the present.

In **Figure TA 8-29**, the percentage of modeled futures for each alternative in which monthly releases from Hoover Dam remain within the range observed during the 2007 Interim Guidelines period (2008 to 2025) is evaluated according to the percentage of months specified by each row. The highlighted row identifies the preferred minimum performance level, specifically, that monthly releases remain within the historical range in 100 percent of months within each modeled future.

Alternatives that achieve this preferred performance level in a higher percentage of futures are more effective at maintaining releases within the historically observed range. Conversely, alternatives meeting this threshold in a lower percentage of futures are less effective in this regard. Higher rows represent conditions in which releases remain within the historical range for a greater share of months and are more difficult to achieve, while lower rows represent less restrictive conditions that are easier to achieve.

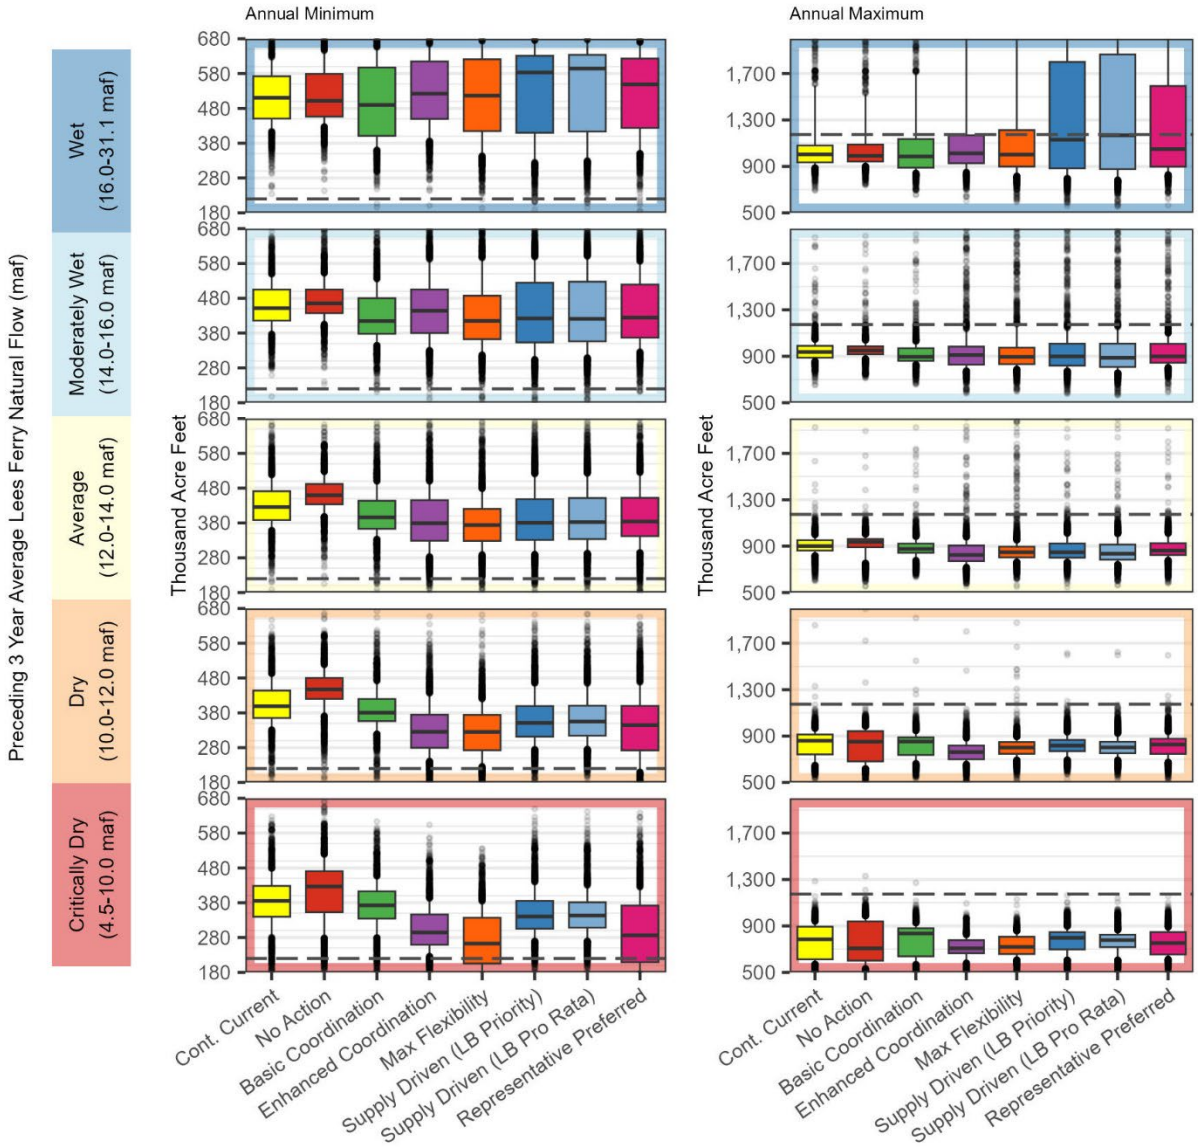
Figure TA 8-29
Below Hoover Monthly Flows: Robustness.
Percentage of futures in which monthly releases from Hoover Dam are within the range observed during the 2007 Interim Guidelines period in the percentage of months specified by each row

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

Over the full modeling period, the No Action Alternative, CCS Comparative Baseline, and Basic Coordination Alternative perform similarly and are the most robust, meeting the preferred performance level in 67 percent, 62 percent, and 59 percent of futures, respectively. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs somewhat lower, meeting the preferred performance level in 34 percent of futures under the LB Priority approach and 32 percent under the LB Pro Rata approach. The Enhanced Coordination Alternative performs similarly to the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) at 27 percent of futures, while the Maximum Operational Flexibility Alternative performs the worst, meeting the preferred performance level in only 15 percent of futures. Despite these differences, results indicate that all alternatives maintain releases within the historical range for more than 92 percent of months across all modeled futures.

Decadal modeling shows the No Action Alternative, CCS Comparative Baseline, and Basic Coordination Alternative perform similarly and are the most robust, meeting the preferred performance level in 75 to 88 percent of futures. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs somewhat lower, meeting the preferred performance level in 56 to 64 percent of futures. The Enhanced Coordination Alternative performs similarly to the

Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) at 47 to 58 percent of futures, while the Maximum Operational Flexibility Alternative performs the worst, meeting the preferred performance level in 32 to 45 percent of futures. Despite these differences, the results indicate that all alternatives maintain releases within the historical range in more than 90 percent of months across all modeled decadal futures.



The Representative Preferred Alternative meets the minimum performance level (100 percent of months) in 20 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The No Action Alternative (88 percent), CCS Comparative Baseline (86 percent), and Basic Coordination Alternative (82 percent) are most robust. The Maximum Operational Flexibility (32 percent), Representative Preferred (41 percent), and Enhanced Coordination (47 percent) Alternatives are least robust in the 2027-2039 modeling period. The Supply Driven Alternative (both LB Priority and Pro Rata approaches) performs in the middle, achieving monthly releases from Hoover Dam that fall within the range observed during the Interim Guidelines in 100 percent of months in 64 percent and 61 percent of futures respectively.

Figure TA 8-30 shows monthly release volumes from Hoover Dam under each alternative. The left column reports the smallest monthly release in each year, and the right column reports the maximum monthly release in each year, both in thousand acre-feet (kaf). Each row represents a range of the preceding 3-year average inflows at Lees Ferry, from Wet conditions at the top (16.0–31.1 maf) to Critically Dry at the bottom (4.5–10.0 maf). The colored boxplots depict the distribution of releases under each alternative, with longer boxes indicating greater variability. Dashed lines represent the historical minimum (left column) and maximum (right column) monthly releases observed between 2008 and 2025. For the minimum release panels, outcomes are considered favorable when boxplots occur above the reference line at 220 kaf, while for the maximum release panels, outcomes are considered favorable when boxplots occur below the reference line at 1,174 kaf.

In the Wet Flow Category, most alternatives exhibit similar distributions of minimum and maximum monthly releases, indicating comparable operational responses during high-inflow periods. The exception is the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), which tends to result in annual maximum monthly releases much higher than the other alternatives. As hydrologic conditions become drier, differences in annual minimum releases become more apparent. The No Action and Basic Coordination Alternative and CCS Comparative Baseline maintain relatively higher release volumes in the Critically Dry Flow Category, indicating continued high releases even during drought scenarios.

In contrast, the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives result in lower minimum releases in drier flow categories. In the Critically Dry Flow Category, minimum releases remain above the 220 kaf reference line in about 90 percent or more years, except for the Maximum Operational Flexibility Alternative, which stays above in less than 75 percent of years. The results of the Representative Preferred Alternative box plots are within the range analyzed across the other alternatives.

Figure TA 8-30
Hoover Dam Monthly Releases Under Varying 3-Year Average Lees Ferry Inflows with Alternative Futures. Boxplots Show the Distribution of Annual Minimum (Left) and Annual Maximum (Right) Monthly Releases Across Simulated Futures, Thousand Acre-Feet

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

These patterns suggest that the No Action and Basic Coordination Alternatives and CCS Comparative Baseline sustain higher release volumes during drought conditions, which may increase the rate of decline in Lake Mead's elevation. The other alternatives implement larger shortage volumes, which may help maintain Lake Mead elevations closer to recent historical levels (at or above 1,040.92 feet, the lowest elevation Lake Mead has reached) while continuing to support aquatic habitats in the LCR MSCP reaches downstream of Hoover Dam. In combination with the patterns shown in **Figure TA 8-29**, these results suggest that the LCR MSCP reaches will likely remain relatively similar to conditions observed during the 2008–2025 time period.

The Representative Preferred Alternative exhibits the following outcomes for the Dry Flow Category: For the annual maximum flow, the median was 826.9 kaf, with 25th and 75th percentiles of 746.4 and 876.6 kaf. The annual minimum flow median was 344.6 kaf with 25th and 75th percentiles of 272.3 and 399.9 kaf. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the annual maximum flow, the median was 752.8 kaf with 25th and 75th percentiles of 654.1 and 847.2 kaf. Finally, for the annual minimum flow, the median was 286.4 kaf, with 25th and 75th percentiles of 209.1 and 372.0 kaf. With respect to the critical thresholds of 220 and 1,174 kaf, the Representative Preferred Alternative falls within this threshold in about 75 percent of years in the Dry and Critically Dry Categories.

Within the LCR MSCP, the highest priority of the habitat conservation plan is the protection and preservation of backwater, isolated ponds, refuge (predator-free), and marsh habitats, especially with respect to areas occupied by ESA-listed species (LCR MSCP 2024). These areas are vital for maintaining the ecological integrity and biodiversity of the Lower Basin (Holmquist-Johnson et al. 2016; LCR MSCP 2024) and for allowing ESA-listed species to complete their life cycles. Because downstream habitats are largely re-regulated by Hoover Dam releases, changes in aquatic habitat are reflected in the patterns of those releases. Further, elevations and flows at Lake Mohave and Lake Havasu follow a guide curve and stay nearly constant across alternatives following releases from Hoover Dam. Multiple scenarios involving downstream impoundments were modeled and evaluated, but no significant differences were found to warrant further analysis at those locations. As a result, this analysis focuses on releases from Hoover Dam as a surrogate for all impoundments and features downstream. As described, modeled results suggest that most alternatives downstream of Hoover Dam would result in similar future conditions for fish in terms of modeled flows. These flows would also presumably influence water temperature and water quality in ways comparable to conditions experienced from 2008 to 2025, assuming similar fisheries and aquatic management practices continue. As a result, habitats within the LCR MSCP reaches are expected to remain generally similar to historical conditions, and fish communities would likely remain comparable to those observed during the 2008 to 2025 period.

TA 8.2.6 Summary Comparison of Alternatives

The preceding analysis uses a combination of hydrologic modeling, ecological indicators, temperature thresholds, and robustness/vulnerability assessments to compare management alternatives and their effects on aquatic habitats, native and nonnative fish populations, and ecosystem resilience along the Colorado River from Lake Powell downstream to the international boundaries. A summary matrix of robustness analysis results is provided to depict differences among

alternatives across all issues and indicators (**Figure TA 8-31** and summarized in **Appendix S,** Additional Description of Alternatives).

Figure TA 8-31
Summary of Robustness Results across Issues by Indicator at Reported Thresholds for Each Alternative

Issue	Indicator	Impact Threshold	Alternative[1]: Continued Current Strategy Baseline	No Action	Basic Coordination	Enhanced Coordination	Maximum Operational Flexibility	Supply-Driven (Priority)	Supply-Driven (Pro Rata)	Representative Preferred Alternative
1	**Lake Powell Elevation**									
	Critical Habitat (Colorado River)	Lake Powell is below 3,598 feet ≥70% of months, and Critical Habitat of Colorado Pikeminnow and Razorback Sucker is not inundated in the Colorado River Inflow								
	Critical Habitat (San Juan River)	Lake Powell is below 3,600 feet ≥70% of months, and Critical Habitat of Colorado Pikeminnow and Razorback Sucker is not inundated in the San Juan River Inflow								
	Piute Falls (nonnative barrier)	Lake Powell is below 3,666.5 feet for 100% of months, and the Piute Farms Waterfall remains a barrier to upstream fish passage								
	Smallmouth Bass Entrainment	Lake Powell is above 3,570 feet ≥70% of months, and the risk of smallmouth bass entrainment is reduced								
2	**Water Temperature**									
	Lee's Ferry 20	Number of Days Exceeds 20°C at Lees Ferry (0 days)								
	Little Colorado River 12	Number of Days Exceeds 12°C at the Little Colorado River (≥110 days)								
	Little Colorado River 16	Number of Days Exceeds 16°C at the Little Colorado River (≥110 days)								
	Havasu Creek 12	Number of Days Exceeds 12°C at Havasu Creek (≥110 days)								
	Havasu Creek 16	Number of Days Exceeds 16°C at Havasu Creek (≥110 days)								
	Pearce Ferry 12	Number of Days Exceeds 12°C at Pearce Ferry (≥110 days)								
	Pearce Ferry 16	Number of Days Exceeds 16°C at Pearce Ferry (≥110 days)								
	Smallmouth Bass Population	5-year Smallmouth Bass growth rate (lambda) at Lees Ferry is less than 1								
	Smallmouth Bass Entrainment	Smallmouth Bass entrainment through Glen Canyon Dam is less than 50 individuals								
3	**Lake Mead Elevation**									
	Within Historical Bounds	Lake Mead Elevations Remain Within Historical Bounds experienced from 2008–March 2026, ≥90% of months								
	Pearce Ferry Rapid (nonnative barrier)	Colorado River water levels at Pearce Ferry Rapid are Below 1,090 Feet Above Mean Sea Level, ≥90% of months								
4	**Hoover Dam Releases**	Monthly Releases from Hoover Dam are within the range Observed During 2008–2025, 100% of months								

Percent Futures that Meet Level of Performance: 0-10, 11-20, 21-30, 31-40, 41-50, 51-60, 61-70, 71-80, 81-90, 91-100

[1] Alternative robustness is reported for the full modeling period, except for the Representative Preferred Alternative, for which results are reported for 2027–2039.

Issue 1 assesses the impact of lake elevation on several native fish indicators. One of the greatest threats to native fish and a priority for management agencies would be the establishment of smallmouth bass downstream of Glen Canyon Dam, which becomes more likely with lower lake elevations. Additionally, reservoir elevations below 3,666.5 feet will help to reduce the threat of nonnative fish movement in the San Juan River. Finally, higher lake elevations would inundate Colorado pikeminnow and razorback sucker critical habitat and reduce habitat value for those species. When considering the risk of smallmouth bass entrainment at Glen Canyon Dam, the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform best by maintaining higher elevations and cooler water, reducing the likelihood of entrainment and downstream invasion. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and CCS Comparative Baseline keep lake elevations low enough to maintain the Piute Farms Waterfall as a fish barrier, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives allow for a higher potential of inundation and fish passage. The low Lake Powell elevations produced by the No Action Alternative increase the length of exposed riverine habitat for Colorado pikeminnow and razorback sucker, benefiting these endangered species, while all other alternatives tend to decrease habitat through inundation with higher lake levels. However, this comes at the cost of reduced lake habitat for sportfish, which could negatively impact recreational fishing.

The Representative Preferred Alternative generally performs in the middle of the range of alternatives for Issue 1, showing moderate robustness but not outperforming the top-performing option. Across indicators related to protecting riverine critical habitat in the Colorado and San Juan River inflows, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) consistently performs best, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the least robust because they more frequently produce higher Lake Powell elevations that inundate critical habitat, negatively affecting primary constituent elements such as river channel integrity that is preferred by the endangered Colorado pikeminnow and razorback sucker. The Representative Preferred Alternative performs better in protecting critical habitat than these least robust alternatives but does not achieve the level of robustness observed for the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), and, in some cases, performs similarly to or slightly below the CCS Comparative Baseline. It also performs less effectively than the Enhanced Coordination and Maximum Operational Flexibility Alternatives in maintaining elevations above 3,570 feet to reduce the risk of smallmouth bass entrainment. Overall, the Representative Preferred Alternative represents a moderate outcome among the alternatives, providing some protection of riverine habitat and fish barriers but remaining vulnerable to both relatively dry and wet hydrologic conditions compared with the strongest-performing alternatives for individual indicators.

Issue 2 assesses several factors and measures that influence nonnative fish populations. The primary threat to native fish populations below Glen Canyon Dam is the invasion of warmwater nonnative fish species such as smallmouth bass. Colder water temperatures and reduced entrainment through Glen Canyon Dam, resulting from higher lake levels, help prevent these populations from establishing and expanding. The Enhanced Coordination and Maximum Operational Flexibility Alternatives generally keep Lake Powell higher and are more likely to maintain cooler water temperatures at Lees Ferry, the Little Colorado River confluence, Havasu Creek, and Pearce Ferry.

The colder water limits smallmouth bass population growth but may also restrict native fish spawning and early life-stage recruitment patterns. These two alternatives also keep smallmouth bass population growth rates (lambda) below 1.0 more consistently than all other alternatives. The No Action Alternative, Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), and CCS Comparative Baseline are generally less robust, often failing to maintain preferred temperature and entrainment thresholds, especially under drought scenarios. While warmer water temperatures can benefit native fish growth and recruitment, they also favor nonnative species like smallmouth bass, which increases competition and predation risks. Thus, alternatives that limit the number of days above critical temperature thresholds (Enhanced Coordination and Maximum Operational Flexibility Alternatives) are preferable for controlling nonnative fish, despite trade-offs to native fish reproductive success.

Overall, the Representative Preferred Alternative demonstrates moderate performance relative to the other alternatives across the water temperature indicators. It generally performs better than the No Action Alternative and the CCS Comparative Baseline at maintaining thermally suitable conditions for native fish growth in downstream reaches, but not as strongly as the Enhanced Coordination or Maximum Operational Flexibility Alternatives at maintaining cooler temperature regimes. The Representative Preferred Alternative performs best in indicators associated with sustaining temperatures above 12 °C at downstream locations such as Havasu Creek and Pearce Ferry, which support humpback chub growth. However, it performs less strongly for indicators focused on limiting warmer temperatures that could benefit nonnative species, such as maintaining temperatures below 20 °C at Lees Ferry and limiting conditions favorable for smallmouth bass population growth.

Other factors, such as flow regimes and associated water quality, can also impact the native fish community throughout the Grand Canyon. Dissolved oxygen concentrations downstream of Glen Canyon Dam fluctuate seasonally, largely influenced by reservoir elevation and penstock water quality. Salmonid species, such as trout, are more susceptible to low dissolved oxygen, with optimal concentrations for growth and survival between 6–9 mg/L, and thresholds below 3 mg/L leading to reduced survival and feeding efficiency. Across alternatives, dissolved oxygen levels in wetter years are similar, typically between 7 and 8 mg/L, but decrease and become more variable under drier conditions. Modeling assumptions may overestimate dissolved oxygen during low reservoir elevations for some alternatives, but only the Enhanced Coordination and Maximum Operational Flexibility Alternatives are projected to maintain higher minimum dissolved oxygen concentrations—above 3 and 4 mg/L—in most futures, making them more robust in sustaining adequate dissolved oxygen and protecting fish health during extended droughts and low-flow scenarios.

Issue 3 assesses the alternatives based on their impacts on Lake Mead and tributary inflow and shoreline habitats. The No Action Alternative and CCS Comparative Baseline are most robust in maintaining Lake Mead elevations below 1,090 feet for at least 90 percent of months, helping to prevent upstream movement of nonnative fish by maintaining the fish barrier at Pearce Ferry and preserving the existing native species composition in the Grand Canyon. However, the fish barrier also works against upstream movement by native species such as razorback sucker, flannelmouth sucker, or humpback chub (as examples) into habitats within the Grand Canyon. Furthermore, the Representative Preferred and Basic Coordination Alternatives provide moderate protection for

maintaining the Pearce Ferry fish barrier. In contrast, the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both the LB Priority and LB Pro Rata approaches) Alternatives are less protective from a Grand Canyon perspective. These alternatives more frequently allow lake elevations to exceed critical thresholds at Pearce Ferry Rapid, which could enable upstream movement of fish. While this movement may benefit native species, it also increases the risk of nonnative fish expanding upstream into the largely native fish community in the Grand Canyon. The Supply Driven Alternative (LB Pro Rata approach) performs best at maintaining Lake Mead above the historical minimum elevation, which would support greater stability in reservoir fish habitat. Shoreline habitat projections in Lake Mead indicate that the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are most likely to maintain conditions similar to those experienced in the recent past, particularly in later modeled decades. If the historical shoreline of Lake Mead is maintained, it can be presumed that native fishes will continue adapting to changing shoreline conditions.

Issue 4 assesses the alternative's effects on water quantity, timing, temperature, and quality released from Hoover Dam into the Lower Colorado River, including MSCP conservation habitats. Most alternatives, including the No Action, Basic Coordination, and Representative Preferred Alternatives and the CCS Comparative Baseline, are more robust in maintaining monthly releases within the historical range observed during the 2007 Interim Guidelines period (2008–2025); thus, supporting stable fish communities and habitat conditions. Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are less robust, with a lower percentage of futures maintaining desirable release patterns. Flow modifications under less robust alternatives may negatively affect backwaters, marshes, and spawning sites for listed species such as razorback sucker and bonytail, and may increase risks from predators like flathead catfish. However, it should be noted that any threshold below 92 percent of months across all traces yields historically observed flows out of Hoover Dam, conditions under which native fish species have persisted. Assuming that fisheries management practices continue as in recent years, all alternatives are expected to result in habitat and population dynamics similar to those experienced during the historical period, compared with modeled futures.

The No Action Alternative and CCS Comparative Baseline are more effective at preserving riverine habitats above Lake Powell and limiting upstream movement of nonnative species. The comparative analysis of alternatives across all issues suggests that the Enhanced Coordination and Maximum Operational Flexibility Alternatives generally perform best in controlling nonnative fish risks and maintaining cooler water temperatures below Glen Canyon Dam. Overall, each alternative presents trade-offs between supporting native endangered species, controlling nonnative fishes, and maintaining recreational sportfish habitats.

Fish Species Life Histories

This page intentionally left blank.

TA 8 Attachment 1. Fish Species Life Histories

Introduction

Historically, the Colorado River from present-day Lake Powell downstream to the Southerly International Boundary (SIB) was a dynamic, seasonally warm, and turbid river, with flows ranging dramatically from approximately 1,000 to 120,000 cubic feet per second. This natural variability created a diverse and productive aquatic ecosystem, supporting a food base rich in organic material and providing suitable habitat for several warmwater native fish species (Miller 1961). However, the construction of major dams, beginning with Hoover Dam in 1935, along with increasing water demand and changing land use practices, fundamentally altered the river's flow patterns, sediment loads, turbidity, salinity, and temperature. The river was segmented into a series of impounded reservoirs separated by regulated stretches of flowing water, each altered from its original state by upstream impoundments. These changes had profound effects on both the aquatic food base and fish communities throughout the Colorado River ecosystem.

One of the most significant impacts of dam construction, particularly with Glen Canyon Dam, was the shift from natural seasonal flow variability to highly regulated daily fluctuations driven by hydropower production. Prior to dam construction, river levels remained relatively stable on hourly and daily timescales. With the advent of hydropower operations, water releases now peak during daylight hours to meet electricity demand and decrease at night, resulting in daily water level changes of 2-3 feet in some locations. This artificial "tidal" cycle has had a detrimental effect on the abundance and diversity of aquatic insects, which are a critical component of the river's food web (Kennedy et al. 2016). Insect eggs laid along the high-water mark are often left exposed and desiccate rapidly when flows recede, leading to reduced insect populations and, in turn, impacting the food availability for sensitive native fish species.

The closure of Glen Canyon Dam in 1963 marked a turning point for the Grand Canyon reach of the Colorado River, which historically experienced wide seasonal water temperature ranges—from 0 degrees Celsius (°C; 32 degrees Fahrenheit [°F]) in winter to nearly 30 °C (86 °F) in late summer and supported a habitat for several warmwater native fish species (Topping et al. 2003; Cole and Kubly 1976). Yet, even under natural conditions, only 8 of the 35 native fish species of the Colorado River were commonly found in this reach, with others confined to tributaries or present only seasonally (Gloss and Coggins 2005). The altered flow regime and cooler, clearer water released from upstream dams further reduced habitat suitability for native fish, while also affecting nutrient cycling and reducing the productivity of the aquatic food base. As a result, the fish community and food web in the Colorado River have been significantly transformed, with ongoing challenges for the persistence of native species and overall ecosystem health.

Native Fish Species

Threatened and Endangered Species

Humpback Chub

The humpback chub (*Gila cypha)* is a medium-sized, long-lived fish species endemic to the Colorado River System. This member of the minnow family attains a length of about 450 millimeters (mm) (17.7 inches), a weight of about 1,000 grams (2.2 pounds), and it may live as long as 40 years (Hendrickson 1993; Valdez and Ryel 1995; Andersen et al. 2010; FWS 2018a). The humpback chub was federally listed as endangered in 1967 and transferred into the protection of the Endangered Species Act (ESA) in 1973. It was reclassified from endangered to threatened on October 18, 2021 (FWS 2021). Critical habitat for the humpback chub includes 379 miles of the Colorado River system (59 *Federal Register* 13374). Within the analysis area, critical habitat includes the Colorado River from Nautaloid Canyon (river mile [RM] 35, river miles downstream from Lees Ferry) to Granite Park (RM 209) (FWS 1994). The lower 8 miles of the Little Colorado River are also critical habitat, but are outside of the analysis area.

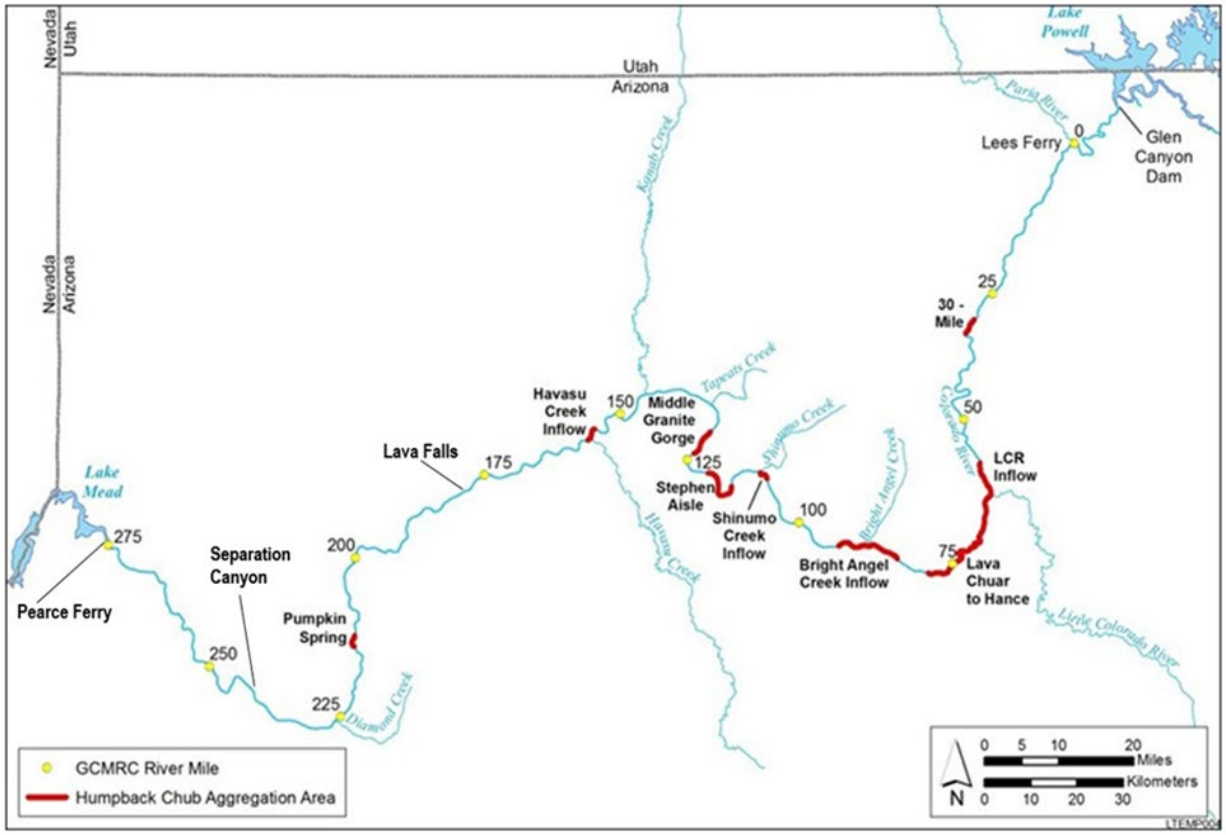
In downlisting the humpback chub, the U.S. Fish and Wildlife Service (FWS) evaluated the stressors associated with the listing factors detailed in the species' status assessment (FWS 2018a). These include river flows (Factor A) and predatory, nonnative fish (Factor C) in Upper Basin populations. They also include water temperature (Factor A), food supply (Factor A), and predatory, nonnative fish (Factor C) in the Lower Colorado River Basin (Lower Basin; FWS 2021). Minimizing these threat factors was important for downlisting the species and preventing it from becoming endangered again. However, smallmouth bass present the highest potential impacts on humpback chub because the species can co-occur with humpback chub in certain canyon habitats and is a potential predator across its entire life history (FWS 2018a). Downlisting the species was also possible because a large reproducing aggregation became established in the western Grand Canyon following a decline in the water level of Lake Mead that exposed historical habitat, and because of warmer releases from Glen Canyon Dam due to a lower level in Lake Powell (Rogowski et al. 2018; Van Haverbeke et al. 2017).

Distribution and Abundance

Five populations of humpback chub can be found in the Colorado River Basin: four in the Upper Basin and one in the Lower Basin (FWS 2018a). The Upper Basin populations are in (1) the Colorado River in Cataract Canyon, Utah; (2) the Colorado River in Black Rocks, Colorado; (3) the Colorado River in Westwater Canyon, Utah; and (4) the Green River in Desolation and Gray Canyons, Utah. The population in the Green and Yampa Rivers in Dinosaur National Monument was recently extirpated with an effort to reintroduce and reestablish the species in this area beginning in 2021 (Valdez et al. 2021). The population in the Lower Basin is found in the Colorado River from about 30-Mile Spring (RM 30) downstream to Pearce Ferry Rapid (RM 281) in the Lake Mead inflow (Rogowski et al. 2018 and 2025), in the lower 8 miles of the Little Colorado River to Chute Falls, and from translocations to Havasu Creek and Bright Angel Creek and above Chute Falls (Schelly 2019; FWS 2018a).

Historically, the humpback chub occurred in warm whitewater regions of the Colorado River upstream of present-day Hoover Dam and some larger tributaries in Arizona, Utah, Colorado, and Wyoming. The humpback chub is a specialized derivative of the *Gila robusta* complex that arose in response to the special conditions of large erosive and turbulent Colorado River habitats (Smith et al. 1979). The first description and photographic documentation of the humpback chub ("bony tail") was from an apparent spawning aggregation in 1908 near the mouth of the Little Colorado River near Beamer's Cabin in Grand Canyon (Kolb and Kolb 1914). The species was described in 1945 by Miller (1946) from three partial specimens caught near Bright Angel Creek in the Grand Canyon. The earliest cataloged collections of humpback chub and two congeneric species are from downstream of Lava Cliff Rapid (RM 246) in the 1940s, before the area was inundated by Lake Mead (Miller 1958). These collections consist of 27 specimens archived at the University of Michigan, including 5 humpback chub, 16 bonytail (*Gila elegans*), and 6 roundtail chub (*Gila robusta*); these specimens were described and confirmed morphologically and meristically by Bookstein et al. (1985). Wallis also reported eight juvenile humpback chub from Spencer Creek in 1950 (referenced in Valdez and Ryel 1997).

Following completion of Glen Canyon Dam in 1963, humpback chub were commonly reported in creel census from the Colorado River near Lees Ferry during 1963-1967 (Stone 1964, 1966; Stone and Queenan 1967), but sampling of seven major tributaries (excluding the Lower Colorado River) between Lees Ferry and Lake Mead in 1968 yielded none (Stone and Rathbun 1968). Holden (1973) collected 15 humpback chub in July 1967 and 1 in August 1970 in the Colorado River within a few hundred meters downstream of Glen Canyon Dam. Humpback chub have not been captured within 45 miles of the dam since the late 1970s (Carothers and Minckley 1981), or about the time Lake Powell stratified and cold-water releases began to persist year-round (Stanford and Ward 1991). Humpback chub were probably excluded from the tailwater by cold releases, high dam releases in 1983-1984, and by predation from large rainbow trout (*Oncorhynchus mykiss*) weighing up to 7 kilograms (kg; 15 pounds; Carothers and Brown 1991).



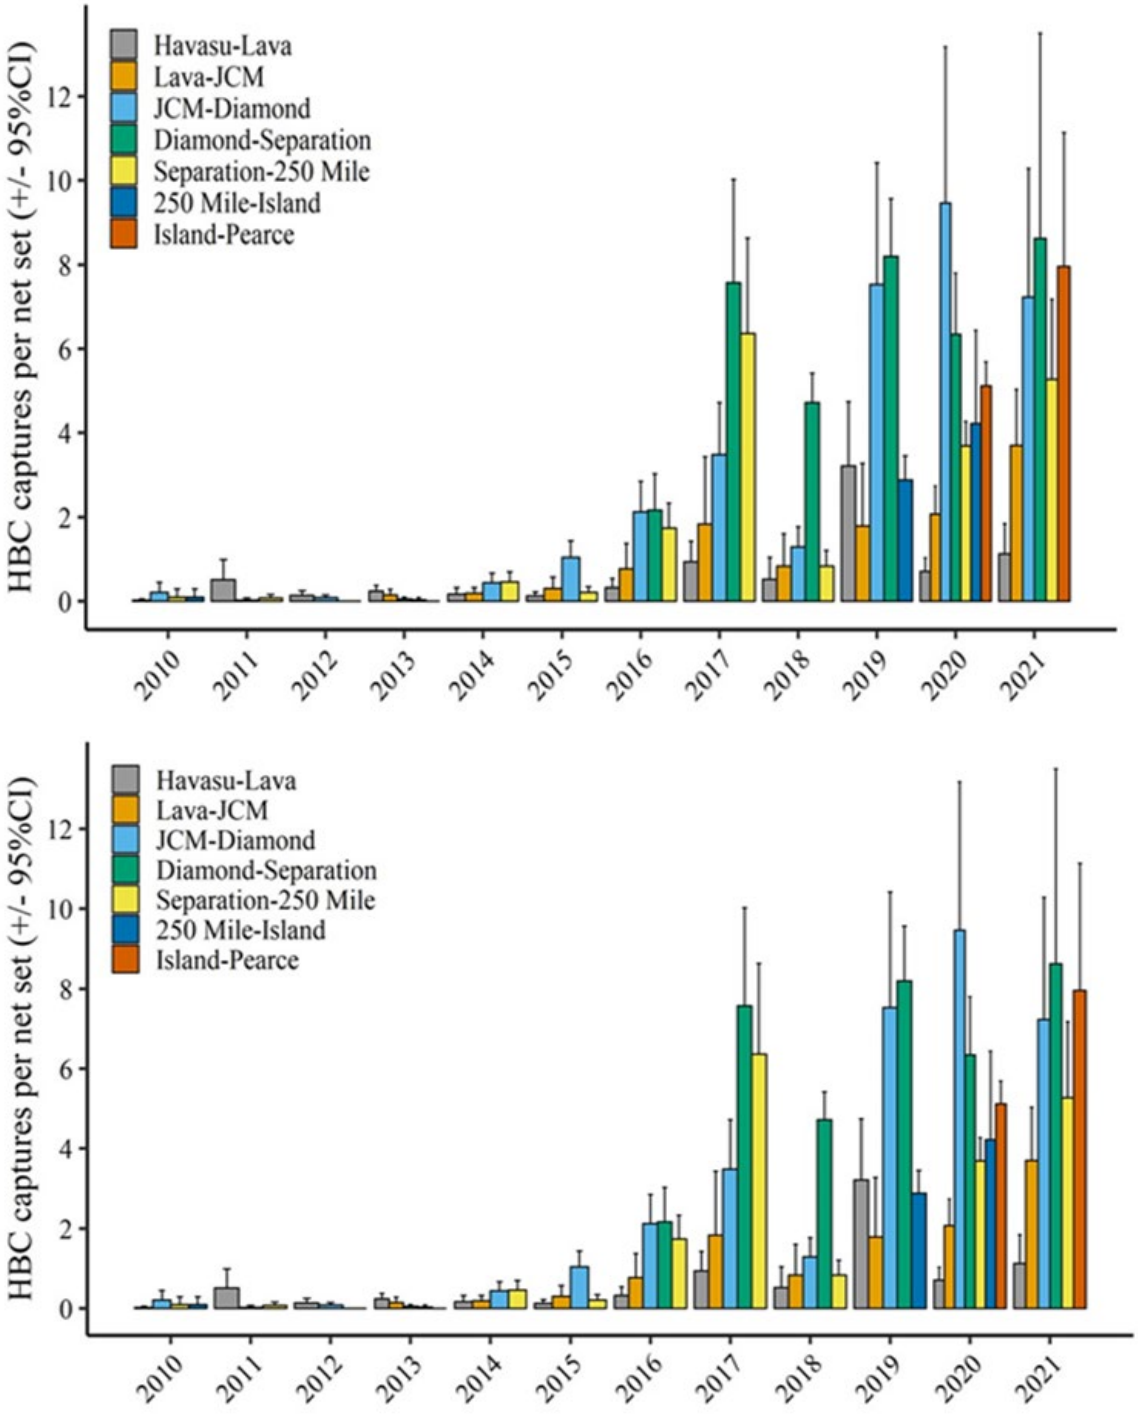
From 1970 through 1976, Suttkus and Clemmer (1977) reported young-of-year (YOY) and juvenile humpback chub between President Harding Rapid (RM 44) and Shinumo Creek (RM 108). Researchers from the Museum of Northern Arizona (Carothers and Minckley 1981) also captured chubs during six river trips in 1977-1979, including adults between North Canyon (RM 20) and Boulder Wash (RM 194) and one juvenile (less than 100 mm total length [TL; 3.9 inches]) just upstream of Granite Rapid (RM 93). Of 19 tributaries sampled from the Paria River (RM 1) to Travertine Creek (RM 230), humpback chub were captured only in the Little Colorado River.

From 1980 through 1981, biologists from the FWS captured 504 adult humpback chub between Nankoweap Canyon (RM 52) and Unkar Rapid (RM 72) (Kaeding and Zimmerman 1983). Fish abundance was reported to resemble a normal or "bell-shaped" distribution with the greatest numbers near the Little Colorado River inflow. Humpback chub smaller than 145 mm (5.7 inches) TL were not caught in the Colorado River upstream of the Little Colorado River inflow, although many small specimens were caught in spring and fall downstream of the inflow, providing the first evidence that post-dam humpback chub reproduction was occurring primarily in the Little Colorado River. From 1984 through 1989, the Arizona Game and Fish Department (AZGFD) (Maddux et al. 1987; Kubly 1990) reported humpback chub in the Colorado River from South Canyon (RM 32) to

RM 217, mostly in or near the Little Colorado River (RM 61). Ninety-six percent of humpback chub captured were between RM 32 and RM 87, and specimens were also captured at the inflows of four tributaries, including Bright Angel, Shinumo, Kanab, and Havasu Creeks, but not in the tributaries.

From 1990 to 1995, Valdez and Ryel (1995, 1997) sampled the Colorado River from Lees Ferry (RM 0) to Diamond Creek (RM 226) and found 5,940 YOY, juvenile, and adult humpback chub in nine aggregations (consistent and disjunct groups of fish with no significant exchange of individuals with other aggregations) (**Figure TA 8 Attachment 1-1**). The largest of these aggregations was associated with the Little Colorado River and included an estimated 3,482 adults that moved from the mainstem to the Little Colorado River in spring for spawning. The second largest aggregation was about 98 adults in Middle Granite Gorge, an area of talus slopes and debris fans, and the smallest aggregations had fewer than 10 fish. These aggregations became the basis for ongoing monitoring of humpback chub in the Grand Canyon (Persons et al. 2016; Rogowski et al. 2018).

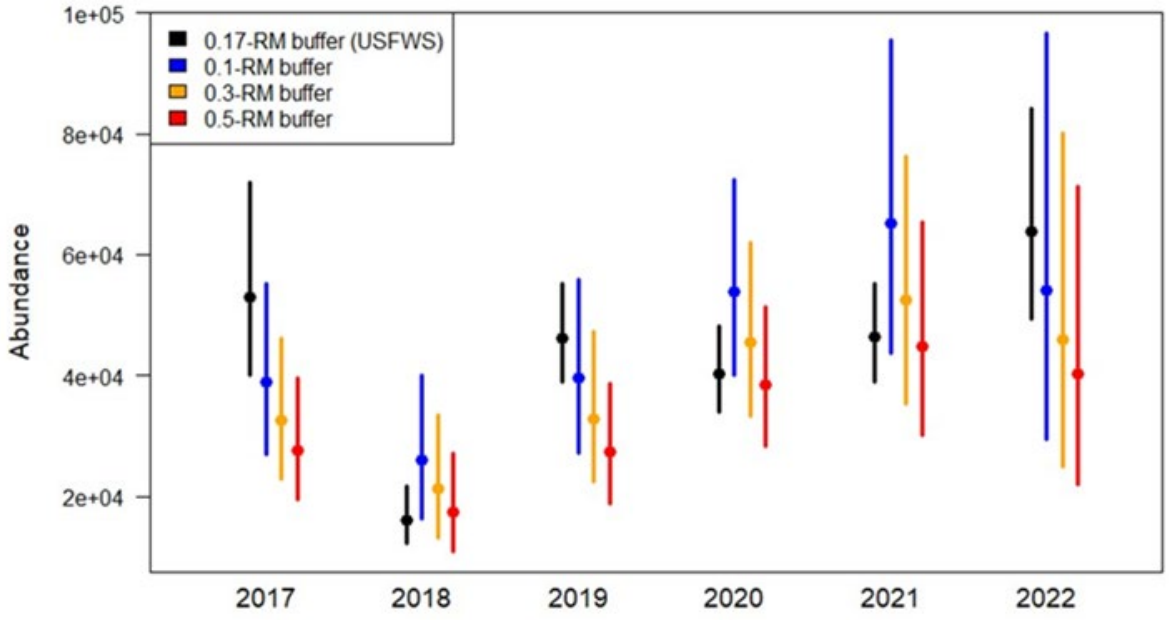
Figure TA 8 Attachment 1-1
Humpback chub Aggregation Areas along the Colorado River between Glen Canyon Dam and Lake Mead, and the Area of Western Grand Canyon with the Expanded Population of Humpback Chub



Sources: Valdez and Ryel 1995; Persons et al. 2016; Rogowski et al. 2018

Monitoring humpback chub in the Colorado River through Grand Canyon showed that numbers and distribution in the mainstream river were increasing at a time of warmer water releases from Glen Canyon Dam. In 2015, catch rates of humpback chub downstream of Havasu Rapids began to increase and then tripled starting in 2017 (Van Haverbeke et al. 2017; Dzul et al. 2023) (**Figure TA 8 Attachment 1-2**).

Mark-recapture estimates of adults in the Colorado River in western Grand Canyon (Havasu Rapids to Pearce Ferry) showed an increase in numbers of about 20,000 in 2018 to about 66,000 in 2022 (Dzul et al. 2023; Van Haverbeke et al. 2023) a median adult population abundance of 70 000 (40 000–200 000; 95% credible interval) in 2024 (Dzul et al. 2026) (**Figure TA 8 Attachment 1-3**). Since about 2017, the western Grand Canyon has been populated by humpback chub representing all size classes, with the highest density of adults consistently between Lava Falls and Separation Canyon (RMs 180–240; Dzul et al. 2023). It was unclear if the humpback chub downstream of Havasu Rapids were a new population or an expansion of aggregations found upstream, but recent genetic studies have confirmed humpback chub in the Grand Canyon to be genetically homogenous (Dzul et al. 2025). The humpback chub in the western Grand Canyon now comprises the largest group of humpback chub in the Colorado River System. These numbers compare to about 10,000–15,000 adults in the Little Colorado River/Colorado River aggregation (GCDAMP 2023; Yackulic et al. 2022) and about 4,000 adults for the sum of the four Upper Basin populations (FWS 2018a).



Since 2009, translocations of humpback chub have been made by the FWS to introduce juvenile fish upstream of Chute Falls in the Little Colorado River, and by the National Park Service (NPS) to introduce juveniles into Shinumo, Havasu, and Bright Angel creeks, with the goal of establishing additional spawning populations within the Grand Canyon (Healy et al. 2019; NPS 2013a, 2013b). Survey data from 2013–2015 suggest that translocated humpback chub have successfully spawned in Havasu Creek (Healy et al. 2020; NPS 2013a). Fish translocated to Shinumo Creek were extirpated by a fire and debris flow in August 2014 that scoured the stream channel and displaced or killed most of the fish that were translocated in 2010 (Nelson et al. 2014).

Habitat

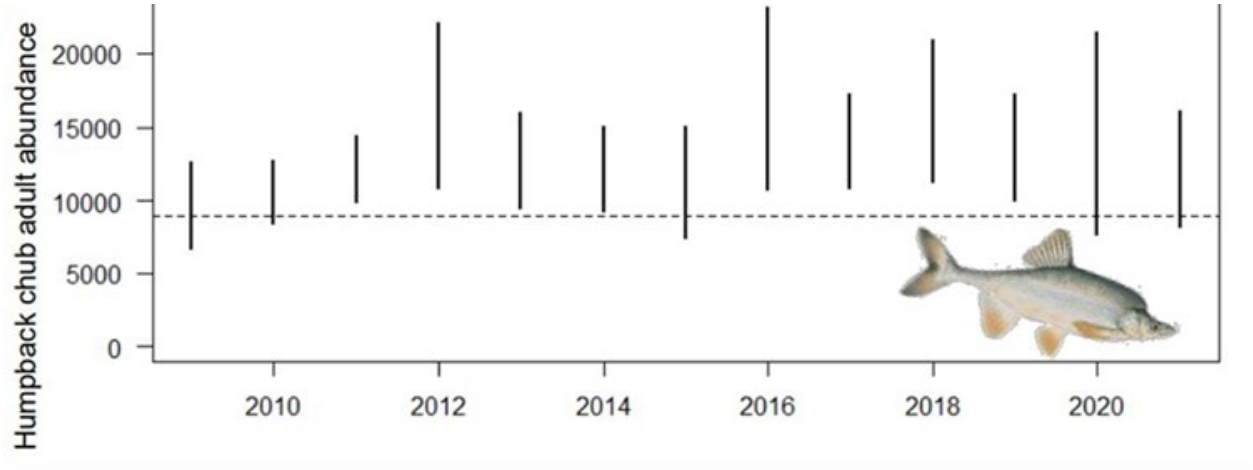
The humpback chub is typically found in canyon-confined, whitewater reaches of large rivers, with adults, juveniles, YOY, and spawning occurring in distinct habitats within those reaches (FWS 2018a). Adults are usually associated with large deep eddy complexes (Tyus and Karp 1990; Valdez and Hoffnagle 1999), talus shorelines, and warm tributaries or springs (Valdez and Ryel 1995). Subadults and juveniles are found at the highest densities along shorelines comprised of vegetation, talus, and large boulders compared to shorelines with bedrock, cobble, or sand (Converse et al. 1998). Juvenile humpback chub along shorelines respond to changing river flows by shifting position to maintain similar habitat conditions of depth, velocity, and cover (Valdez and Ryel 1995; Korman et al. 2004).

Recent studies of an expanding population in western Grand Canyon found humpback chub in open, silt-laden habitats (Boyer et al. 2024), suggesting this species may be able to occupy a wider range of habitats than originally described. This habitat is found in exposed deltaic sediments at the inflow of Lake Mead following a decline in lake elevation. The humpback chub nearshore ecology study collected juvenile humpback chub (under 3 years old) in all types of nearshore habitats, with the highest numbers collected from talus slopes (Dodrill et al. 2015). Prior to about 2017, the largest numbers of young humpback chub in the mainstream river were in and downstream of the mouth of the Little Colorado River, but since then, large numbers of young have been found in the mainstream river, especially downstream of Havasu Rapid to the Lake Mead inflow (Dzul et al.

2023). This indicates that mainstream spawning is occurring and may be widespread with increased water temperatures due to warmer water released from Glen Canyon Dam.

Nearshore habitats are important to humpback chub (and other native fish) because they provide shallow, productive, warm refugia for YOY and juveniles (Reclamation 1995; Hoffnagle 1996). Backwaters are a feature of the mainstream river as sheltered habitat that form at the downstream end of recurrent channels in large eddy complexes and are one objective of high-flow experiments (HFEs; Melis et al. 2011). Temperature differences between the main channel and backwaters can be pronounced in backwaters. The extent of warming is variable and depends on the timing of the daily minimum and maximum flows, the difference between air and water temperatures, and the topography and orientation of the backwater relative to solar insolation (Korman et al. 2006). For example, summertime water temperatures in backwaters have been reported as high as 25 °C (77 degrees Fahrenheit [°F]), while main channel temperatures have been near 10 °C (50 °F) (Maddux et al. 1987), although mainstream temperatures have become warmer in recent decades due to warmwater releases from Glen Canyon Dam.

The amount of warming that occurs in backwaters is affected by daily fluctuations, which drain and fill backwater habitats with cold main channel waters (Valdez 1991; Angradi et al. 1992; Behn et al. 2010). During the low, steady, summer flow experiment conducted in 2000 of about 8,000 cubic feet per second, daytime temperatures in one backwater were as much as 13 °C (23 °F) warmer than in the adjacent main channel; temperature differences were much less at night (Vernieu and Anderson 2013). Backwater temperatures in summer have been reported up to 2–4 °C (3.6–7.2 °F) warmer under steady flows than under fluctuating flows (Hoffnagle 1996; Trammell et al. 2002; Korman et al. 2006; Anderson and Wright 2007). In general, the levels of warming observed in nearshore areas and backwaters during the low summer, steady flows in 2000 persisted only for short periods and were smaller than seasonal changes in water temperatures (Vernieu and Anderson 2013). Consequently, the temperature effects of steady flows on native fish were probably small.



Juvenile humpback chub in the Grand Canyon use backwater habitats when they are available, but the spatial extent of these habitats in the Colorado River is small compared to other nearshore habitats, such as talus slopes. Dodrill et al. (2015) reported that the total abundance of juvenile humpback chub was much higher along talus shorelines than in backwaters, and that when relative densities were extrapolated using estimates of backwater prevalence after an HFE, the majority of juvenile humpback chub were found outside backwaters.

When monitored with radiotelemetry or mark-recapture, adult humpback chub occupied localized habitats and showed little movement from those locations (Valdez and Clemmer 1982; Valdez and Ryel 1995). Radio-tagged adults in Grand Canyon exhibited a high degree of spatial fidelity for specific river locales; mean net movement was 1.49 kilometers (km; range= 0-6.11; 0.9 miles) for 69 radio-tagged fish and 1.64 km (range= 0-99.8; 1 mile) for 238 passive integrated transponders (PIT)-tagged fish (Valdez and Ryel 1997). A separate mark-recapture study reported that approximately 87 percent of recaptured fish were collected in the same mainstream river reach or tributary where they were originally tagged, with 99 percent of all fish recaptured in and around the Little Colorado River (Paukert et al. 2006). Van Haverbeke et al. (2022) reported 288 unique humpback chub detections near the Little Colorado River confluence (RM 60.19–61.53) in 2021. Forty-four additional unique

detections were documented outside of the Little Colorado River confluence. Although most adults have high fidelity to specific river locales, some marked fish have moved as much as 100-154 km (62-102 miles) through the Grand Canyon (Valdez and Ryel 1997; Paukert et al. 2006). This large amount of movement is unique to the Grand Canyon and possibly driven by a need to reach seasonally warmed spawning sites, as radio-tagged fish in the Upper Basin did not exhibit long-range movements with spawning sites nearby (Valdez and Clemmer 1982; Kaeding et al. 1990).

Humpback chub have not been observed spawning in the wild because of the associated high turbidity and deep, turbulent habitats. Where adults have been captured expressing eggs and milt and recently scraped abdomens, the fish were associated with shoreline or mid-channel bars of cobble/gravel substrate with moderate velocity, where females release eggs that are fertilized by an aggregation of multiple males (Valdez 1990; Tyus and Karp 1990; Gorman and Stone 1999). The main spawning area for the humpback chub within the Grand Canyon has been the Little Colorado River, which provides warm temperatures suitable for spawning and shallow, low-velocity pools for larvae (Gorman 1994). Many of the larval fish remain in the Little Colorado River for one or more years, and growth rates and survival are relatively high compared to estimates for the colder waters of the mainstream Colorado River (Dzul et al. 2014; Yackulic et al. 2014). Spring abundance estimates for age-1 humpback chub within the Little Colorado River from 2009 to 2012 ranged from about 1,000 to more than 9,000 individuals (Dzul et al. 2023), and numbers of adults ranged from about 10,000 to 15,000 (**Figure TA 8 Attachment 1-4**). Within the Little Colorado River, young humpback chub prefer shallow, low-velocity, nearshore pools and backwaters; they move to deeper and faster areas with increasing size and age (AZGFD 2001a; Stone and Gorman 2006). In the mainstream Colorado River, YOY fish may be found in backwater and other nearshore, slow-velocity areas that serve as nursery habitats (AZGFD 2001a; Robinson et al. 1998; Valdez and Ryel 1995). Valdez and Masslich (1999) found YOY humpback chub in a warm spring at RM 30, which indicates spawning, about 45 miles downstream of Glen Canyon Dam.

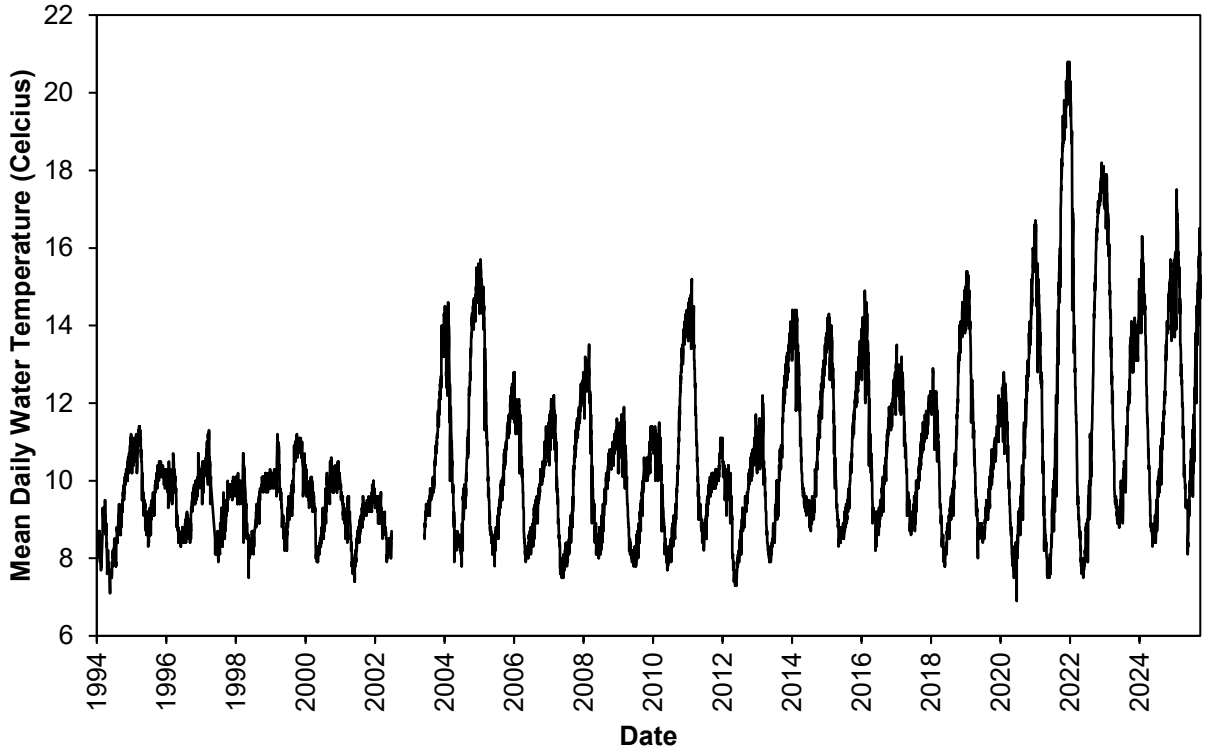
Life History



The humpback chub spawns annually in spring, starting at 4-5 years of age, and females broadcast up to 2,500 eggs that are 2-3 mm (0.08 to 0.1 inches) in diameter and are fertilized by multiple males over cobble/gravel substrates. The eggs are semi-adhesive and incubate 4–11 days at 16–22 ºC (60.8-71.6 ºF; Hamman 1982) before hatching into larvae that are 6-7 mm long (0.2 to 0.3 inches; Muth 1990). There is little evidence of long-distance larval drift, as with other native cyprinids such as the Colorado pikeminnow (*Ptychocheilus lucius*), and the larvae are carried passively by currents to nearby sheltered shorelines consisting of boulders, cobble, and gravel (Valdez 1990). The larvae transform to juveniles at 30-40 days of age, to subadults at about 1 year of age, and to adults at 4-5 years of age. There is strong evidence of skipped spawning by humpback chub in the Little Colorado River population, where individuals, especially females, may not spawn every year, possibly due to the need to build up resources prior to spawning in a subsequent year (Pearson et al. 2015).

Although the humpback chub is a warmwater fish species, it persisted in the Colorado River through the Grand Canyon after the construction of Glen Canyon Dam and subsequent cold-water releases. Cold-water temperatures from 1970 to about 2000 provided suitable conditions for the species to persist in the mainstream river as small aggregations but precluded mainstream spawning. Instead, adults of the most proximate aggregation moved annually to spawn in the Little Colorado River, and there was no reproduction in the other aggregations (Valdez and Ryel 1995; Douglas and Marsh 1996). Cold mainstream temperatures limited spawning and growth in the mainstream river but enabled the species to live longer (Yackulic et al. 2014), with better body condition (Meretsky et al. 2000), and low infestations of diseases and parasites (Hoffnagle et al. 2006). Nine aggregations identified by Valdez and Ryel (1995) were mostly associated with warm springs and warm tributary mouths that enabled the species to persist in the mainstream river as juveniles, subadults, and adults, while the largest and only center of reproduction was in the Little Colorado River, from which young fish drifted or moved to the mainstream river.

The Grand Canyon humpback chub population has changed dramatically, starting in about 2004 with warmer dam releases. Humpback chub were mostly unable to reproduce in the mainstream Colorado River because of cold water temperatures, except for local reproduction at 30-Mile Spring (Andersen et al. 2010; Valdez and Masslich 1999). Nearly all reproduction was thought to occur in the lower 8 miles of the Little Colorado River (AZGFD 2001a; Van Haverbeke et al. 2017). Declining reservoir elevations in Lake Powell began in about 2002 (Vernieu et al. 2005; Dibble et al. 2021), leading to warmer releases. Warmer water in the mainstem river allowed for higher juvenile humpback chub survival and growth that likely led to increases in the Little Colorado River population (Finch et al. 2016; Limburg et al. 2013; Yackulic et al. 2014). In western Grand Canyon, warmer water conditions led to reproduction and recruitment in the mainstream (Van Haverbeke et al. 2017), as well as better survival and what is now the largest population of humpback chub in the entire Colorado River system (Dzul et al. 2023). It is notable that in the 1940s, before Lake Mead filled, 5 humpback chub, 16 bonytail, and 6 roundtail chub were captured downstream of Lava Cliff Rapid (Bookstein et al. 1985; Miller 1958), an area that was inundated by Lake Mead for nearly 60 years and is now occupied by this large population of humpback chub following the decline in reservoir elevation and exposure of the original river channel.

The life-history model for humpback chub is mostly known from the Little Colorado River population. Here, adult humpback chub move into the Little Colorado River from the Colorado River to spawn from March to May (Kaeding and Zimmerman 1983; Gorman and Stone 1999; FWS 2018a; Valdez and Ryel 1995). This species requires a minimum temperature of 15.5 °C (60 °F) to reproduce, but mainstream water temperatures typically ranged from 7–12 °C (45–53.6 °F) because of cold releases from Glen Canyon Dam (Andersen et al. 2010). Drought-induced warming and the lower levels of Lake Powell have resulted in mainstream water temperatures consistently exceeding 12 °C (53.6 °F) in summer and fall since 2004. Increased spawning and survival likely played a role in the increase of humpback chub in the Colorado River through the Grand Canyon (Andersen et al. 2010; Coggins and Walters 2009; Yackulic et al. 2014) that led to the rapid and large expansion of humpback chub in western Grand Canyon (Van Haverbeke et al. 2017; Dzul et al. 2023). Rapid growth of small subadults was observed in the mainstream Colorado River near the Little Colorado River during July–October 2021–2023 that corresponded with the warmest water temperatures observed in decades (**Figure TA 8 Attachment 1-5**).

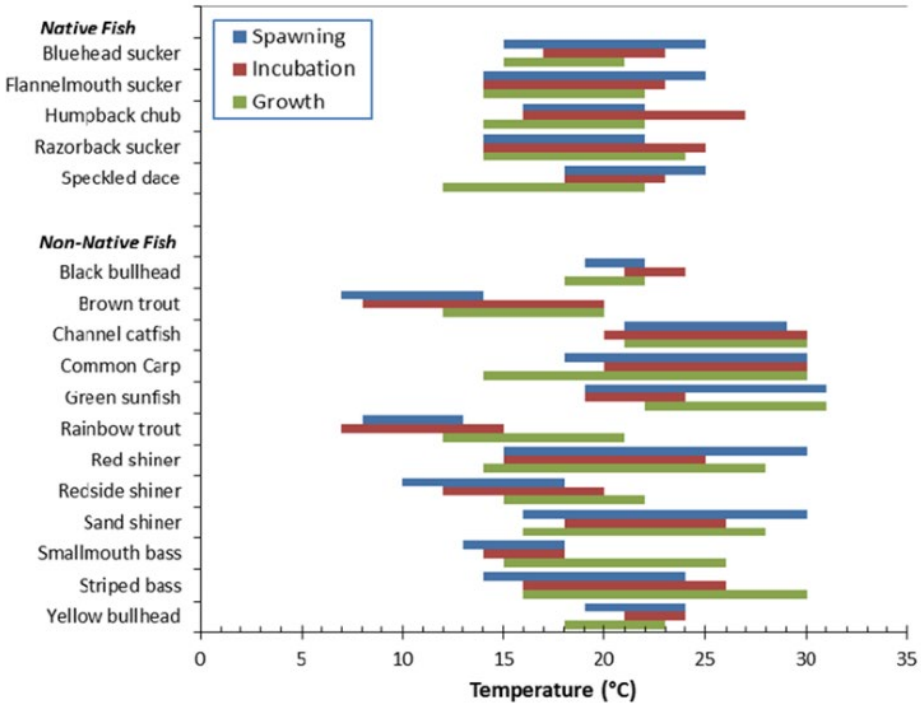


Figure TA 8 Attachment 1-5
Water Temperatures of the Colorado River at Lees Ferry as Measured at United States Geological Survey Gage #09380000, 1995 to Present

Source: USGS 2026
Note: Warmest temperatures of greater than 20 °C (greater than 68 °F) in 2022 were in late September and early October.

In 2022 and 2023, observed river temperatures downstream of the dam were the highest since the filling of Lake Powell; the temperatures were within the range of spawning temperatures for smallmouth bass (*Micropterus dolomieu*), green sunfish (*Lepomis cyanellus)*, and other warmwater nonnative fish (**Figure TA 8 Attachment 1-6**). Smallmouth bass and humpback chub share overlapping temperature preferences for growth, survival, and recruitment. However, prior to 2022, temperatures were sufficient for humpback chub populations to increase while smallmouth bass were relegated primarily to the Lees Ferry sub-reach in low numbers. Evidence of reproduction by smallmouth bass in 2023 raised concerns that smallmouth bass would become established in the Grand Canyon, where they would be likely to prey on humpback chub and other native fish species (Van Haverbeke et al. 2017; Gilbert et al. 2022; Dzul et al. 2023; Smallmouth Bass Ad Hoc Group 2023).

Figure TA 8 Attachment 1-6
Temperature Ranges for Spawning, Egg Incubation, and Growth by Native and Nonnative Fish of the Colorado River System downstream of Glen Canyon Dam

Source: Valdez and Speas 2007

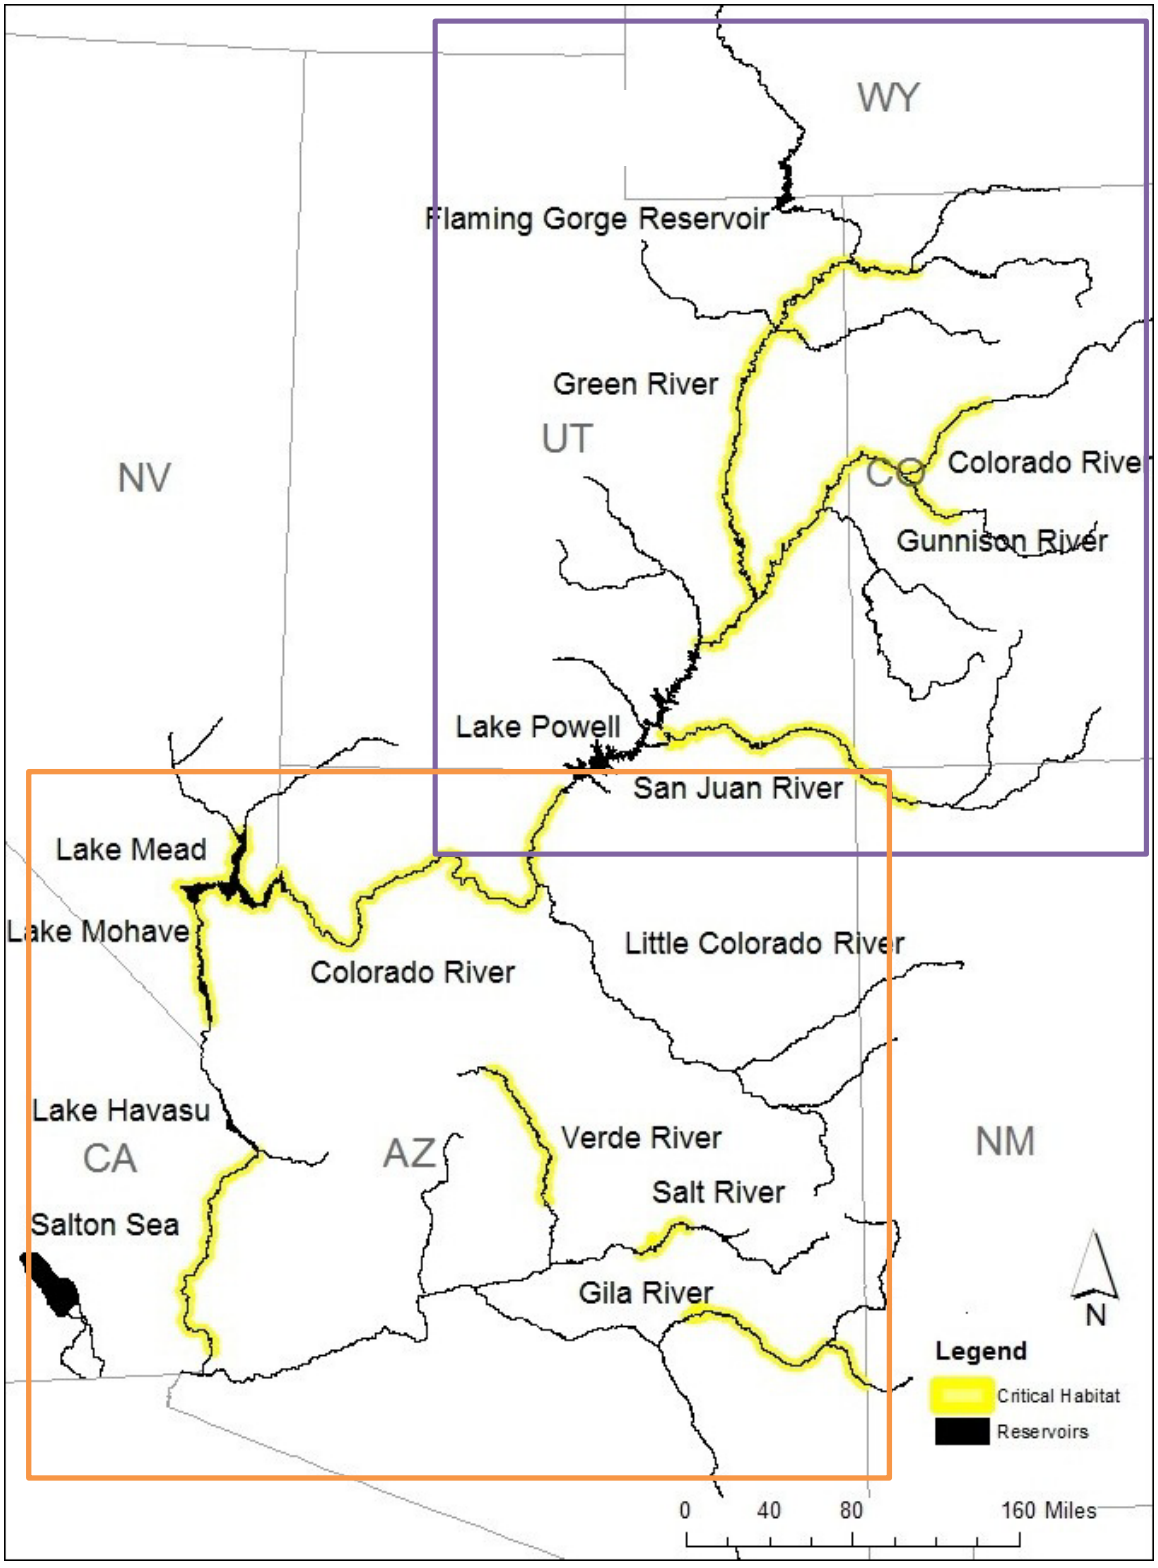
Increased water temperatures can benefit humpback chub growth and survival, but can also allow for the establishment and expansion of warmwater nonnative species, which could result in increased predation on humpback chub (Ward 2011; Yard et al. 2011). Smallmouth bass, green sunfish, and walleye are of greatest concern, but predation by channel catfish (*Ictalurus punctatus)* and black bullhead is also thought to threaten humpback chub in the Grand Canyon, particularly with warmer water conditions (NPS 2013b). Because of their larger size, adult humpback chub are less likely to be preyed on by trout; however, emergent fry, YOY, and juvenile humpback chub in the

mainstream Colorado River in the vicinity of the Little Colorado River are susceptible to predation by trout (Yard et al. 2011).

Under cold-water conditions, predation by rainbow trout and brown trout (*Salmo trutta*) at the Little Colorado River confluence was identified as a mortality source affecting humpback chub survival, reproduction, and recruitment (Valdez and Ryel 1995; Marsh and Douglas 1997; Yard et al. 2011). This may change with warmer mainstream temperatures. Ward and Morton-Starner (2015) conducted laboratory studies that showed predation by rainbow trout on YOY humpback chub decreased from approximately 95 percent to 79 percent as water temperature increased from 10–20 °C (50–68 °F); however, predation success by brown trout was about 98 percent and did not change significantly over the same temperature range. Yard et al. (2011) examined the effects of temperature on trout piscivory in the Colorado River and reported no relationship between water temperature and the incidence of piscivory by rainbow trout, but a significant positive correlation between increased water temperature and the incidence of piscivory by brown trout.

An additional concern for the humpback chub in Grand Canyon is nonnative fish parasites, including the Asian tapeworm (*Bothriocephalus acheilognathi*) and anchor worm (*Lernaea cyprinacea*) that affect the condition and survival of individuals (Clarkson et al. 1997; Hoffnagle et al. 2006; Andersen et al. 2010). While cold-water releases from Glen Canyon Dam have limited reproduction and recruitment of humpback chub (and other native fish) in the mainstream Colorado River, warmer mainstream temperatures over the last two decades have been sufficiently high to allow these parasites to complete their life cycles and expand, as well as other diseases and parasites (Hoffnagle et al. 2006).

Prevailing ecological conditions and water management actions within the Grand Canyon can affect the food base of the humpback chub. The humpback chub is primarily an insectivore, with larvae, juveniles, and adults all feeding on a variety of aquatic insect larvae and adults, including dipterans (primarily chironomids and simuliids), Thysanoptera (thrips), Hymenoptera (ants, wasps, and bees), and amphipods (such as *Gammarus lacustris*) (AZGFD 2001a; Cross et al. 2013; Kaeding and Zimmerman 1983; Valdez and Ryel 1995). Feeding by all life stages may occur throughout the water column, at the water surface, and on the river bottom.



Razorback Sucker

The razorback sucker (*Xyrauchen texanus*) is a large river sucker (Catostomidae) endemic to the Colorado River system. The razorback sucker is one of four endemic Colorado River fishes that Minckley (1973) described as rare in the Lower Basin. It is a large fish that may live more than 50 years, with adults reaching lengths of up to 1,000 mm TL (39 inches) and weights of 5–6 kg (11–13 pounds). However, they are more typically found within the 400–700 mm TL (16–28 inch) range and weigh less than 3 kg (7 pounds; FWS 2018b). Historically, razorback suckers were used extensively as food by native cultures, and populations were commercially harvested as recently as 1949 (FWS 2018b). The razorback sucker was listed as federally endangered in 1991(56 Federal Register 54957) and, more recently, has been included under the auspices of the Lower Colorado River Multi-Species Conservation Program, with the goal of working toward the recovery and persistence of rare fishes in the Lower Basin. A Species Status Assessment (FWS 2018b) found that the status of the razorback sucker has improved, and a Proposed Rule in 2021 (*Federal Register* Vol.

86, No. 127, July 7, 2021) proposed to reclassify the species from endangered to threatened because the *"...species' status has improved due to conservation actions and partnerships, and the threats to the razorback sucker identified at the time of listing in 1991 have been eliminated or reduced to the point that the species is no longer currently in danger of extinction throughout all or a significant portion of its range, but it is still likely to become so within the foreseeable future without current active and intensive management."*

Critical habitat was designated as 2,776 km (1,724 miles) of the Colorado River Basin on March 21, 1994 (59 *Federal Register* 13374). This was composed of 1,519 km (944 miles) in the Upper Basin and 1,255 km (780 miles) in the Lower Basin (**Figure TA 8 Attachment 1-7**). Within the analysis area, critical habitat includes (a) the Colorado River and its historical from Westwater Canyon to full-pool elevation, upstream of North Wash and including the Dirty Devil arm of Lake Powell, (b) the San Juan River and its historical floodplain from the Hogback Diversion to the full-pool elevation at the mouth of Neskahai Canyon on the San Juan arm of Lake Powell, (c) the Colorado River and its historical floodplain from the confluence with the Paria River to Hoover Dam, including Lake Mead to the full-pool elevation, (d) the Colorado River and its historical floodplain from Hoover Dam to Davis Dam, and (e) the Colorado River and its historical floodplain from Parker Dam to Imperial Dam including Imperial Reservoir to the full-pool elevation or historical floodplain, whichever is greater.

Figure TA 8 Attachment 1-7
Critical habitat designated for the razorback sucker in 1994 (yellow highlight), and general areas defined as Upper and Lower Basins (modified from FWS 2018b)

Distribution and Abundance

Razorback sucker are endemic to the Colorado River Basin, which encompasses parts of seven western states, including Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming, as well as parts of Sonora and Baja California, the United Mexican States (Mexico). The Upper and Lower Basins are split at Lees Ferry, Arizona, which is 15 miles downstream of Glen Canyon Dam. Glen Canyon Dam provides physical separation between the Upper and Lower Basins. Historically, razorback sucker were widespread and common throughout the larger rivers of the entire Basin, with particularly high razorback sucker abundance in the Lower Basin near Yuma, Arizona. Razorback sucker are thought to have been uncommon in turbulent, canyon-bound reaches, with robust populations typically being found in calm, flatwater river reaches. Historical populations were affected by the construction of multiple in-stream impoundments in the early to mid-1900s, which changed riverine conditions. Razorback suckers have persisted in some resulting reservoirs but have been extirpated in others (Marsh and Minckley 1989; FWS 2018b).

Razorback sucker adults are present and spawning across much of the Colorado River Basin, but some areas have patchy distributions. Species presence is likely due to its ability to utilize both lotic (rapidly moving fresh water, like a river) and lentic (still, fresh water, like a reservoir or lake) environments. Four populations, all maintained by stocking, are currently present in the Upper Basin, including in the Green, Colorado, and San Juan subbasins and Lake Powell. Lower Basin populations currently occur in Lake Mead (and the Colorado River upstream of Lake Mead), Lake Mohave, the Colorado River between Davis and Parker Dams (Lake Havasu), and the Colorado River downstream of Parker Dam, and all except the first are maintained by stocking. Although other, smaller, isolated, and more localized sources of razorback sucker can be found in various ponds, backwaters, and other habitat types common to the Lower Basin, they are not included herein as not all are sampled routinely or with the specific purpose to produce abundance estimates (FWS 2018b), and they are not in the analysis area.

Ten historical records exist for razorback sucker between Glen Canyon Dam and the upper extent of the inflows of Lake Mead between 1944 and 1990 (Valdez and Carothers 1998, FWS 2018b). Razorback sucker were detected in 1990 at the confluence of the Little Colorado River, but they were thought to be functionally extirpated in the Grand Canyon (Clarkson and Childs 2000).

Until recently, the razorback sucker was considered extirpated from the Grand Canyon, with the last individual collected in 1993 at RM 39.3. However, subsequent captures of razorback suckers and flannelmouth-razorback sucker hybrids in the Little Colorado River (Marsh and Douglas 1997) and western Grand Canyon (Bunch et al. 2012; Rogowski and Wolters 2014; Rogowski et al. 2015) indicated the species' continued presence. Notably, four sonic-tagged fish from Lake Mead were detected in Grand Canyon National Park up to Quartermaster Canyon (RM 260) in 2012 (Kegerries and Albrecht 2012), and additional adults were collected near Spencer Creek (RM 246) in 2012 and 2013 (Bunch et al. 2012; GCMRC 2014). Since 2010, studies in the Lake Mead inflow and, since 2014, in the lower Grand Canyon have verified razorback sucker spawning and larval production within Grand Canyon National Park, with larvae documented as far upstream as RM 179 (Albrecht et al. 2014), and in 2019, eight larvae were captured between RM 127.3 and RM 279.0, extending the known upstream distribution by 17.5 RM compared to the previous record (Rogers et al. 2023).

However, no razorback sucker larvae have been detected since 2019, suggesting that spawning in the mainstream river may be limited or no longer occurring.

Although captures of any life stage of razorback sucker are rare in the Grand Canyon, telemetry of translocated razorback sucker has been useful for documenting use and movement since 2014 (Albrecht et al. 2014). Since 2014, six translocated fish have been detected through telemetry above RM 30 (Rogers et al. 2023). Most recently, Roger et al. (2023) reported that a translocated adult razorback sucker was detected via sonic telemetry to have been near RM 15.

The largest reservoir population of razorback sucker, estimated at 75,000 in the 1980s, occurred in Lake Mohave, Arizona and Nevada, but at present, no wild fish remain because of a lack of recruitment (Marsh et al. 2003; Marsh et al. 2005; Marsh et al. 2015). However, Lake Mohave remains an actively managed and important genetic refuge for the species where larvae are collected, reared in the hatchery, and released back into the reservoir at larger sizes to improve survival, as little to no natural recruitment occurs because of predation (Marsh et al. 2015; FWS 2018b). Razorback sucker were also often reported in the riverine Lower Basin downstream of Lake Mohave from the early 1940s through the early 1980s (FWS 2018b), and currently one of the largest populations of this species occurs in the reach between Davis Dam and Parker Dam (LCR MSCP 2024).

The Gila River system encompasses the Verde, Gila, and Salt Rivers and their tributaries. Razorback sucker historically occupied all larger streams in the Gila River Basin, including the Salt, Verde, and Gila Rivers (FWS 2018b). By the 1970s, the species was extirpated from the Basin, and by 1981, efforts to reestablish razorback suckers had begun, but lack of survival precluded additional work in these locations (FWS 2018b).

The decline of the razorback sucker throughout its range has been attributed primarily to habitat loss due to dam construction, the loss of spawning and nursery habitats as a result of diking and dam operations, and alteration of flow hydrology (AZGFD 2002a; FWS 2018b). For example, the 80 percent reduction in the historical distribution of this species has been attributed to the construction of Hoover, Parker, Davis, and Glen Canyon Dams on the Colorado River and Flaming Gorge Dam on the Green River (Mueller et al. 2000). In addition, competition with and predation by nonnative fish have also been identified as important factors in the decline of this species (Minckley et al. 1991; FWS 2002a). In the Grand Canyon, the decline of native fish, including razorback sucker, has been attributed to multiple factors, including modifications to river temperatures and discharge patterns due to Glen Canyon Dam and the subsequent establishment of nonnative fish populations. This has led to more than 2 decades of experimental actions to understand the factors that influence the occurrence, abundance, and distribution of native fish in the Grand Canyon (Coggins et al. 2011; Mueller et al. 2000; FWS 2018b). More recent studies have documented increased native fish abundance throughout the Grand Canyon (e.g., Kegerries et al. 2015 and 2020; Fennell et al. 2024).

Razorback sucker in the Grand Canyon have been observed, and evidence of spawning has been observed in the river from at least Lava Falls through the entirety of Lake Mead, and it maintains a reproducing population in the analysis area (Albrecht et al. 2014; Kegerries et al. 2015). Currently, there is little information on the habitat use and life-history needs of the species in the Grand Canyon and Lake Mead.

Habitat

The razorback sucker uses a variety of habitats, ranging from mainstream channels to slow backwaters of medium and large streams and rivers (AZGFD 2002a; FWS 2018b). In rivers, habitat requirements of adults in spring include deep runs, eddies, backwaters, and flooded off-channel areas; in summer, runs and pools, often in shallow water associated with submerged sandbars; and in winter, low-velocity runs, pools, and eddies. (FWS 2018b). In reservoirs, adults prefer areas with water depths of 1 meter (3.3 feet) or more over sand, mud, or gravel substrates. Young require nursery areas with quiet, warm, shallow water such as tributary mouths, backwaters, and inundated floodplains along rivers, and coves or shorelines in reservoirs (FWS 2018b). Captures of larval razorback sucker in the western Grand Canyon in 2014 and 2019 found the highest density of larvae in isolated pools, which comprised less than 2 percent of all habitats sampled (Albrecht et al. 2014; Kegerries et al. 2019). Similar results were found in 2015, when the highest catch of larval razorback sucker was found in isolated pools, followed by backwaters, which comprised 2.1 percent and 9.1 percent of habitats sampled, respectively (Kegerries et al. 2015). Marsh et al. (2024) provide an exhaustive review of the current concepts related to the role of isolated backwaters and their creation for this species, the need for genetic monitoring, and other pertinent management actions for razorback sucker in the Lower Basin.

Life History

Adults and immature razorback sucker are omnivorous, feeding on algae, zooplankton, and aquatic insect larvae. In Lake Mohave, their diet is dominated by zooplankton, diatoms, filamentous algae, and detritus (Marsh 1987). Razorback suckers exhibit relatively fast growth in the first 5 to 7 years of life, after which growth slows and possibly stops (AZGFD 2002a). Both sexes mature by about age 4. Spawning in rivers occurs over bars of cobble, gravel, and sand substrates during spring runoff at widely ranging flows and at water temperatures typically greater than 14 °C (57 °F) (FWS 2002a, 2018b). In reservoirs, spawning occurs over rocky shoals and shorelines. Temperatures for spawning, egg incubation, and growth of this species range from 14–25 °C (57–77 °F).

Hatching success is temperature dependent, with 100 percent mortality occurring at temperatures less than 10 °C (50 °F); optimum temperatures for adults are around 22–25 °C (72–77 °F) (AZGFD 2002a). Based on back calculation from the dates of larval collection, Kegerries et al. (2015) estimated that the onset of spawning in western Grand Canyon was in mid-February when average daily water temperatures were between 10 °C and 12 °C (50 °F and 53.6 °F). Spawning appeared to peak toward the end of March when water temperatures were in the range of 12–14 °C (54–57 °F), although the entire spawning period was estimated to range from mid-February to July (Kegerries et al. 2015).

Historically, this species exhibited upstream migrations in spring for spawning, although current populations include groups that are sedentary and others that move extensively (Minckley et al. 1991). Adults in the Green River subbasin move as much as 62 miles to specific areas to spawn (Tyus and Karp 1990). In Lake Mohave, individuals move 12-19 miles between spring spawning and summer use areas (Mueller et al. 2000). Kegerries et al. (2015) reported that sonic-tagged razorback suckers moved up to 224 miles within the western Grand Canyon, the Colorado River inflow to Lake Mead, and throughout Lake Mead as a habitat used by all life stages of this species.

Bonytail

The bonytail is a medium-sized fish species endemic to the Colorado River and its tributaries. The species was historically widespread and common from Mexico to Wyoming, but by the 1970s had declined to fewer than 50 known individuals (FWS 2002b). The bonytail was listed as an endangered species in 1980 because of extirpation from most of its range caused by habitat alteration (45 *Federal Register* 27710; April 23, 1980). Critical habitat for the bonytail (59 *Federal Register* 13374, March 21, 1994) includes 502 km (312 miles) of the Colorado River system. Within the analysis area, critical habitat includes (a) the Colorado River from Brown Betty Rapid to Imperial Canyon in the Lake Powell inflow, (b) the Colorado River from Hoover Dam to Davis Dam including Lake Mohave up to its full-pool elevation, and (c) the Colorado River from the northern boundary of Havasu National Wildlife Refuge to Parker Dam including Lake Havasu up to its full-pool elevation. The elevation at Imperial Canyon is 3,680 feet, which is within the full-pool elevation of Lake Powell of 3,700 feet, the defined analysis area of this Final Environmental Impact Statement (EIS).

A Bonytail Recovery Plan was approved in 1990 and amended and supplemented by Recovery Goals in 2002 (FWS 2002b). A Species Status Assessment has not been developed for the bonytail, and the most recent 5-Year Status Review (FWS 2024a) recommended no change in the listing status. The current Recovery Priority Number of 5C is indicative of a species facing a high degree of threat, having a low recovery potential, and is listed at the species level, and there is the potential for conflicts between needed recovery actions and economic activities. The bonytail is included in the Upper Colorado River Recovery Program and the Lower Colorado River Multi-Species Conservation Program. These programs undertake management actions for the conservation of the species, including stocking, flow management, nonnative fish control, and habitat development. Despite management efforts, signs of bonytail survival in the wild remain rare, and the ecology of the species remains poorly understood (Bestgen et al. 2008). Without viable, wild bonytail populations, the species continues to rely on hatchery propagation to persist in the wild and to advance recovery efforts. The present hatchery propagation program is based on a founder population of 11 individuals (6 females and 5 males) taken from Lake Mohave between 1976 and 1978 (FWS 2002b).

Distribution and Abundance

The bonytail was historically widespread and common throughout the larger rivers and tributaries of the Colorado River system, with historical captures documented from Mexico to Wyoming (Behnke and Benson 1980; Minckley and Deacon 1991; Mueller and Marsh 2002; FWS 2002b). The first recorded bonytail from the Upper Basin was in 1889, when one specimen was captured from the Green River. Subsequent historical collections, limited largely to anecdotal and historical interviews with limited scientific documentation, indicate a once-expansive range of bonytail inhabitance (FWS 2002b). During the 1950s, bonytail populations underwent a large but poorly documented decline in abundance following extensive biotic and abiotic habitat modifications, including dam construction, water withdrawal, land use practices, and widespread introductions of nonnative fish (Miller 1961). Holden (1991) described the effects of a large-scale rotenone treatment in the upper Green River and provided insight into the rather large population of bonytail present until 1962, at the time of the treatment. Bonytail numbers were drastically reduced in the Green River following the closure of Flaming Gorge Dam in 1963 (Vanicek and Kramer 1969; Holden and Stalnaker 1975). Very few bonytail have been captured in the Upper Basin since the 1980s, including one from Desolation

Canyon of the Green River during 1979-1981 (Tyus et al. 1982), 14 juveniles and adults from Cataract Canyon during 1985-1988 (Valdez 1990), and one from Black Rocks (Kaeding et al. 1986). These were probably the last wild bonytail captured in the Upper Basin before widespread stocking of hatchery fish (Bestgen et al. 2008).

Bonytail numbers in the Lower Basin followed a similar trend of rapid decline (FWS 2002b). FWS (2002b) summarizes and references historic captures downstream of present-day Lake Powell. In the 1940s, 16 individuals were captured from the Grand Canyon (as referenced in FWS 2002b). In the 1950s, a large aggregation estimated at 500 adults was located spawning over a shelf of angular rock and gravel in Lake Mohave. Because of the low numbers of bonytail seen in the wild, the FWS and its cooperators initiated a program in 1974 to collect the few remaining wild bonytail and establish a broodstock for reintroducing the species and reestablishing wild populations (FWS 2002b). Thirty-four bonytail were captured in Lake Mohave from 1976 to 1988, and 11 of these fish (6 females and 5 males) were used to establish a hatchery broodstock, the progeny were stocked into Lake Mohave and Lake Havasu, as well as in the Upper Basin (Minckley et al. 1989; Minckley et al. 1991; FWS 2002b). From 1981 to 2013, approximately 209,500 bonytail were stocked into Lake Havasu (Humphrey et al. 2014), and from 1991 to the end of 2022, 483,224 bonytail were stocked in the Lower Basin (Marsh et al. 2024). Of these, approximately 98,172 were stocked into Lake Mohave and lakeside backwaters (the mouths of inundated desert washes separated from the reservoir by wind-generated gravel berms), 284,392 into Lake Havasu and adjacent habitats, 99,591 into the mainstream Lower Colorado River and its connectives downstream of Lake Havasu, and 1,069 into inland impoundments and isolated backwaters along the Lower Colorado River. Bonytail stockings into the Lower Colorado River or connected backwaters have produced no evidence of long-term survival, reproduction, or recruitment, while stockings into habitats free of nonnative fishes have demonstrated survival, reproduction, and even recruitment, suggesting that the future of this species may depend on isolated habitats and intensive nonnative fish management (Marsh et al. 2024).

Hatcheries in the Upper Basin produce and stock over 35,000 adult bonytail per year into Upper Basin rivers, including the Green, White, Yampa, Dolores, Gunnison, San Rafael, Price, and Colorado (Integrated Stocking Plan Revision Committee 2015). The hatcheries include Utah's Wahweap Hatchery (Big Water, Utah), the FWS's Ouray Hatcheries (Grand Junction, Colorado and Randlett, Utah), and Colorado's Native Aquatic Species Recovery Facility (Alamosa, Colorado). Bonytail have spawned naturally in ponds at Wahweap State Fish Hatchery, creating an overabundance of fish that exceeds hatchery capacity. Hence, hatchery managers released over 150,000 untagged juvenile bonytail into Lake Powell between 2016 and 2023 in addition to their traditional stocking targets (FWS 2024a).

Two bonytail were captured recently in the Colorado River downstream of Glen Canyon Dam (FWS 2024a). In July 2023, an untagged bonytail was found downstream of the dam in the -12-mile slough. The size of the bonytail indicates it was likely part of a 2023 stocking event from Wahweap that survived in Lake Powell and passed through the dam penstocks. A second bonytail was captured in Glen Canyon in fall of 2023 that was PIT-tagged and released alive. Additional bonytail were detected in Lake Powell. One bonytail was captured in a gill net in Lake Powell in March 2023. When sampling for larval razorback sucker in the Colorado River arm of Lake Powell in 2022, Utah Division of Wildlife Resources biologists found two larval bonytail, indicating that the species

naturally reproduced in the Colorado River inflow area. Finally, Rogers et al. (2024) summarize the capture of a single adult bonytail in good health in Lake Mead near the Las Vegas Wash inflow.

Habitat

Information on bonytail habitat use is limited because of the small numbers of individuals left in the wild and due to the extirpation of this species prior to extensive sampling of the Colorado River (Bestgen et al. 2008; Marsh et al. 2024). Early fisheries surveys indicate that bonytail were found in high gradient, gravel, riverine sections, but this observation is probably based on locations of the last few wild fish captured in the Upper Basin (Bestgen et al. 2008). Bonytail are characterized as being adapted to the swifter sections of the Colorado River, with affinity for areas of high flow and rocky habitat types (Miller 1946). Like other native fishes, backwaters and other slackwater habitats are thought to serve as important nursery areas for young bonytail (FWS 2002b). Available information suggests that adult bonytail display similar habitat affinities to those of other native fishes, with a preference for deep, fast-water sections, as well as eddy and pool habitats. Vanicek (1967) noted bonytail habitat selection coincided with habitats occupied by roundtail chub and found these species not only in pools and eddies near "fast-flowing" riverine areas but also in slower sections. Valdez (1990) reported that wild bonytail used the same habitats as humpback chub, with individuals being found in shoreline eddy habitats, boulders, and cobble, and near swift water sections in Cataract and Desolation canyons. Miller (1946) hypothesized that the unique morphological characteristics of the bonytail (long, slender body, adnate scales, and thin, powerful tail) and the humpback chub (large stabilizing dorsal hump and large falcate fins) made these species uniquely adapted to the swift currents, high turbidity, and high salinity of the Colorado River. A laboratory study by Pimentel and Bulkley (1983) showed that hatchery bonytail, when given the opportunity, selected water with high levels of total dissolved solids. Bonytail can persist in water with total dissolved solids of 4,700 mg/L, the highest tolerance reported for any of the *Gila* species of the Colorado River. However, hatchery-produced bonytail may not exhibit the same habitat selection as wild bonytail. Bestgen et al. (2008) found stocked bonytail occupying nearly all habitat types, including riffles that were thought to be too demanding for this species energetically, and likely an atypical habitat choice.

Bonytail were observed spawning over rocky substrate in a reservoir (FWS 2002b) and likely use similar habitat to spawn in both flowing and standing water (Mueller 2006). In the Lower Basin, documented successful natural reproduction in Cibola High Levee Pond indicates that bonytail spawned on shorelines associated with riprap materials (large-diameter gravel, cobble, and boulder substrates) in water 3–6 feet deep (Mueller et al. 2003). Sonic-telemetry studies have also revealed that adult bonytail prefer interstitial spaces associated with shoreline riprap during daylight hours, whereas open-water areas are more commonly used at night, possibly because of the high clarity associated with the off-channel pond. Individuals spawning in Lake Mohave displayed similar diel habitat shifts where adults were found in deeper habitats during the day, and at dark they formed congregations along shallower shoreline habitats (Mueller and Marsh 2002). Intensive telemetry surveillance showed a high degree of site-specific habitat fidelity, with individually marked bonytail consistently returning to the same cavities within the riprap-type shoreline. Young bonytail were most often associated with areas of dense overhead cover in depths greater than 1 m, and they schooled in warm, shallow areas of an oxbow pond (Mueller et al. 2003; Mueller 2006). These findings suggest that habitat for bonytail should include riprapped shoreline materials, and that

bonytail are a highly cover-affiliated (likely vegetation and/or turbidity) species with one of the few specific habitat preferences that has been well documented.

Life History

The life history of the bonytail is believed to be like that of other closely related chub species that are warmwater spring broadcast spawners. Vanicek and Kramer (1969) documented the last substantial spawning of a wild, riverine population of bonytail in Dinosaur National Monument. Ripe fish were collected from mid-June through early July (1964–1966) in water temperatures around 18 °C (64 °F). Bonytail estimated between 5 and 7 years old were determined to be sexually mature (Vanicek 1967), whereas in controlled hatchery environments, Hamman (1982) found that bonytail began to mature sexually at age 2. Johnston (1999) classified bonytails as being broadcast spawners and suggested that the loss of eddy habitats due to the construction of impoundments probably contributed to the apparent reproductive failure of the bonytail and a closely related species, the humpback chub. Marsh (1985) reported that bonytail eggs are adhesive throughout the incubational period, which is thought to be an adaptive strategy to swift-moving currents of the mainstream Colorado River.

As stated previously, active spawning of a large (approximately 500 individuals) aggregate of bonytail in Lake Mohave was observed spawning over angular rock and gravel substrates near shore and in water up to 30 feet deep. Eggs were described as adhesive, and one individual female contained over 10,000 eggs, suggesting a high level of fecundity, a trait that appears to be typical for Colorado River endemic species (FWS 2002b). Even higher levels of fecundity were found in a hatchery, with individual egg production averaging over 25,000 eggs per female (Hamman 1982). Spawning bonytail in Cibola High Levee Pond were observed using shoreline riprap materials, typically in mid-April, frequently during nighttime hours, and in water temperatures ranging from 20.4–21.6 °C (68.7–70.9 °F) (Mueller et al. 2003).

Bonytail egg survival is highly influenced by incubation temperature. Hamman (1982) found 90 percent survival at water temperatures of 20–21 °C (68–70 °F), 55 percent survival at 16–17 °C (61–63 °F), and only 4 percent survival at temperatures of 12-13 °C (54-55 °F). Incubation periods ranged from 99 hours to nearly 500 hours, depending upon water temperatures. Newly hatched fry averaged 6.8 mm (0.27 inches; Hamman 1982). This research is corroborated by Marsh (1985), who found that bonytail embryos have the highest survival rates at temperatures near 20 °C (68 °F) and indicated that newly hatched larvae averaged 6.0–6.3 mm (0.24 inches) in size. In summary, the literature and hatchery evidence show that strong reproductive output and production of young are key characteristics of this species in the absence of predators.

The bonytail's diet is reportedly comprised of a wide variety of aquatic and terrestrial insects, worms, algae, plankton, and plant debris (Mueller and Marsh 2002). This information corroborated earlier findings by McDonald and Dotson (1960) and Vanicek (1967), who also found that Colorado River chub species (including bonytail) fed omnivorously. More detailed and quantitative descriptions of the bonytail diet, including differences in stomach composition by life stage, are limited. However, bonytail stocked into Cibola High Levee Pond fed omnivorously, with adults consuming algae, vegetative material, small fish, and crayfish (various species), while the young fed near the pond surface, consuming zooplankton and invertebrates. Bonytail appear to be cannibalistic as they were

observed consuming their own gametes, as well as young razorback sucker larvae (Mueller et al. 2003).

Colorado Pikeminnow

The Colorado pikeminnow is the largest freshwater fish endemic to the Colorado River system and is the largest member of the minnow family (Cyprinidae) native to North America. Historically, individuals estimated to weigh over 100 pounds and nearly 6 feet in length were reported from the Lower Basin (Seethaler 1978). The Colorado pikeminnow was included in the 1967 List of Endangered Species (32 *Federal Register* 4001; March 11, 1967) and was encompassed in the protection of the ESA in 1973. A Recovery Plan was first developed in 1978, revised in 1989 (Upper Colorado River Basin Coordinating Committee 1989), and amended and supplemented by Recovery Goals in 2002 (FWS 2002c). The most recent recovery plan was approved in September 2023 (FWS 2023). A Species Status Assessment was completed in March 2020 (FWS 2020). The most recent 5-Year Status Review (FWS 2020) concluded that the Colorado pikeminnow is currently in danger of extinction throughout all its range because of the cumulative effects of threats, despite ongoing activities to address threats throughout the species' current distribution.

Critical habitat was designated in 1994 (*Federal Register* Vol. 59, No. 54, 13374-13399, March 21, 1994) and includes 1,148 miles of the Colorado River system. Within the analysis area, critical habitat includes the Colorado River and its historical floodplain downstream to North Wash near Hite Marina (RM 168; river miles upstream of Lees Ferry), including the Dirty Devil arm of the Lake Powell inflow. It also includes the San Juan River and its historical floodplain downstream to the mouth of Neskahai Canyon. At full-pool elevation (37,00 feet), Lake Powell inundates the lower 34 miles of critical habitat on the Colorado River (Imperial Canyon to North Wash, RM 202-168) and the lower 34 miles on the San Juan River (Clay Hills to Neskahai Canyon). A reservoir elevation below 3,603 feet exposes all critical habitat upstream of North Wash on the Colorado River, and an elevation below 3,600 feet exposes all critical habitat upstream of Neskahai Canyon on the San Juan River. Exposing the river channel through critical habitat may be beneficial to the Colorado pikeminnow, as historic riverine habitat provides the lotic environment preferred by the species. There is no critical habitat designated for Colorado pikeminnow in the Lower Basin.

Distribution and Abundance

Colorado pikeminnow historically occurred throughout the warmwater reaches of the Colorado River system, including the Green, Colorado, and San Juan River subbasins in Wyoming, Colorado, Utah, and New Mexico; downstream through the mainstream Colorado River in Arizona, Nevada, California, and Mexico; and the Gila River subbasin in Arizona and New Mexico. Colorado pikeminnow were largely extirpated from the Lower Basin by the 1960s following extensive dam construction, water development, erosive land use practices, and widespread introductions of nonnative fish (Miller 1961). In the Upper Basin, construction of large dams and diversions was more diffuse, leaving longer reaches of river available for habitat and unimpeded movement. Still, Colorado pikeminnow populations in the Upper Basin occur in contracted ranges and reduced abundances. Biochemical genetics show evidence of multiple stocks of Colorado pikeminnow in tributaries of the Upper Basin, with genetic panmixia indicating constant interchange of genes among the stocks or subpopulations (Morizot et al. 2002). This hypothesis of multiple interconnected stocks is supported by long-distance movements and strong fidelity of adults in

contemporary subpopulations to particular tributaries and reflects the development of powerful selection mechanisms that evolved over thousands of years (Irving and Modde 2000; Tyus 1990). Hence, the contemporary populations in the Green River, Upper Colorado River, and San Juan River subbasins are likely derived from stocks with fidelity to those subbasins but with interchange of individuals.

The Colorado pikeminnow currently consists of three populations in the Upper Basin, including wild self-sustaining populations in the Green River and Upper Colorado River subbasins, and a wild population sustained by annual hatchery stocks in the San Juan River subbasin (FWS 2023). About six million young Colorado pikeminnow were stocked from hatcheries into the San Juan River from 1994 to 2020, where the species is reproducing but with limited recruitment. Colorado pikeminnow are not stocked in the Green River or Upper Colorado River. The most recent estimates of abundance are 429 adults (95 percent confidence interval [CI], 334-561) for the Colorado River, and 885 (95 percent CI, 679-1,171) for the Green River for 2015 and 2018, respectively (FWS 2022, 2023). The most recent estimate for the San Juan River is 214 adults (95 percent CI, 162-320) for 2022, including wild and stocked fish (Schleicher et al. 2023). All ages of fish are naturally produced in the Green River and Upper Colorado River populations, and the fish in the San Juan River consist of a mix of naturally produced fish and stocked fish.

Colorado pikeminnow were likely extirpated from the Lower Basin by the mid-1970s, and during 1981–1990, over 623,000 juveniles were reintroduced into the Salt and Verde Rivers, tributaries of the Gila River subbasin in Arizona (Hendrickson 1993), as a nonessential experimental population under Section 10(j) of the ESA. Survival of these fish was low, with few persisting, and the AZGFD stocked the remaining Colorado pikeminnow from their Bubbling Ponds Hatchery in 2018, with no plans to continue stocking into the future. With low survival of stocked fish and a lack of subsequent captures, this experimental population is considered functionally extirpated (FWS 2020). In a separate effort, the FWS recently assessed the potential recovery viability for Colorado pikeminnow in the Colorado River in the Grand Canyon with the intent of stocking fish experimentally (Dibble et al. 2023), but no further action has been taken.

Colorado pikeminnow have not been documented downstream of Glen Canyon Dam since the mid-1970s (FWS 2020), and the last specimen reported from the Grand Canyon was in 1968 (Behnke and Benson 1980). In the first fish surveys of the Colorado River through Glen Canyon before dam construction, McDonald and Dotson (1960) reported only one immature Colorado pikeminnow, and in post-dam surveys, the species was considered rare (Stone and Rathbun 1968). In Lake Powell, Colorado pikeminnow have been captured in small numbers and occur as extensions of populations in the Upper Colorado River and San Juan River subbasins (FWS 2020).

The diversion channels on Glen Canyon Dam closed in March 1963 and began forming Lake Powell. The reservoir reached a full capacity of 3,700 feet elevation on June 20, 1980, but continued to rise to a maximum level of 3,708.34 feet above sea level on July 14, 1983 (Ferrari 1988). At maximum elevation, the reservoir inundated approximately 187 miles of Glen Canyon and Cataract Canyon. As the reservoir was filling, Colorado pikeminnow were caught occasionally in nets for monitoring the fish in Lake Powell. In the spring of 1980, 45 adult Colorado pikeminnow were captured in the Colorado River inflow near Gypsum Canyon (RM 197) when the reservoir was near

full pool (Gustaveson et al. 1985). Some of these fish were radio tagged and later detected in the Colorado River near Grand Junction, Colorado, over 200 miles upstream (Kaeding and Osmundson 1989).

For the Colorado River inflow to Lake Powell, Valdez (1990) sampled Cataract Canyon from Mineral Bottom to Palmer Canyon (RM 195) in 1984-1989 and found 111 larval and YOY Colorado pikeminnow (3 percent of 4,161 total captured) in the Lake Powell inflow downstream of the Big Drops Rapid in Cataract Canyon. These fish were captured in backwaters that had formed in silty deltaic sediments as Lake Powell was receding. Continued sampling of the inflow from 1990 to 1994 (except for 1992) yielded an additional 219 larval and YOY Colorado pikeminnow (Valdez and Cowdell 1994). In 1986, the Interagency Standardized Monitoring Program began, and through that program, YOY Colorado pikeminnow were sampled in the Upper Basin but did not extend into Cataract Canyon or the Lake Powell inflow. The Colorado River inflow to Lake Powell is sampled as an occasional extension of humpback chub monitoring in Cataract Canyon (sampled in 2021, but no Colorado pikeminnow were reported; Ahrens 2022), and the numbers and distribution of Colorado pikeminnow in the inflow are not unknown.

The San Juan River Basin Recovery Implementation Program was established in 1992 to promote recovery of the endangered Colorado pikeminnow and razorback sucker while allowing water development to continue. Surveys to monitor larval fish have been conducted as part of the San Juan River Basin Recovery Implementation Program since 1998 between RM 147.9 (Shiprock, New Mexico) and RM 2.9 (Clay Hills Crossing, Utah) (Farrington et al. 2023). Small-bodied fish monitoring has been conducted from RM 180.6 (Farmington, New Mexico) downstream to RM 3.1 (Clay Hills Crossing, Utah) (Barkalow and Zeigler 2022).

A large waterfall referred to as the Piute Farms Waterfall formed in the transition zone between the San Juan River and Lake Powell and has served as an impassable upstream barrier to fish since 2001, except once for 2 weeks in late July and mid-August in 2011 (Cathcart et al. 2018). During monitoring conducted from 2002 through 2005, 22 YOY Colorado pikeminnow were collected between Clay Hills and Lake Powell from November 2004 to November 2005 (Golden et al. 2006). In 2005 and 2006, 287 and 256 juvenile Colorado pikeminnow were captured, respectively, with only two collected downstream of the waterfall (Jackson 2006; Elverud and Jackson 2007). Studies of stocked Colorado pikeminnows in the San Juan River from 2002 through 2005 (Golden et al. 2006) collected 22 young between Clay Crossing and Lake Powell from November 2004 to November 2005. These data indicate that in the early 2000s, small numbers of Colorado pikeminnow were present near the waterfall (upstream and downstream) when Lake Powell elevations were below 3,666.5 feet.

In 2015–2017, 24 Colorado pikeminnow were captured downstream of the waterfall; most were subadults except for one adult in 2016 (Cathcart et al. 2018). In 2023, three juveniles were captured in the San Juan River arm of Lake Powell near Piute Canyon (RM -34.1) and Neskahai Canyon (RM ~32.0; Schleicher et al. 2024). Two of the fish had been stocked in McElmo Creek on October 25, 2022, about 10 miles upstream of the confluence with the San Juan River and moved over 110 miles downstream to and past the waterfall, while the third fish was untagged (Schleicher et al. 2024). The San Juan River inflow to Lake Powell, like the Colorado River inflow, is periodically sampled.

Hence, the numbers and abundances of Colorado pikeminnow in these inflows are not known with certainty.

Habitat

Colorado pikeminnow inhabit large warm rivers and tributaries of the Colorado River system and require uninterrupted stream passage for spawning migrations and dispersal of young. The species is adapted to a hydrologic cycle characterized by large spring peaks of snowmelt runoff and low, relatively stable base flows (Bestgen 2018; Elverud et al. 2020). High spring flows create and maintain in-channel habitats and reconnect floodplain and riverine habitats. Through most of the year, juveniles, subadults, and adults use relatively deep, low-velocity pools, large eddies, and deep runs that occur in nearshore areas of main river channels (Tyus and McAda 1984; Valdez and Masslich 1989; Tyus 1990, 1991; Osmundson et al. 1995). In spring, Colorado pikeminnow adults use floodplains, flooded tributary mouths, flooded side canyons, and eddies that are available only during high flows (Tyus 1990, 1991; Osmundson et al. 1995). Such environments may be particularly beneficial to Colorado pikeminnow as riverine fish that gather in the floodplain serve as prey for the pikeminnow. Such low-velocity environments also provide resting areas for adults and subadults.

Adults are potadromous (highly migratory within a river basin) and move over 600 miles to rocky canyon-confined spawning areas in summer (late June and July) following spring runoff. Spawning takes place in low-velocity runs less than 1 meter (m) deep on cobble, gravel substrate (Tyus and McAda 1984; Tyus 1985, 1990, 1991; Irving and Modde 2000). After hatching and emerging from the spawning substrate, Colorado pikeminnow larvae drift passively downstream to backwaters in sandy, alluvial regions, where they remain for most of their first year of life (Holden 1977; Tyus and Haines 1991; Muth and Snyder 1995; Bestgen and Hill 2016a).

Colorado pikeminnow larvae occupy in-channel backwaters soon after hatching. The greatest number of larvae occurs in backwaters that are large, warm, deep (average, about 1 foot), and turbid (Tyus and Haines 1991; Bestgen and Hill 2016a). Such backwaters are created when a secondary channel is cut off at the upper end and remains connected to the river at the downstream end. These chute channels are deep and may persist even when discharge levels change dramatically. An optimal river-reach environment for growth and survival of early life stages of Colorado pikeminnow has warm, relatively stable backwaters, warm river channels, and abundant food (Muth et al. 2000). Juveniles and adults use deep, low-velocity eddies, pools, and runs, but move into flooded habitats and bottomlands during spring runoff (Tyus and McAda 1984; Valdez and Masslich 1989; Tyus 1990, 1991; Osmundson et al. 1995).

Life History

The Colorado pikeminnow is a large piscivorous minnow that spawns annually in spring, starting at 5-7 years of age and may live up to 50 years (FWS 2020). The species is adapted to warm rivers and requires uninterrupted passage for spawning migration and larval drift, and a hydrologic cycle characterized by large spring peaks of snowmelt runoff and low, relatively stable base flows (Bestgen et al. 2018; Elverud et al. 2020). Adults are potadromous and may move up to 590 miles to and from spawning sites in summer (Tyus and McAda 1984; Tyus 1990; Irving and Modde 2000).

Archaeological remains from several sites along the Lower Colorado River and its tributaries indicate that the species was historically widespread, abundant, and the largest fish in the river (Seethaler 1978; Miller 1955). The largest of six specimens from Catclaw Cave (now inundated by Lake Mohave), dating from AD 1100, was at least 1.7 m long (5.6 feet) (Miller 1955). Early expeditions of the Lower Basin provided the type specimen (Girard 1856) and reports of fish frequently taken near Yuma, Arizona, reaching lengths of 1.2-1.5 m (4-5 feet) (Gilbert and Scofield 1898) and *"…fish would easily weigh 100 lb. (45 kg)"* (Chamberlain 1904). The largest confirmed weights are 27 and 34 pounds for two fish from Lake Mead (Wallis 1951). The largest Colorado pikeminnow recently caught was about 930 mm (36.6 inches) TL from the Upper Colorado River (Elverud et al. 2020), and about 900 mm (35 inches) TL from the Green River (Bestgen et al. 2018); these fish are estimated to weigh 25–27 pounds. Contemporary sizes of adult Colorado pikeminnow are not as large as estimated for historical archaeological specimens and accounts from the Lower Basin, where the species is now extirpated. Growth and size in the Upper Basin appear limited by colder temperatures and a shorter growing season (Kaeding and Osmundson 1989). Bulkley et al. (1981) estimated the thermal preference of juvenile and adult Colorado pikeminnow as 24.6 ºC (76.3 °F) and 25.4 ºC (77.7 °F), respectively. Mean temperature of the Colorado River near Cisco, Utah, from 2006–2023 for July, which is the warmest month, is 23.6 ºC (74.5 °F) (United States [U.S.] Geological Survey Surface-Water Monthly Statistics for Utah), which is slightly below the preferred temperature of Colorado pikeminnow. Young Colorado pikeminnow have very specific streamflow and temperature requirements. Kaeding and Osmundson (1989) correlated lower water temperatures with reduced growth of age-0 Colorado pikeminnow and concluded that fish 45-100 mm (1.8-3.9 inches) TL would not grow at water temperatures below 13 ºC (55 °F).

Spawning of Colorado pikeminnow occurs after spring runoff (typically late June through August) at water temperatures of 18–23 °C (64–73 °F) (Vanicek and Kramer 1969; Hamman 1981). Females are broadcast spawners that attract multiple males to fertilize eggs in the water column. Average fecundity is about 66,000–77,000 eggs/female (Hamman 1986), and females broadcast adhesive eggs over cobble bars where the eggs incubate 90–121 hours at 20–24 °C (68–75 °F) (Hamman 1981; Marsh 1985). The larvae emerge from the substrate after about 5 days and drift up to 125 miles to nursery backwaters where survival is critical to recruitment (Holden 1977; Tyus and Karp 1989; Haines and Tyus 1990; Tyus 1991; Tyus and Haines 1991; Bestgen et al. 1997, 1998; Converse et al. 1999).

Nursery areas consist of ephemeral backwaters and shoreline embayments with little or no current (Tyus and Haines 1991). Bestgen (1996) reported that Colorado pikeminnow larval growth rate declines at water temperatures below 22 ºC (72 °F). As summarized in Valdez (2006 and 2014), spawning begins after spring runoff when water temperatures reach at least 16 °C (60.8 °F), with reproduction often initiated between 16–23°C depending on the river system. Their adhesive eggs are scattered over cobble substrates and incubate in interstitial spaces, with laboratory studies showing highest hatching success at temperatures of 20–24°C and incubation times of 90–121 hours. In the wild, eggs typically incubate for about five days before hatching. The mean size of Colorado pikeminnow larvae is 7.7 mm (0.3 inches) TL, and they transition to juveniles at 35.2 mm (1.4 inches) TL, or at about 60 days of age (Snyder 1981). In the Green and Upper Colorado Rivers, most of the juveniles remain in shallow, warm, productive backwaters through summer, fall, and winter, and are flushed from these habitats with the following spring runoff (Valdez and Cowdell

1994). In the San Juan River, the larvae use zero velocity habitats, including backwaters and embayments, and juveniles remain in available low-velocity habitats (Barkalow and Zeigler 2022).

Adult Colorado pikeminnow are primarily piscivores starting in their first year of life, although they lack jaw, palatine, or vomerine teeth. Instead, they have pharyngeal teeth, which are modified gill rakers that process and masticate swallowed food items passing through their gullet (FWS 2002c). Young Colorado pikeminnow consume zooplankton and midge (chironomid) larvae (Vanicek 1967; Jacobi and Jacobi 1982; Muth and Snyder 1995), and piscivorous juveniles, subadults, and adults eat soft-rayed native and nonnative fish (Osmundson 1999), as well as a variety of insects and animals, including Mormon crickets (*Anabrus migratorius*) (Tyus and Minckley 1988), mice, birds, and rabbits (Beckman 1963).

Special Status Species

In addition to threatened and endangered species, the Colorado River also supports special status fish species that are not currently classified as threatened or endangered but are of conservation concern or have significant ecological importance. These species include flannelmouth sucker (*Catostomus latipinnis*), bluehead sucker (*Pantosteus discobolus*), and speckled dace (*Rhinichthys osculus)*, as described below.

Flannelmouth Sucker

The flannelmouth sucker is a medium to large river sucker (Catostomidae). It has a maximum TL greater than 600 mm (23.6 inches; AZGFD 2001b; Rees et al. 2005). It is a long-lived species that lives up to 30 years (AZGFD 2001b). The flannelmouth sucker is categorized by the International Union for Conservation of Nature (IUCN) as a species of least concern and not a focus of wildlife conservation because it is still plentiful in the wild. The species does not qualify as federally endangered, threatened, or conservation dependent. It is a Bureau of Land Management (BLM)-sensitive species in Utah and Arizona. The flannelmouth sucker is included in the Range-Wide Conservation Agreement and Strategy that has developed and implemented conservation measures in lieu of federal listing (UDWR 2006).

Distribution and Abundance

The flannelmouth sucker is endemic to the Colorado River system. Historically, the species ranged throughout the Colorado River in moderate to large rivers in Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming (Bezzerides and Bestgen 2002; Rees et al. 2005). Within the analysis area, flannelmouth sucker are found in Lake Powell mostly in the Colorado River and San Juan River inflows, they are abundant in the Colorado River between Glen Canyon Dam and Pearce Ferry, they are in Lake Mead and in tributary inflows, and they are absent downstream of Hoover Dam except for a small, reintroduced population in the Colorado River downstream of Davis Dam (Mueller and Wydoski 2004). Within the Virgin River, this species may be found in the mainstream river and its tributaries downstream to at least Halfway Wash, with specimens also being captured near the Virgin River inflow of Lake Mead, in lentic habitats (Kegerries et al. 2018; Rogers et al. 2024).

In the Grand Canyon, this species is also found in the mainstream Colorado River and its tributaries, including the Little Colorado and Paria Rivers and Shinumo, Bright Angel, Kanab, and Havasu Creeks (AZGFD 2001b; Bezzerides and Bestgen 2002; Douglas and Marsh 1998; Weiss 1993). In contrast to bluehead sucker, flannelmouth sucker are only found downstream of the barrier falls in Shinumo and Havasu Creeks. During annual monitoring conducted between 2000 and 2022, flannelmouth sucker were present in all reaches of the river between Lees Ferry and the inflow to Lake Mead (Makinster et al. 2010; Fonken et al. 2023). Abundance, across all reaches measured as catch-per-unit-effort, has been increasing since 2000, especially since 2004 (Makinster et al. 2010). However, abundance had been decreasing within the reach between RM 0 and RM 179 since about 2005, while increasing downstream of RM 179. Surveys of the small-bodied and larval fish communities in the western Grand Canyon (Lava Falls to Pearce Ferry) found flannelmouth sucker present in the western Grand Canyon, accounting for over 38 percent of the total larval catch in this area (Albrecht et al. 2014).

Abundance estimates using monitoring data and age-structured mark-recapture models show an increase in the abundance of age-1 (juvenile) and age-4 (adult) flannelmouth suckers in the Grand Canyon between 2000 and 2008 (Wolters et al. 2012). Abundance of age-1 flannelmouth sucker increased from about 2,500 in 2000 to about 10,000 in 2008, while abundance of age 4+ adults increased from about 10,000 to about 25,000 for this same period (Wolters et al. 2012). Other abundance estimates based on electrofishing catch-per-unit-effort for this same time period showed an increase in abundance from less than 1,000 in 2000 to about 12,000 in 2009, while the estimated abundance of age-4+ adults increased from about 2,500 in 2001 to about 31,000 in 2009 (Wolters et al. 2012). Long-term fish monitoring by AZGFD (Rogowski et al. 2018) shows flannelmouth sucker in the Colorado River from Lees Ferry to Pearce Ferry increased slowly in catch-per-unit-effort from 2000 to 2011, followed by a general decline to 2014 and an increase to 2017. Based on flannelmouth sucker recaptures in 2002, Mueller and Wydoski (2004) estimated the Reach 3 population to be 2,286 individuals (95 percent confidence interval 1,847–2,998). From 2006 through 2010, estimates ranged from 1,044–2,171 (Best and Lantow 2012). The relative abundance of adult flannelmouth sucker remained high through 2023 (Rogowski et al. 2023).

Habitat

The flannelmouth sucker is generally found in moderate to large rivers. Adults prefer deep water when not feeding (Rinne and Minckley 1991), while larvae and young are often associated with shallow, slow-moving nearshore areas such as backwaters and shoreline areas of slow runs or pools (AZGFD 2001b; Rees et al. 2005). Although it is a riverine species, the flannelmouth sucker has been collected from the inflow areas of Lake Mead (Rogers et al. 2024). In the Virgin River, both adults and subadults are found in low-velocity, nearshore habitats with large amounts of cover, such as eddies and runs over sandy bottoms. Juveniles and adults may be considered habitat generalists and can be found using pool, run, and eddy habitats.

The flannelmouth sucker has been collected from Flaming Gorge and Fontenelle Reservoirs of the Upper Basin. In the Colorado River in the Grand Canyon, subadults are found in eddies and runs over sand bottoms. In the Little Colorado River, adult and juvenile flannelmouth sucker use low-velocity, nearshore habitats with large amounts of cover during the daylight, and faster, more exposed mid-channel habitats at night (Gorman 1994). Juveniles and adults may be considered

habitat generalists and can be found using pool, run, and eddy habitats. Surveys of larval flannelmouth sucker in western Grand Canyon (from Lava Falls to Pearce Ferry) found the highest abundance of larvae in embayments, isolated pools, backwaters, and other low-velocity habitats (Albrecht et al. 2014).

Life History

The flannelmouth sucker is a spring broadcast spawner, where females release eggs into the water column to be fertilized by multiple males. The semi-adhesive eggs fall into crevices of cobble and gravel substrate where they incubate for about 5 days and emerge as larvae 14-16 mm (0.6 inches) TL. The larvae drift passively downstream into low-velocity nursery areas.

Flannelmouth sucker prefer water temperatures ranging from 10–27 °C (50–80.6 °F) and appear to prefer temperatures of about 26 °C (78.8 °F) (Sublette et al. 1990). Water temperatures reported during spawning activity range from 6–18.5 °C (42.8–65.3 °F) but are usually above 14 °C (57.2 °F) (Bezzerides and Bestgen 2002). In the Lower Basin, flannelmouth sucker typically spawn in March and April (Bezzerides and Bestgen 2002). Water temperature has been suggested as a primary cue for spawning in other parts of this species' range, but it does not appear to provide a spawning cue in the Grand Canyon, where relatively synchronized spawning has been reported among sucker stocks from creeks with different temperature and flow regimes (Weiss 1993; Weiss et al. 1998). In the Paria River, the timing of spawning has been correlated with the receding limb of the hydrograph (Weiss 1993).

In the Grand Canyon, flannelmouth sucker apparently spawn in certain tributaries, and fish may move considerable distances to reach spawning sites (Douglas and Marsh 1998; Weiss et al. 1998; Douglas and Douglas 2000). Tributary spawning in the Grand Canyon may be timed to take advantage of warm, ponded conditions at tributary mouths that occur during high flows in the mainstream Colorado River (Bezzerides and Bestgen 2002). Valdez and Ryel (1995) reported large concentrations of bluehead sucker and flannelmouth sucker in tributary mouths through Grand Canyon in spring as presumed spawning runs.

The body condition of flannelmouth sucker is variable throughout the Grand Canyon, but is greatest at intermediate distances from Glen Canyon Dam, possibly because of the increased number of warmwater tributaries in this reach (Paukert and Rogers 2004). Mean condition peaks during the pre-spawn and spawning periods and is lowest in summer and fall (McKinney et al. 1999; Paukert and Rogers 2004). Sucker condition in September was positively correlated with Glen Canyon discharge during summer (June–August), possibly due to an increased euphotic zone and greater macroinvertebrate abundance observed during higher water flows (Paukert and Rogers 2004).

The flannelmouth sucker is characterized by lower lips that are noticeably bulky with thick and fleshy lobes that it uses to feed along river bottoms and around structures. The species is an omnivorous benthic feeder, foraging on invertebrates, algae, plant seeds, and organic and inorganic debris (Bezzerides and Bestgen 2002; Rees et al. 2005; Seegert et al. 2014). The larvae feed primarily on aquatic invertebrates, crustaceans, and organic debris (Childs et al. 1998). As they become juveniles and adults, their diet shifts and becomes primarily comprised of benthic matter, including organic debris, algae, and aquatic invertebrates (Rees et al. 2005; Seegert et al. 2014).

Bluehead Sucker

The bluehead sucker is a medium-sized river sucker (Catostomidae). Adults may reach 300-450 mm (11.8-17.8 inches) TL in large rivers but may be smaller in tributaries; they may live from 6 to 8 years to as many as 20 years (AZGFD 2003; Bezzerides and Bestgen 2002; Sigler and Sigler 1987). The bluehead sucker is categorized by the IUCN as a species of least concern and not a focus of wildlife conservation because it is still plentiful in the wild. The species does not qualify as federally endangered, threatened, or conservation dependent. It is a BLM-sensitive species in Utah and Arizona. The bluehead sucker is included in the Range-Wide Conservation Agreement and Strategy, which has developed and implemented conservation measures in lieu of federal listing (UDWR 2006).

Distribution and Abundance

The bluehead sucker is native to the Colorado River and its tributaries from Lake Mead upstream into Arizona, Colorado, New Mexico, Utah, and Wyoming. This species is also found in the Snake River (Idaho and Wyoming), the Bear River (Idaho and Utah), and Weber River (Utah and Wyoming) drainages (AZGFD 2003; Bezzerides and Bestgen 2002).

Within the analysis area, bluehead sucker are rare in Lake Powell, common in the Colorado River between Glen Canyon Dam and Pearce Ferry, in tributary inflows in Lake Mead, and absent downstream of Hoover Dam. In the Grand Canyon, the bluehead sucker is found in the mainstream Colorado River and its tributaries, including the Little Colorado River, Clear Creek, Bright Angel Creek, Kanab Creek, and Havasu Creek (AZGFD 2003; NPS 2013b; Ptacek et al. 2005; Rinne and Magana 2002). Prior to 2014, it was also found in Shinumo Creek but was largely displaced from that system by large debris flows (Healy et al. 2014). Annual fish monitoring during 2000—2024 in the Colorado River between Glen Canyon Dam and the inflow to Lake Mead shows the bluehead sucker present throughout the mainstream river (Makinster et al. 2010; Kegerries et al. 2015; Rogers et al. 2024). This species is rare in the upper sections of Grand Canyon National Park because of cold dam releases, and increases in number near the Little Colorado River inflow and downstream with warmer water temperatures (Bunch et al. 2012). Bluehead suckers are found more often in Grand Canyon National Park with warmer dam releases.

Within Lake Mead, the bluehead sucker is found periodically in the Colorado River inflow area in limited numbers. Annual native fish monitoring conducted between 2010 and 2024 at the Colorado River inflow area of Lake Mead has produced a total of four individuals (Rogers et al. 2024; BIO-WEST unpublished data). Most contacts occur within the flowing portions of the Colorado River upstream of Pearce Ferry (Rogers et al. 2023).

Abundance estimates using monitoring data and age-structured mark-recapture models show a high variability in the numbers of bluehead sucker over time and location. The abundance of age-1 (juvenile) bluehead sucker in the Grand Canyon appears to have declined from 1990 to 1995, increased from 1995 to 2003, and then declined through 2009 (Wolters et al. 2012). Similar estimates for age-4 (adult) fish show that abundance began increasing from the late 1990s until 2005 or 2006, after which abundance also declined. The estimated abundance of age-1 bluehead sucker has ranged from 1,000 or fewer to as many as 60,000 fish between 2000 and 2009 (Walters et al. 2012). The estimated abundance of age-4+ adults during this same period ranged from about 5,000 to as many

as 75,000 fish. Relatively high numbers of individuals remain in the Lower Colorado River between Lava Falls Rapid (RM 179) and Lake Mead (Bunch et al. 2012). Bluehead sucker larvae were reported throughout the western Grand Canyon between Lava Falls and Pearce Ferry during larval fish community monitoring throughout the area (Albrecht et al. 2014). In this area, the bluehead sucker was the most abundant species in the larval fish community, comprising almost 40 percent of the total catch. Larval fish sampling from Bright Angel Creek (RM 88.5) downstream to Pearce Ferry reported that approximately 26 percent of the larval fish were bluehead sucker (Rogers et al. 2023). Long-term fish monitoring conducted by AZGFD (Rogowski et al. 2018) indicates that bluehead sucker populations in the Colorado River from Lees Ferry to Pearce Ferry increased in catch-per-unit-effort between 2000 and 2010. After this period of growth, their numbers generally declined, with some year-to-year variability, but then rebounded to previous high levels in 2016 and 2017. More recent data show that the relative abundance of bluehead sucker has exhibited a downward trend with considerable fluctuations through 2022 (Fonken et al. 2023).

Habitat

The bluehead sucker typically inhabits rivers and large streams and may be found in smaller streams and creeks (AZGFD 2003; Sigler and Sigler 1987). Riverine habitats may range from cold (12 °C [53.6 °F]), clear streams to warm (28 °C [82.4 °F]), turbid rivers. Large adults live in deep water (6 to 10 feet), while juveniles use shallower, lower velocity habitats (Bezzerides and Bestgen 2002). In clear streams, bluehead sucker stay in deep pools and eddies during the day and move to shallower habitats (for example, riffles or tributary mouths) to feed at night, while in turbid waters they may use shallow areas throughout the day (AZGFD 2003; Beyers et al. 2001). In the Grand Canyon, larval and young bluehead sucker inhabit backwater areas and other nearshore, low-velocity habitats such as eddies, embayments, and isolated pools (Albrecht et al. 2014; AZGFD 2003; Childs et al. 1998). In Lake Mead, larval and young bluehead suckers inhabit slack water, backwater, and lentic habitats (Kegerries et al. 2015).

Life History

The bluehead sucker is a spring broadcast spawner, where females release eggs into the water column to be fertilized by multiple males. The semi-adhesive eggs fall into crevices of cobble and gravel substrate where they incubate for about 5 days and emerge as larvae 12-14 mm (0.5-0.6 inches) TL. The larvae drift passively downstream into low-velocity nursery areas. This species has been reported to be as large as 500 mm (19.6 inches) TL in the mainstream Colorado River in Grand Canyon, with tributary fish being smaller (AZGFD 2003; Valdez and Ryel 1995; Walters et al. 2012). A related subspecies, the Zuni bluehead sucker, occurs in the headwaters of the Little Colorado River along with the bluehead sucker that is the same subspecies as in the mainstream Colorado River (AZGFD 2002b).

Bluehead sucker spawn in spring and summer after water temperatures exceed 16 °C (60.8 °F). Valdez and Ryel (1995) reported large concentrations of bluehead sucker and flannelmouth sucker in tributary mouths through Grand Canyon in spring as presumed spawning runs. Spawning in Grand Canyon tributaries occurs mid-March through June in water depths ranging from a few inches to more than 3 feet and at temperatures of 16–20 °C (60.8–68 °F) over gravel-sand and gravel-cobble substrates (AZGFD 2003; NPS 2013b). In Kanab Creek, spawning has been reported to occur at temperatures of 18.2–24.6 °C (64.8–76.3 °F) (Maddux and Kepner 1988). Smaller tributaries may

provide nursery areas for populations of large adjacent rivers (Rinne and Magana 2002). In Lake Mead, larvae have been captured at temperatures of 18.2–24.6 °C (64.8–76.3 °F) at the Colorado River inflow monitoring site (Kegerries et al. 2015).

The bluehead sucker is an omnivorous benthic forager with a modified lower cartilaginous jaw used as a scraping radula. It feeds by scraping diatoms, detritus, algae, invertebrates, and other organic and inorganic material off rocks and other hard surfaces (Ptacek et al. 2005). Larvae drift to backwaters and other areas of low current, where they feed on diatoms, zooplankton, and dipteran larvae.

Speckled Dace

The speckled dace is native to the western U.S. and is one of eight species in the genus *Rhinichthys*. It is a small fish, typically less than 76 mm (3.0 inches) TL, and has a relatively short lifespan of about 3 years (Sigler and Sigler 1987). The speckled dace is categorized by the IUCN as a species of least concern and not a focus of wildlife conservation because it is still plentiful in the wild. The species does not qualify as federally endangered, threatened, or conservation dependent. It is a BLM-sensitive species in Arizona. Possession or importation of *Rhinichthys osculus* is prohibited or regulated in Colorado and Nevada.

Distribution and Abundance

The speckled dace is the most ubiquitous fish in the western U.S., ranging from the Columbia River drainage (north to southern British Columbia) to the southern Gila River drainage of Arizona and Sonora, Mexico (FWS 2024a). The speckled dace is native to the western U.S. and is one of eight species in the genus *Rhinichthys*.

Although this species is the most widely distributed and abundant native fish species in the Grand Canyon ecosystem, its abundance and distribution could be affected by many of the same factors that affect the abundance and distribution of the other native fish in the ecosystem, namely altered temperature, flow, and sediment regimes and predation by nonnative fish (AZGFD 2002c; Gloss and Coggins 2005).

Within the analysis area, speckled dace are commonly found along shorelines in Lake Powell as well as in the inflows of the Colorado and San Juan Rivers. They are abundant in the Colorado River between Glen Canyon Dam and Pearce Ferry and are also present in Lake Mead and its tributary inflows. Downstream of Hoover Dam, speckled dace occur in smaller numbers. In the Grand Canyon, this species inhabits both the mainstream Colorado River and its tributaries, including the Little Colorado River (Makinster et al. 2010; Robinson et al. 1995; Ward and Persons 2006). Long-term fish monitoring of the Colorado River downstream of Glen Canyon Dam since 2000 shows the speckled dace is the third most common fish species (and most common native species) in the river between Glen Canyon Dam and the Lake Mead inflow, and it was captured most commonly in the western Grand Canyon and the inflow to Lake Mead (Makinster et al. 2010). More recently, Rogers et al. (2024) showed speckled dace were the second most common native species since 2014.

Within the Virgin River, this species occurs within the mainstream and its tributaries, including the Beaver Dam Wash Creek (Kegerries et al. 2018). Long-term fish monitoring of the Virgin River

since 1996 shows the speckled dace to be the third most common fish species (and most common native species) in the lower Virgin River (Kegerries et al. 2018).

Habitat

The speckled dace is found in a variety of habitats, including large rivers, cold, fast-flowing mountain streams, ponds, and warm intermittent desert streams and springs (FWS 2024a). It occurs in rocky runs, riffles, and pools of headwater streams, creeks, and small to medium rivers, typically in waters with depths less than 1.6 feet (AZGFD 2002c), and it rarely occurs in lakes (Page and Burr 1991). Valdez and Ryel (1995) reported finding speckled dace in gravel/cobble fans at arroyos and side canyons of the Colorado River through Marble and Grand Canyons.

Life History

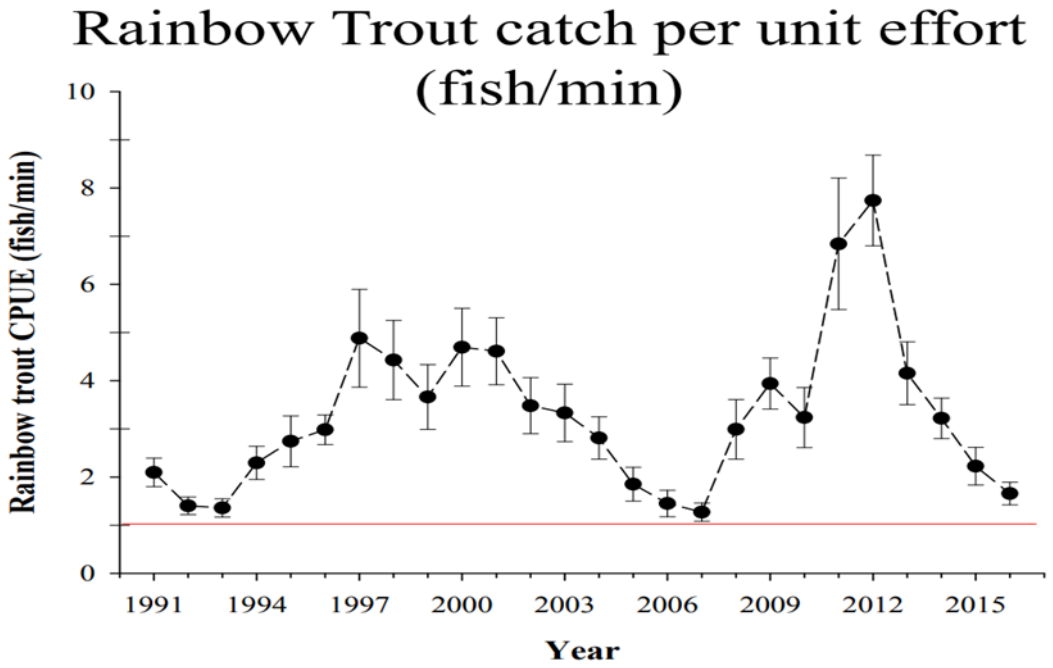
The speckled dace is a small, short-lived minnow that spawns in spring. Adults mature at 2 years of age and are 100-130 mm (3.9-5.1 inches) TL. Spawning occurs in spring when a single female broadcasts 200-500 adhesive eggs over the gravel stream bed, and the eggs are fertilized by multiple males. Speckled dace are omnivorous, feeding on filamentous algae and other plant material, insect larvae and other invertebrates, as well as fish eggs (Seegert et al. 2014). Its young are mid-water plankton feeders (Sigler and Sigler 1987). Speckled dace can spawn twice a year, once in spring and again in late summer when water temperatures are 21–29 ºC (69.8-24.2 ºF; AZGFD 2002c).

High-Risk Nonnative Fish Species

Nonnative fish species have been established in the Colorado River by various means for over a century. Starting in the mid to late 1800s, federal and state agencies distributed nonnative common carp (*Cyprinus carpio*) and channel catfish to rural communities along the Colorado River as a food source. Then, with dam construction in the early 1900s, state agencies began to introduce a variety of warmwater and cold-water species for recreational sports fisheries and as forage to support those fisheries. Changes in flow, temperature, sediment, turbidity, salinity, and physical and biological habitat components altered the river's ecological functions and the collective fish communities (Miller 1961). Understanding the past and present condition and status of fish in the analysis area of this Final EIS is essential to understanding the potential impacts of proposed actions. The following are descriptions of nonnative fish species found in the analysis area.

Rainbow Trout

The rainbow trout is a member of the Salmonidae family, and the life history of this species is extremely variable, depending on location, environmental conditions, and genetic strain (Scott and Crossman 1973). It is one of the most popular and widespread cold-water fish in North America. It is native to cold-water tributaries of the Pacific Ocean in North America and is extensively cultured in hatcheries for stocking as a sportfish throughout the U.S. Angling for rainbow trout is regulated by state game and fish agencies that limit the number of fish taken daily. It is the main sportfish in the 15-mile Lees Ferry sub-reach designated by the AZGFD as a Blue-Ribbon Rainbow Trout Fishery. The species can attain lengths ranging from 30 to 60 cm (centimeters; 12 to 24 inches) and can reach weights of 1.5 to 3 kg (3.3 to 6.6 pounds), although larger individuals have been recorded.



Distribution and Abundance

The rainbow trout was originally introduced into tributaries of the Grand Canyon in 1920-1940 by NPS, including Bright Angel Creek, Tapeats Creek, Havasu Creek, Clear Creek, and Phantom Creek (Runge et al. 2018). With the completion of Glen Canyon Dam in 1963 and the filling of Lake Powell, hypolimnetic dam releases provided a cold, clear, and productive environment for trout in the tailwater. The AZGFD, in cooperation with NPS, began to stock cold-water species in the Lees Ferry sub-reach to establish a recreational fishery. Rainbow trout were stocked in this reach in 1964–1998, and the fish survived successfully, but high fluctuating dam releases precluded most natural reproduction. In 1991, dam operating criteria were modified to increase minimum flows and reduce daily variability in discharge associated with hydropower production. These changes in dam operation allowed the rainbow trout to reproduce and recruit naturally, and stocking the species in the Lees Ferry sub-reach ceased in 1998. Except for localized spawning in and near the confluence of some downstream tributaries (for example, Nankoweap, Clear, Bright Angel, Shinumo, Tapeats, Deer, and Havasu Creeks), most rainbow trout reproduction in the mainstem Colorado River downstream of Glen Canyon Dam occurs within the Lees Ferry sub-reach. Rainbow trout have also been stocked into Lake Mead, Lake Mohave, and Reach 3 of the Lower Colorado River.

Rainbow trout recruitment and population size within the Lees Ferry sub-reach appear to be largely driven by dam operations (McKinney et al. 1999; McKinney et al. 2001; Makinster et al. 2011; Wright and Kennedy 2011; Korman et al. 2011; Korman et al. 2012). The decline in abundance observed in rainbow trout from 2001 to 2007 (**Figure TA 8 Attachment 1-8**) was attributed to the combined influence of increased trout metabolic demands due to warmer water releases from Glen Canyon Dam, together with a static or declining food base, periodic dissolved oxygen deficiencies, and high numbers of the invasive New Zealand mud snail (*Potamopyrgus antipodarum)* serve as a poor food source for fish (Cross et al. 2011).

From 2008 through 2010, the relative abundance of rainbow trout in the Lees Ferry sub-reach increased to near historic high levels (**Figure TA 8 Attachment 1-8**). The highest catch rates in 2011 and 2012 were likely because of warmer releases from Glen Canyon Dam and an input of nutrients from a changed reservoir elevation of Lake Powell (Rogowski et al. 2023). This was after a fall steady flow experiment and equalization flows in 2011 that boosted food base production in the Lees Ferry sub-reach and contributed to greater growth and an increase in abundance of rainbow trout. The population declined tenfold by 2016 due to a combination of lower recruitment and reduced survival of larger trout, which were likely driven by changes in nutrients and invertebrate prey availability (Yard et al. 2023). Survival rates for trout 8.8 inches or longer in 2014, 2015, and 2016 were 11 percent, 21 percent, and 22 percent, respectively, lower than average survival rates between 2012 and 2013. Abundance would have been threefold to fivefold higher had survival rates for larger trout remained at the elevated levels estimated for 2012 and 2013.

Figure TA 8 Attachment 1-8
Mean (±2 Standard Error) Electrofishing Catch Rates of Rainbow Trout in the Glen Canyon Reach, 1991–2016

Source: Rogowski et al. 2023.

Growth declined between 2012 and 2014 due to reduced prey availability, which led to poor fish condition by fall of 2014 (approximately 0.9–0.95, fish condition). Poor condition in turn resulted in low survival rates of larger fish during the fall of 2014 and winter of 2015, which contributed to the population collapse. Korman et al. (2012) found that recruitment of rainbow trout in Lees Ferry was positively and strongly correlated with annual flow volume and reduced hourly flow variation, and that recruitment increased after two of three high-flow releases related to implementation of equalization flows. In Glen Canyon, large recruitment events driven by high flows can lead to increases in the population that cannot be sustained due to limitations in prey supply. In the absence of the ability to regulate prey supply, flows that reduce the probability of large recruitment events can be used to avoid boom-and-bust population cycles (Korman et al. 2017).

Habitat

Adult rainbow trout in streams typically use deep pools, eddies, runs, and overhanging banks for resting, and they feed in open riffles. Juveniles use shallow habitats with in-stream and overhead cover, with recently hatched fry using shallow shorelines (Sigler and Sigler 1996). In the Lees Ferry reach of Grand Canyon, Korman et al. (2011) found the proportion of the age-0 population in low-angle shorelines, which are potentially more sensitive to flow variability, declined from 70 percent in June to 20 percent in November as fish grew and made an ontogenetic habitat shift to deeper habitat, often along steep angle shorelines, which were less sensitive to flow variability. This study

demonstrated how flow variability from daily hydropower production can affect age-0 rainbow trout along low-angle shorelines.

Life History

The rainbow trout can reach a maximum size of nearly 50 pounds and typically matures between 3 to 5 years, with females producing 500-3,161 eggs in streams and 935-4,578 eggs in lakes (Sigler and Sigler 1996). Females prepare individual nests or redds in gravel riffles or runs where they deposit eggs that are fertilized by multiple males. Spawning typically takes place in spring at 10–15 ºC (50-59 ºF), although spawning in the Colorado River downstream of Glen Canyon Dam can occur as early as November and as late as June, with a peak in redd counts from late February to early March (Avery et al. 2015). A strong seasonal pattern in relative condition was seen for rainbow trout in Lees Ferry and was driven by seasonal changes in growth in length and weight (Yard et al. 2015). Body condition was usually at a minimum in January and increased rapidly in spring to attain a peak by July. The decline in condition from July to September was relatively small in clear conditions compared with the other reaches influenced by high levels of turbidity (Korman et al. 2016).

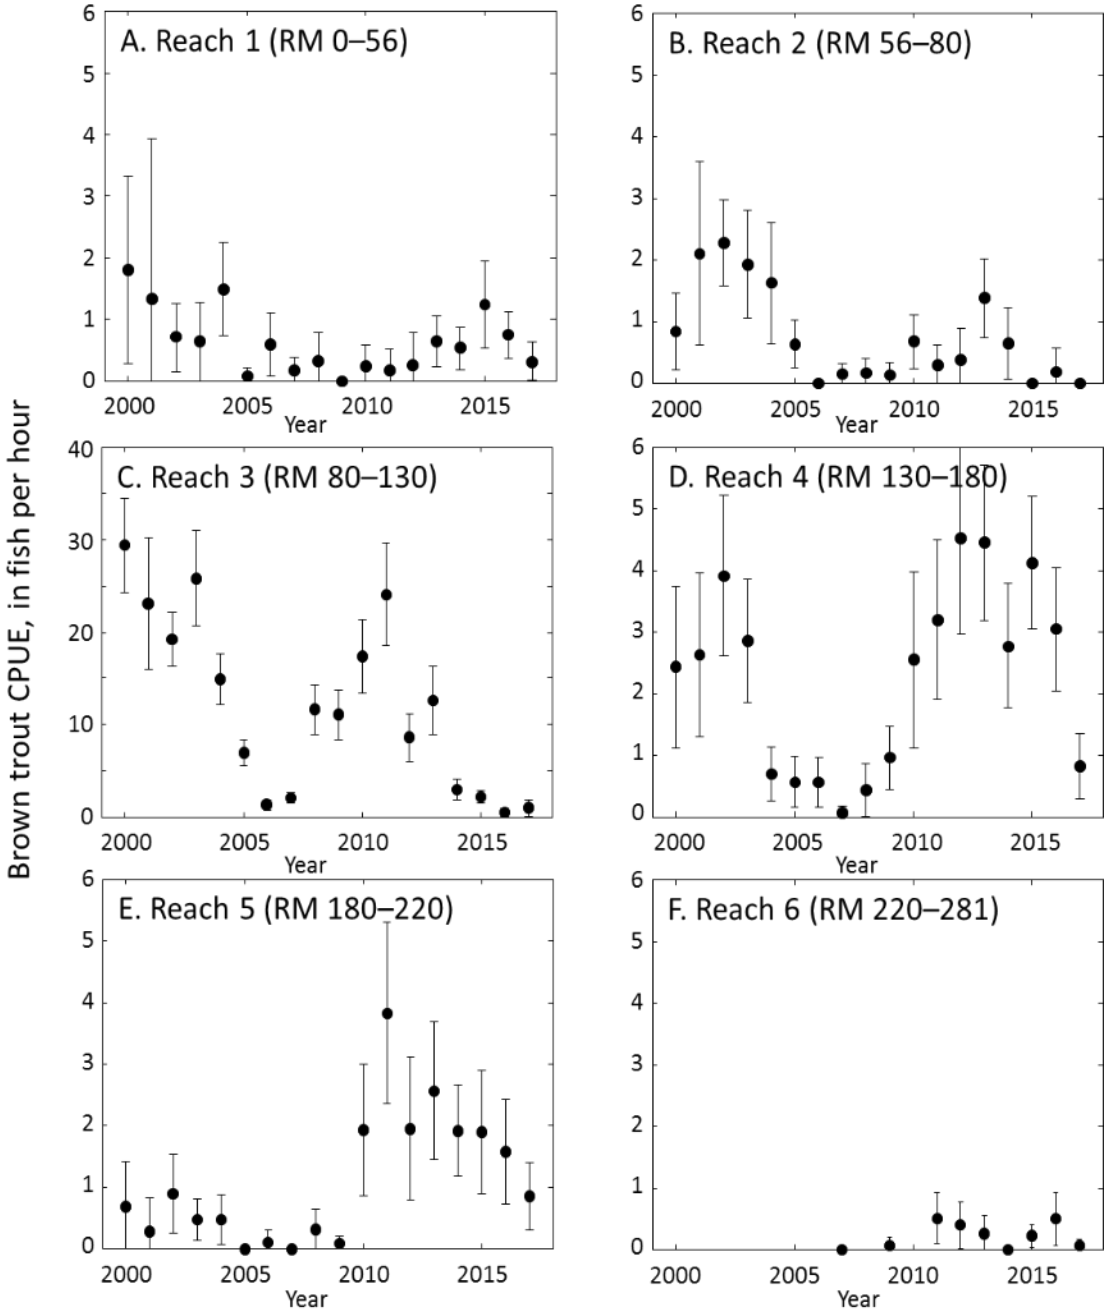
The rainbow trout has a variable diet and will forage throughout the water column on various items (Sigler and Sigler 1996), depending on the fish's genetic strain. In general, the fish's diet changes with the seasons, and generally the species forages near the bottom or near structure (Scott and Crossman 1973). In smaller lake systems, rainbow trout are primarily insectivorous, foraging on Dipetera (e.g., chironomids), Ephemoptera (mayflies), Plecoptera (stoneflies), Crustacea (e.g., amphipods such as *Gammarus* sp.), etc. (Scott and Crossman 1973).

Brown Trout

The brown trout is native to Europe, North Africa, and Western Asia, and it has been introduced as a sportfish into streams, rivers, and lakes around the world. The species was first imported into the U.S. from Germany in 1883 by the U.S. Fish Commission (Mather 1889). Since then, the species has been stocked in virtually every state of the country, including the seven states of the Colorado River system. It was first introduced into Grand Canyon National Park in 1919 by NPS to provide recreational fishing opportunities for park visitors (Runge et al. 2018). Brown trout were introduced into Shinumo Creek, Garden Creek, and Bright Angel Creek in the 1920s and 1930s (Carothers and Minckley 1981), and they were last stocked in the Grand Canyon in Bright Angel Creek in December of 1934, where a reproducing population became established (Runge et al. 2018).

The brown trout is one of four nonnative fish species in Glen Canyon National Recreation Area (NRA) and Grand Canyon National Park identified by NPS as a species presenting a "(1) Very High" level of threat to native fish populations (NPS 2021). The other species with this threat level include smallmouth bass, walleye, and flathead catfish (*Pylodictis olivaris)*. With warmer releases from Glen Canyon Dam as seen in 2004, brown trout can disperse and pose a potential threat to rainbow trout in the Lees Ferry reach and to humpback chub in downstream aggregations (Runge et al. 2018).

Distribution and Abundance



As with rainbow trout, brown trout are not native to the Colorado River and were stocked in Grand Canyon in the first half of the 1900s. Brown trout are no longer stocked in the Colorado River downstream of Glen Canyon Dam and are now found primarily in Lees Ferry and in and near Bright Angel Creek, which supports a naturally spawning population (Reclamation 2011).

Electrofishing catch rates of brown trout have been monitored annually starting in 2000 in six reaches of the Colorado River from Lees Ferry (RM 0) to Pearce Ferry (RM 281) (**Figure TA 8 Attachment 1-9**). Catch rates in most reaches declined from 2000 to 2006 and then increased to the highest levels in 2011–2013 (Makinster et al. 2010; **Figure TA 8 Attachment 1-9**). Because brown trout in the Grand Canyon spawn primarily in tributaries (e.g., Bright Angel Creek [RM 88] and Shinumo Creek [RM 109]), recruitment and abundance may be more affected by conditions in the tributaries than in the mainstem. Overall, catch rates in all reaches declined after about 2015.

Bright Angel Creek was identified as a potential site for translocation of humpback chub to start a second population in Grand Canyon (Valdez et al. 2000). Before translocations of fish could begin, the NPS determined the need to remove as many brown trout as possible from the creek. A trout control project, using a combination of a fish weir trap and electrofishing, was implemented by the NPS to benefit native species in Bright Angel Creek and humpback chub in the Colorado River. Control measures were implemented in winters 2006–2007, 2010–2011, 2011–2012, 2012–2013, 2013–2014, and 2014–2015 under the 2006 and 2013 EAs and a Finding of No Significant Impact (FONSI; NPS 2006, 2013d). Concurrent with intensive mechanical suppression of invasive salmonids, the predominant stream-wide composition of the fish community in Bright Angel Creek shifted from trout (65 percent) in 2012 to native fish (greater than or equal to 77 percent) in 2015 (Healy and Schelly et al. 2020). By the end of the study in 2018, totals of 43,665 brown trout and 7,824 rainbow trout were removed, and native fish represented 97 percent of the fish community. Population estimates for brown trout steadily declined between 2012 and 2018 from a high of 13,829 to a low of 1,315, resulting in a 91 percent reduction by the 2017–2018 sampling season (Healy and Schelly et al. 2020).

Brown trout in the Grand Canyon have shown an ability to move considerably in the Colorado River, sometimes from one tributary to another. Some brown trout captured in Bright Angel Creek were originally tagged in other parts of the Colorado River, as much as 25 miles from Bright Angel Creek (Reclamation 2011). Small numbers of brown trout are also found in other locations within the Grand Canyon, including in the vicinity of the Little Colorado River confluence, where they pose a threat to humpback chub (Valdez and Ryel 1995). A telemetry study documented brown trout moving both up and downstream from Lees Ferry. Detections included one adult brown trout moving from Lees Ferry to just downstream of the Little Colorado River confluence (Schelly et al. 2021). An indication of the relative abundance of brown and rainbow trout in the vicinity of the Little Colorado River is provided by the numbers captured using electrofishing during trout removal efforts (Coggins 2008). Of 23,000 nonnative fish captured as part of removal from 2003 to 2006, totals of 19,020 were rainbow trout and 470 were brown trout (Reclamation 2011). All brown trout removed during these efforts were in the mainstem.

Figure TA 8 Attachment 1-9
Mean Catch-Per-Unit-Effort (CPUE) of Brown Trout Captured during Electrofishing Surveys on the Colorado River between Lees Ferry and Pearce Ferry for Reaches 1–6 (plots A–F), 2000–2017

Data from AZGFD. Figure from Runge et al. (2018).

The brown trout population at Lees Ferry historically consisted of a small number of large fish supported by low levels of immigration from downstream reaches. Over the period 2014–2016, the number of brown trout captured during routine monitoring in the Lees Ferry reach began to increase (**Figure TA 8 Attachment 1-10**). Brown trout were observed spawning near the -4-mile bar in Glen Canyon during October and November of 2014 and 2015, and an increase in age-1 brown trout was observed in 2015 and 2016, likely the result of local spawning and recruitment (Korman et al. 2015). Management agencies and stakeholders questioned whether this increase in brown trout represents a threat to the rainbow trout sport fishery, as well as to downstream humpback chub aggregations. This population of brown trout showed signs of sustained successful reproduction and recruitment of locally hatched fish into the spawning class, based on analysis with a new integrated population model (Runge et al. 2018). The proximate causes of this change in status are a large pulse of immigration in the fall of 2014 and higher reproductive rates in 2015–2017, but the ultimate causes of this change are not fully clear.

Figure TA 8 Attachment 1-10
Index of Brown Trout Abundance (mean fish caught per minute of electrofishing) in Lees Ferry, 1991–2023

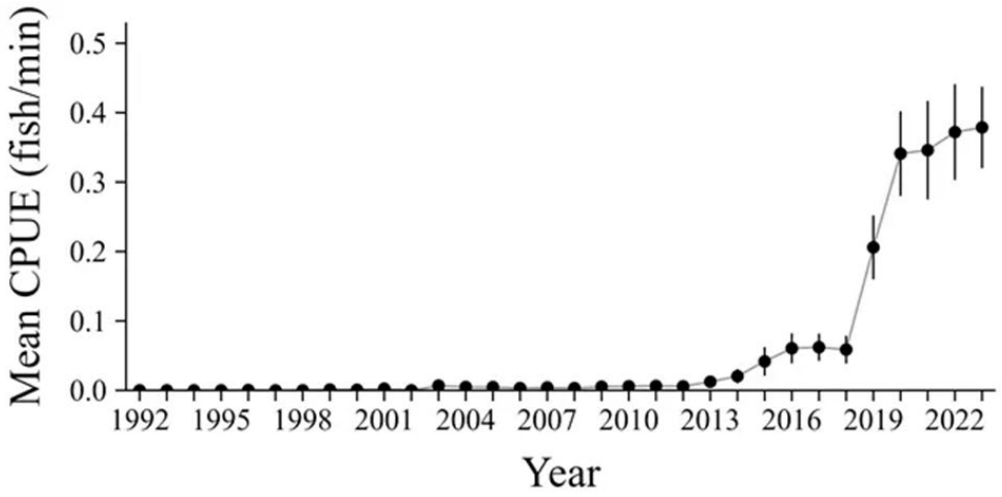


Figure from AZGFD (Rogowski 2023)
Note: The closed circles show the mean value; the whiskers show the 95-percent confidence intervals.

The pulse of brown trout immigrants from downstream reaches in fall 2014 may have been induced by three sequential high-flow releases from the dam in November of 2012–2014 but may also have been the result of a unique set of circumstances unrelated to dam operations. The increase in reproduction may have been the result of any number of changes, including an Allee effect, warmer water temperatures, a decrease in competition from rainbow trout, or fall high-flow releases. Correlations over space and time among predictor variables do not allow for a clear inference about the cause of the changes.

There are interventions that may be effective in moderating the growth of the brown trout population in the Lees Ferry reach (Runge et al. 2018). Across causal hypotheses, it is predicted that removal strategies (e.g., a concerted electrofishing effort or an incentivized take program targeted at

large brown trout) could reduce brown trout abundance by approximately 50 percent relative to status quo management. Reductions in the frequency or a change in the seasonal timing of high-flow releases from Glen Canyon Dam could be more effective, but only under the causal hypotheses that involve effects of such releases on immigration or reproduction. Brown trout management flows (i.e., dam releases designed to strand young fish at a vulnerable stage) may be able to reduce brown trout abundance to some degree, but are not forecast as the most effective strategy under any causal hypothesis.

A cost-effective strategy was identified that involves rewarding anglers monetarily for every brown trout removed from the river, as compared to intensive mechanical removal (i.e., electrofishing) (Runge et al. 2018). An incentivized harvest program was implemented in the Lees Ferry reach on November 11, 2020. For the next 5 to 6 years, eligible anglers would be offered a reward of at least $25 per brown trout over 6 inches in length removed from the Colorado River between Glen Canyon Dam and the mouth of the Paria River. This reward may vary with the seasons or be adjusted annually, but will typically be in the $25-$33 range. The usual reward is $33 per brown trout and $15 for each PIT tag.

Incentivized harvest has been ongoing for over three years (2020–2023) and has increased substantially in the last year. The adult brown trout population declined significantly in 2023, a significant portion of which can be attributed to incentivized harvest. From November 2020 through December 2023, anglers removed 5,597 brown trout and received $423,190 in payouts (NPS 2024).

The number of brown trout greater than 150 mm (5.9 inches) TL appeared to moderate after the incentivized harvest was implemented in late 2020, but the numbers increased to the highest level of over 11,000 fish in 2022 and declined to fewer than 6,500 fish in 2023 (**Figure TA 8 Attachment 1-11**). This indicates that the incentivized harvest of brown trout is working to reduce the numbers of fish, but the effects are confounded by several factors, including survival, recruitment, and environmental conditions.

Figure TA 8 Attachment 1-11
Estimated Numbers of Brown Trout larger than 150 mm (5.9 inches) TL in the Lees Ferry Sub-reach, 2000–2023

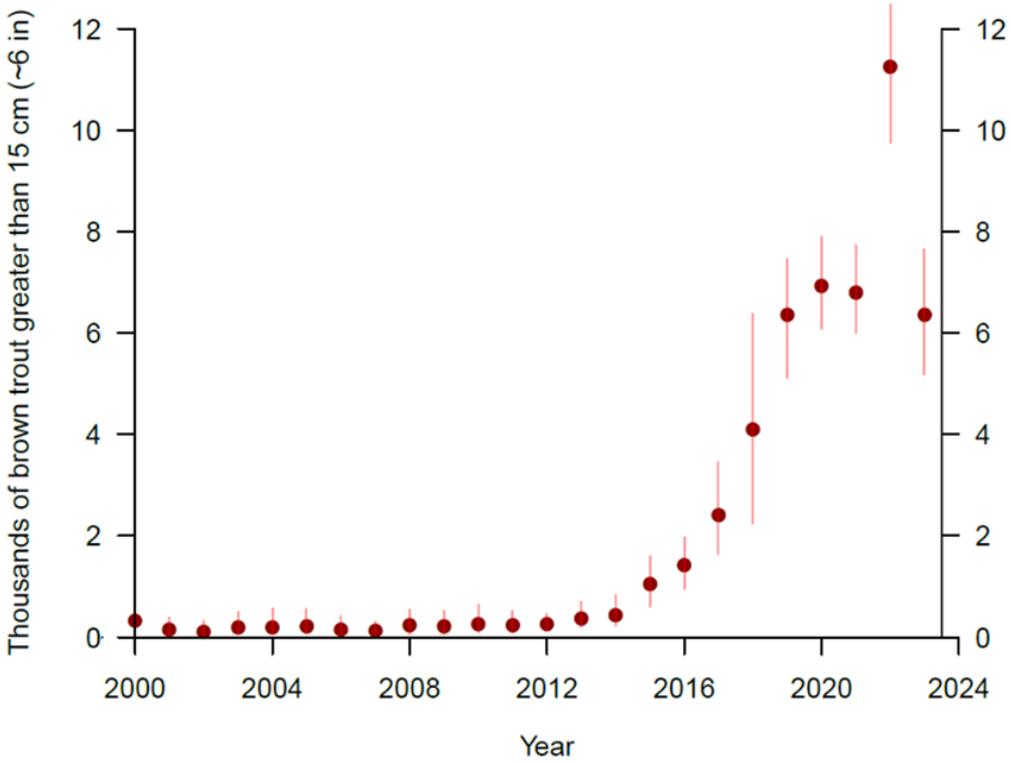

Figure from GCMRC Power Point (Yackulic et al. 2024)

Habitat

The brown trout is a cold-water fish species that inhabits streams, rivers, and lakes, and can migrate to and from salt water. Adults in streams typically use areas with overhead cover and deep pools, eddies, runs, and overhanging banks for resting, and they feed in open riffles. Juveniles use shallow habitats near cover, and recently hatched fry use shallow shorelines (Sigler and Sigler 1996). Brown trout prefer cover, and they can tolerate and feed at high temperatures and in higher turbidity than other salmonids, such as rainbow trout (Sigler and Sigler 1996). The upper limiting temperature for brown trout is 27.2 ºC (81 ºF; Sigler and Sigler 1996). Preferred temperatures for spawning, egg incubation, and growth are 7–14 ºC, 8–20 ºC, and 11–20 ºC (44.6–57.2 ºF, 46.4–68.0 ºF, and 51.8–68.0 ºF), respectively (Valdez and Speas 2007).

In Bright Angel Creek, brown trout use a variety of habitats that include pools, riffles, runs, and cascades. Brown trout from the mainstream Colorado River are attracted to tributaries like Bright Angel Creek by the availability of gravel riffles used as spawning habitat. Limiting access to those habitats by placing a weir at the mouth to intercept upstream adult spawners significantly reduced the numbers of brown trout in the stream, along with ongoing mechanical removal (Healy and Schelly et al. 2020).

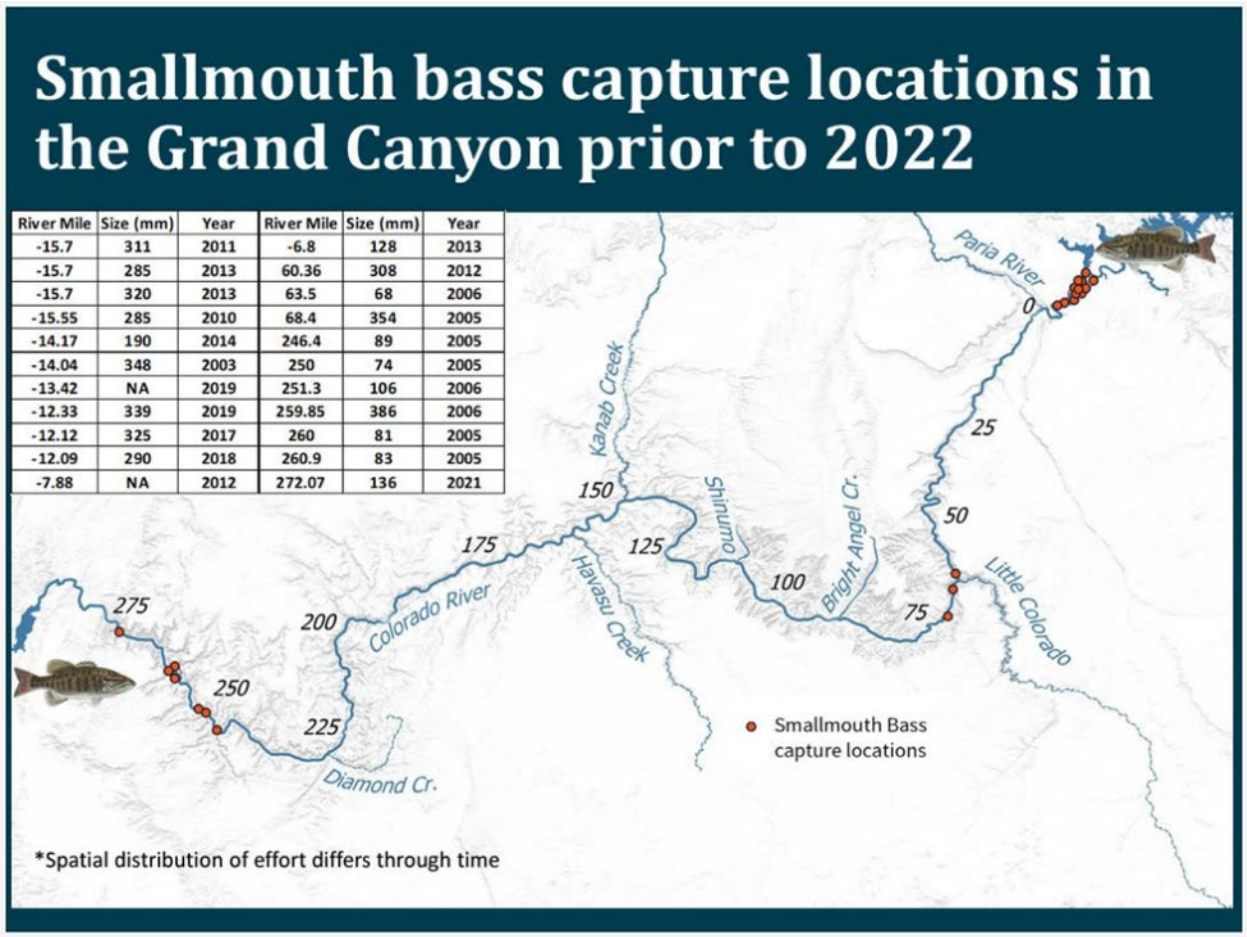
Habitat use in the mainstream Colorado River through Grand Canyon is not well known. Adults appear to have relied on seasonally warmed tributaries, such as Bright Angel Creek, to spawn in an otherwise cold mainstem. With warmer releases from Glen Canyon Dam starting in 2004, brown trout increased in numbers by migrating to the Lees Ferry sub-reach and by apparent successful reproduction and recruitment (Runge et al. 2018). Brown trout appear to be using the same habitats for resting, feeding, spawning, egg incubation, and nurseries as rainbow trout in the Lees Ferry sub-reach, except that brown trout spawn in the fall (October-November) and rainbow trout spawn in early spring (February and early March).

Life History

The brown trout can reach a maximum size of nearly 40 pounds and typically matures between 2 and 3 years of age, with females producing 200–6,000 eggs in streams (Sigler and Sigler 1996). Females prepare individual nests or redds in gravel riffles or runs where they deposit eggs that are fertilized by multiple males. Brown trout initiate spawning in the fall with the onset of decreasing water temperatures in the range of 7.2–10 ºC (45–50 ºF), usually from late October to December. The eggs hatch in 41 days at a constant water temperature of 10 ºC (50 ºF; Sigler and Sigler 1996).

The brown trout has a largely carnivorous diet with younger fish feeding on aquatic and terrestrial insects, as well as mollusks, frogs, and rodents, and older fish feeding primarily on fish and large crustaceans like crayfish (Sigler and Sigler 1996). This propensity for piscivory is why NPS identified brown trout as a "(1) Very High" threat level to rainbow trout and native fish in Glen Canyon NRA and Grand Canyon National Park (NPS 2021). As subadults and adults, brown trout are 17 times more likely to eat other fish than rainbow trout, meaning that even small numbers of brown trout can impose a significant predator threat to native fish (Yard et al. 2011).

Smallmouth Bass



The smallmouth bass is considered the most problematic nonnative fish species in the Upper Basin in terms of negative impacts on native fish populations and endangered fish recovery (Bestgen et al. 2008, 2018; Breton et al. 2015). Based on results of a bioenergetics model, Johnson et al. (2008) ranked smallmouth bass as the most problematic invasive species in the Upper Basin because of their high abundance, habitat use that overlaps with most native fish, and ability to consume a wide variety of life stages of native fish. Expanded populations of piscivores such as smallmouth bass are a major impediment to conservation actions aimed at recovery of the four endangered fish in the Upper Basin (FWS 2018a, 2020). Smallmouth bass also pose a threat to desirable sportfish, such as rainbow trout. The smallmouth bass was introduced into Lake Powell in 1982 and has periodically been detected downstream of Glen Canyon Dam, where it poses a threat to native, endangered, and threatened species, such as humpback chub (Smallmouth Bass Management Review Committee 2024).

Distribution and Abundance

The smallmouth bass is native to eastern North America west of the Appalachian Mountains, but it has been widely introduced throughout the U.S. as a sportfish and for nuisance fish control. The smallmouth bass was introduced into reservoirs of the Upper Basin starting in 1967 (Pettengill et al. 1983). It was stocked into Lake Powell in 1982 and has been detected sporadically in the Colorado River downstream of Glen Canyon Dam since early 2000. Prior to 2022, there were records of 22

individuals being caught between Glen Canyon Dam and Pearce Ferry (**Figure TA 8 Attachment 1-12**). Capture locations show three concentrations of fish, including at the Lees Ferry reach downstream of the dam, near the confluence of the Little Colorado River, and in the newly exposed channel at the inflow to Lake Mead. The likely origin of these fish is passage through the dam, moving down the Little Colorado River from upstream reservoirs, and moving upstream from Lake Mead, respectively. Greater numbers of smallmouth bass have been captured in the Lees Ferry reach in 2022 and 2023, which have either passed from Lake Powell through the dam penstocks or have been recently spawned in the area. Most of the smallmouth bass in the Lees Ferry reach have been caught in and near the -12-mile slough (located 12 miles upstream of Lees Ferry), a small side channel of the Colorado River that can entrain and warm water released from the dam (GCMRC 2014). Prior to 2022, the bass were mostly large subadults and adults, suggesting that these fish survived passing through the penstocks from Lake Powell. Starting in 2022, many of the bass were smaller, indicating that these fish were produced locally, probably in and around the -12-mile slough.

Smallmouth Bass Capture Locations in the Grand Canyon Prior to 2022

Source: GCMRC 2014

Within the analysis area, smallmouth bass are found along rocky shorelines in Lake Powell as a sportfish, in the Lees Ferry reach, near the Little Colorado River, and in the western Grand Canyon; they are also a popular sportfish along rocky shorelines in Lakes Mead, Mohave, and Havasu, and suitable riverine and lake habitats to the SIB.

Habitat

The smallmouth bass inhabits large rivers, streams, lakes, and ponds. Within its native range, it is most abundant in pools of streams that consist of a substantial proportion of riffle habitat, clean, rocky, hard bottoms, and gradients of 0.5-5.0 m/km (2.6-26 feet/mile). In large rivers and lakes, smallmouth bass tend to congregate over hard, rocky bottoms, where currents are present. Currently, smallmouth bass occur in the mainstream Colorado River, in the Verde River, and throughout the Salt River below about 2,200 m (7,218 feet) elevation (Reclamation 2018).

In late summer and autumn during low flows, adults use habitats that consist mostly of low-velocity runs or pools separated by shallow, higher-velocity riffles. Substrate is typically a mix of boulder, cobble, gravel, and sand in low-velocity areas, and cobble and gravel in riffles. Young life stages use shallow riffles with cobble and gravel substrates. Spawning takes place in backwaters and isolated pools that are created by cutoff high-flow side channels and contain cobble, gravel, and fine-grained substrate (Bestgen and Hill 2016b).

Life History

The smallmouth bass is a large member of the sunfish family (Centrarchidae) that can reach sizes of about 69 cm (27 inches) and 5.4 kg (12 pounds). Smallmouth bass spawn in spring, usually mid-April to July, depending on geographical location and water temperature. The species is highly sensitive to flow and water temperature, which greatly influence reproductive success (Winemiller and Taylor 1982; Peterson and Kwak 1999). Large fluctuations in water level can affect the reproductive success of smallmouth bass (Pflieger 1997; Montgomery et al. 1980). Ideal spawning conditions include one or more substantial rises in water level a week or two prior to nesting (Pflieger 1997) and relatively stable water levels while nesting is in progress (Watson 1955; Pflieger 1997). Rising water can flush nest areas with cold water, causing nest desertion and halting embryo development (Watt 1959; Montgomery et al. 1980). Falling water levels can drive guarding males off, limit water circulation around eggs, and increase predation, resulting in lower reproductive success (Neves 1975; Montgomery et al. 1980).

Spawning is initiated when male smallmouth bass construct nests in low-velocity stream habitat, usually channel margin backwaters or cutoff secondary channels, by fanning fine sediment to reveal the gravel and cobble substrate. Nests are built in low-velocity areas because eggs and weak-swimming larvae will otherwise be swept away by even relatively slow water currents 5–22 cm/second (2–9 inches/second; Larimore and Duever 1968). Females are attracted to nests by males, and eggs are deposited and fertilized over the surface of the substrate. Fertilized eggs are semi-adhesive and develop on the surface of the substrate as the male guards them from predators. After hatching, larvae lie on the bottom for several days, and after 1–2 weeks rise from the substrate and gain buoyancy, while still being guarded by the male. Those vulnerable eggs and weak-swimming fry are the life stages most susceptible to changes in flow rates that may sweep eggs and fry away and reduce their survival (Bestgen and Hill 2016b).

Mature females produce 2,000–15,000 golden yellow eggs. Males may spawn with several females on a single nest. On average, each nest contains about 2,500 eggs, but nests may contain as many as 10,000 eggs. Eggs hatch in about 10 days if water temperatures are in the mid-50s (°F), but can hatch in 2–3 days if temperatures are in the mid-70s (°F). Males guard the nest from the time eggs are laid until fry begin to disperse, a period of up to a month.

Temperature is one of the most important factors limiting the distribution of smallmouth bass (Bestgen 2018). Faster growth rates of adults are generally associated with higher summer temperatures. Faster growth rates occur in southern reservoirs, resulting in a shorter life span than in northern regions. In summer, smallmouth bass inhabit warmer shoreline areas of large lakes in the north and deeper, cooler waters in the south. Growth does not begin until water temperatures reach 10–14 °C (50–57 °F). Field data indicate that adults prefer temperatures of about 21–27 °C (70–81 °F) in summer. Smallmouth bass have been reported "sunning" themselves in pools with water temperatures of about 26.7 °C (80 °F) in summer (Edwards et al. 1983). When temperatures drop to 15–20 °C (59–68 °F), adults seek deep, dark areas. At about 10 °C (50 °F), bass become inactive and seek shelter. At 6–7 °C (42.8–44.6 °F), most smallmouth bass are beneath the rock substrate, with few remaining on top. The lower lethal temperature is near freezing. Bass will congregate around warm springs in winter when available.

Fry seem to be especially vulnerable to flood conditions and fluctuating water levels (Larimore 1975). A rapid drop in water level may trap them in areas where they will become desiccated (Montgomery et al. 1980). A stream rise of only a few inches, and consequent increase in water velocity, can displace advanced fry newly risen from the nest (Webster 1954). Most fry remain in shallow water (Doan 1940; Forney 1972), although some can be found at depths of 4.6–6.1 m (15–20 feet) (Stone et al. 1954; Forney 1972). Fry 20–25 mm (0.79–1 inch) in length cannot maintain themselves in current velocities faster than 200 mm/second (7.9 inches/second;Larimore and Duever 1968). An increase in turbulence during flood conditions creates conditions with which smallmouth fry appear unable to cope (Webster 1954). Fry cannot tolerate and are displaced at high turbidities (2,000 Jackson Turbidity Units) combined with an increase in water velocity, but they will not be displaced at moderate turbidities (250 Jackson Turbidity Units) (Larimore 1975). Low water temperatures during flood conditions will reduce fry swimming ability (Larimore and Duever 1968).

Bestgen and Hill (2016b) studied patterns of smallmouth bass reproduction in partially regulated and unregulated reaches of the Green River and the unregulated Yampa River of the Upper Colorado River Basin. Patterns of reproduction in the Yampa River contrasted with regulated or partially regulated Green River reaches, where smallmouth bass reproduction occurred later, and sometimes well after water temperatures reached the threshold 16 °C (60.8 °F). In the regulated reach of the Green River, successful hatching did not occur until relatively low and stable baseflow levels were reached, noting that high streamflow in 2011 delayed hatching. They postulated that stable baseflows were required for smallmouth bass so that spawning habitat was available and suitable for successful reproduction; spawning at higher flows may have been attempted, but could not be determined.

The existence of established smallmouth bass populations in Lake Powell, combined with the passing of epilimnetic water from the lake through Glen Canyon Dam to the Colorado River downstream, creates a conduit for repeated introductions of smallmouth bass downstream of Glen

Canyon Dam. This complicates efforts to minimize the risk of smallmouth bass establishment and expansion in the river downstream of the dam. While directed removal efforts can take place in areas where smallmouth bass have been identified, introductions of smallmouth bass from Lake Powell could continue unless deterrents are developed. A selected option for releases from Glen Canyon Dam is currently being implemented and evaluated as directed by the Secretary of the Interior's designee (LTEMP SEIS, Reclamation 2024). The cool mix option was selected as the most likely to minimize spawning by smallmouth bass. This option involves releasing water from Glen Canyon Dam as a mixture of cold water from the deeper river outlet works (bypass valves or jet tubes) with warmer water through the penstocks that create cooler water conditions to prevent smallmouth bass from reproducing and establishing downstream of Glen Canyon Dam. This release takes place when a mainstream water temperature of 16 °C (60.8 °F) is reached near the confluence of the Little Colorado River (RM 61), the temperature at which smallmouth bass spawning behavior begins for introduced populations in the Upper Colorado River Basin (Bestgen and Hill 2016b). The cool mix releases were conducted under the authority of the 2024 LTEMP SEIS and reflect approved experimental treatments under LTEMP for the Grand Canyon and not as part of this Final EIS.

Green Sunfish

The green sunfish is a medium-sized member of the sunfish family (Centrarchidae) with a maximum length of about 275 mm (10.8 inches) TL and 960 grams (2.1 pounds; Sigler and Sigler 1996). Although not native to the Colorado River, it was common in Glen Canyon before dam construction in 1958-59 (McDonald and Dotson 1960) and shortly after dam construction in 1967-1968 (Stone and Rathbun 1968). It became rare in the mainstream Colorado River after cold dam releases began in the 1970s, except at the mouths of seasonally warmed tributaries like the Little Colorado River and Kanab Creek (Valdez and Ryel 1995). The numbers began to increase in the mainstem with warmer dam releases starting in 2004, and in 2015–2017, green sunfish were found spawning and successfully reproducing in the -12.5-mile slough (Ward 2015; NPS 2018). Evidence of reproduction was found in Kanab Creek (Healy and Ward et al. 2020) and at RM 243 (Smallmouth Bass Management Review Committee 2024). The green sunfish is a small but effective predator of small fish, and a reproducing population in the Grand Canyon poses a risk to native fish populations. The green sunfish is one of six nonnative fish species designated by the NPS as a "(2) High" threat level for native fish in Glen Canyon NRA and Grand Canyon National Park (NPS 2021).

Distribution and Abundance

The green sunfish is native to east-central North America, from southwestern New York, west of the Appalachian Mountains, south to Georgia, Alabama, west and south to Texas, northeastern Mexico, and New Mexico (Sigler and Sigler 1996). It was first introduced into the Colorado River system with various other sportfish after Lake Mead began forming in 1935. It was also introduced by state game and fish agencies as a mixture of sportfish throughout lakes and streams of the system, and is considered a sportfish in Lakes Powell, Mead, Mohave, and other waters of the Lower Basin. It is abundant in tributaries of the Grand Canyon, including the Little Colorado River (Stone et al. 2018). As summarized by Valdez and Ryel (1995), small numbers of green sunfish were found in the Grand Canyon in 1970–73, 1975, 1977–78, 1984–86, and 1990–93. Only one adult green sunfish was captured during the 2000 Low Steady Summer Flow experiment (Trammell et al. 2002),

and no green sunfish were reported in the 2016 System Wide Monitoring Project from Lees Ferry to Lake Mead (Rogowski et al. 2017).

The lower levels of Lake Powell starting in about 2000 have enabled some lake fish to become entrained in the dam penstocks and enter the Colorado River downstream. Lower lake levels have also resulted in warmer dam releases that have enabled warmwater fish like green sunfish and smallmouth bass to spawn downstream of the dam. Although green sunfish have been present in the river since dam construction, their numbers have remained low, and they have not been considered a threat to native fish (Valdez and Ryel 1995). However, numbers began to increase because of dam entrainment and local reproduction, and the NPS decided to act. In November 2015, the NPS found evidence of reproduction by green sunfish in a slough located 3 miles downstream of Glen Canyon Dam (-12-mile slough, 12 miles upstream from Lees Ferry), and the slough was treated with rotenone (a chemical piscicide) to eradicate green sunfish. Additional green sunfish were discovered in the slough in 2016 that were believed to be passing through the dam penstocks from Lake Powell, and in 2018, the Bureau of Reclamation requested temperature reduction options to cool the water in the slough so that green sunfish and other invasive species (e.g., smallmouth bass) could not spawn. A series of temperature reduction options were developed (Greimann and Sixto 2018), but have not been fully implemented. A second rotenone treatment was applied to the -12-mile slough in August 2023.

Numbers and lengths of green sunfish captured in the Lees Ferry reach have been recorded and analyzed as part of the Trout Recruitment and Growth Dynamics project in Glen Canyon between June 2022 and November 2023 (Smallmouth Bass Management Review Committee 2024). These data were used to estimate the capture probability of green sunfish and smallmouth bass. The number of green sunfish is greater and provides more reliable statistics for two sub-reaches, reach 1A (RM -14.3 to -12.5 mile with its downstream end located just upstream of the slough) and 1C (-4.3 to -2.7 mile). The average green sunfish abundance was ~3,900 and 390 in reaches 1A and 1C, respectively. Green sunfish abundance was ~10-fold higher in the reach closer to the dam (1A), located upstream of the slough. The average abundance of smallmouth bass was 182 and 28 in 1A and 1C, respectively. Smallmouth bass abundance in 1A was ~ 6-fold higher than in 1C. Green sunfish abundance was 21-fold higher than smallmouth bass abundance in 1A, and 14-fold higher in 1C. Higher numbers of green sunfish from the sub-reach closer to the dam indicates that the fish were passing through the dam from Lake Powell, but the presence of small fish is evidence of local reproduction (**Figure TA 8 Attachment 1-11**).

Within the analysis area, green sunfish (and other sunfishes) are found along shorelines in Lake Powell, in the Lees Ferry sub-reach, near the Little Colorado River, and in the western Grand Canyon. They are also a popular sportfish along shorelines in Lake Mead, Lake Mohave, and Lake Havasu, and most likely wherever there is suitable riverine and lake habitat downstream to the SIB.

Habitat

Green sunfish inhabit small, warm streams, ponds, and shallow areas of lakes. They occur over a variety of habitats and in a variety of covers, including emergent vegetation, woody debris, and rocks. Green sunfish can tolerate a range of water temperatures from cool (18–21 ºC; 64.4–69.8 °F) to warm (30–32 ºC; 86–89.6 °F) conditions.

Green sunfish spawn in spring in water 0.61–2.44 m (2-8 feet) deep at temperatures of 18.9 ºC (66.0 ºF). They can spawn multiple times until the temperature reaches about 28 ºC (82.4 ºF). Males construct oval nests near rocks, logs, clumps of grass, or other debris, and escort individual females to deposit eggs over the nest. Females produce 2,000–26,000 eggs, and the eggs incubate 3–5 days at 23 ºC (73.4 ºF). More than one female may deposit eggs on the nest, and the male defends the nest aggressively (Sigler and Sigler 1996).

Life History

Green sunfish live up to about 10 years of age and can reach sizes of 275 mm (10.8 inches) TL and 300 grams (0.7 pounds). They have high reproductive survival and are highly predaceous starting with the earliest life stages. They feed on small fish and can dominate small ponds when introduced into a bluegill (*Lepomis macrochirus*)/largemouth bass (*Micropterus salmoides*) fishery. They also consume aquatic and terrestrial insects, crustaceans, and amphibians, and they can hybridize with other species of sunfishes of the genus *Lepomis* (Sigler and Sigler 1996). These aspects of the life history of the green sunfish make it a high threat to local native fish populations.

Flathead Catfish

The flathead catfish is a large North American freshwater catfish species. Adult flathead catfish can reach lengths of between 90 and 120 cm (35 to 47 inches), with some individuals growing even larger. The species have been captured weighing 23 kg to 45 kg (51 to 99 pounds; TPWD 2024). Flathead catfish are gray to brown with dark brown-black mottling that may extend ventrally onto the belly. The undersides of the head and body are white to yellow. Their nasal and maxillary barbels are dark, and their chin barbels are white to yellow. The head is broadly flattened, with a projecting lower jaw. The tail fin is only slightly notched, not deeply forked (Pflieger 1997; Ross 2001; Fuselier 2014; TPWD 2024).

Distribution and Abundance

The flathead catfish is native to the U.S., with its original distribution covering the Mississippi River Basin and Great Lakes region (TPWD 2024). They are widely distributed in the Mississippi River Valley, ranging from South Dakota and Pennsylvania south to the Gulf Coastal Plain. It also occurs in large rivers of the Gulf of America Basin, from the Mobile Basin west to the Rio Grande (Minckley and Deacon 1959; Hubbs et al. 2008; Glodek 1980). Over time, flathead catfish have been introduced to many other water systems across the country, sometimes leading to ecological challenges due to their predatory nature and competition with native species, including in the Lower Colorado River Basin. Due to its desirability as a sportfish, it has been widely stocked outside of its native range (Young and Marsh 1990).

Due to its large size and palatable flesh, flathead catfish have been introduced into parts of Arizona, California, Florida, Idaho, New Mexico, Oregon, and South Carolina (Moyle 1976). The first introduction in the Southwest was to the Gila River system in New Mexico or Arizona sometime prior to 1950 (Young and Marsh 1990). In 1962, the AZGFD stocked flathead catfish at six locations along the Lower Colorado River (Bottroff et al. 1969). Subsequent introductions from 1968 to 1975 occurred in the Salt, Verde, and San Francisco Rivers of Arizona. Since these initial introductions, flathead catfish have spread to inhabit waters throughout the lower Colorado, Gila, Salt, and Verde Rivers in Arizona. Population size varied with discharge in the lowermost Colorado

River and was estimated to range from 155 to 259 flathead catfish per km when discharge was at its maximum in 1986 (Young and Marsh 1990).

Habitat

Flathead catfish prefer habitats in large rivers and streams, as well as reservoirs and lakes with slow-moving or still waters; they favor areas with deep pools, undercut banks, and abundant cover, such as submerged logs, rocks, and debris (Fuselier 2014; Pflieger 1997; TPWD 2024). They occupy a variety of stream types while avoiding high gradients or intermittent flow. It is not likely to be found in headwater creeks (Pflieger 1997). These environments offer both protection and an ample food supply, primarily consisting of live prey such as other fish, as well as crustaceans. Flathead catfish are known to be nocturnal predators, often hunting during the night and relying on their keen sense of smell and taste to locate prey in the dark, turbid waters they inhabit (Ross 2001; Fuselier 2014; TPWD 2024). Optimal water temperatures for flathead catfish range from 25 to 30ºC, but they can tolerate a broader range (TPWD 2024).

Life History

Flathead catfish have a relatively slow growth rate compared to other freshwater fish, with individuals taking several years to reach maturity. They can live for 12 years or more, with some documented cases of individuals living over 20 years (Fuselier 2014; Pflieger 1997; TPWD 2024). Spawning typically occurs in late spring to early summer when water temperatures reach approximately 20 to 26 °C (Fuselier 2014; Pflieger 1997; TPWD 2024). During this time, male flathead catfish prepare nests in secluded, sheltered areas, such as hollow logs, cavities under rocks, or human-made structures like submerged pipes or riprap. Once the nest is prepared, the male attracts a female to the site, where she can lay up to 100,000 eggs, depending on the size of the female. After fertilization, the male takes on the role of guarding the nest from predators (Ross 2001; TPWD 2024).

Flathead catfish are of particular concern as they are voracious predators and pose a substantial threat to native fishes. This species appears to be expanding its range from Reaches 4/5 and upstream within Reach 3 (potentially due to temperature), and as such, it is routinely monitored by FWS personnel. This species had been captured nearly as far upstream as the area between Needles and Fort Mohave in the Lower Colorado River (near Boundary Cone Road crossing) (Rasset and Love-Chezem 2024).

The rapid dispersal and population growth rates of introduced flathead catfish, coupled with their obligate carnivorous feeding habits, have raised concerns among ichthyologists and management agencies. The FWS has ranked flathead catfish as its highest priority among invasive animal species in the southeastern U.S. (Brown et al. 2005).

Acronyms and Abbreviations

°C	degrees Celsius
°F	degrees Fahrenheit
AZGFD	Arizona Game and Fish Department
BLM	Bureau of Land Management
CI	confidence interval
cm	centimeter
CPUE	catch per unit effort
EIS	environmental impact statement
ESA	Endangered Species Act
FWS	United States Fish and Wildlife Service
HFE	high-flow experiment
IUCN	International Union for Conservation of Nature
kg	kilograms
km	kilometers
Lower Basin	Lower Colorado River Basin
m	meters
Mexico	United Mexican States
mm	millimeters
NPS	National Park Service
NRA	National Recreation Area
PIT	passive integrated transponder
RM	river mile
SIB	Southerly International Boundary
TL	total length
U.S.	United States
YOY	young-of-year

Glossary

Analysis Area	Specific geographic boundary and timeframe used to evaluate the potential environmental effects of a proposed action
auspices	Sponsorship, guidance, or protection provided by an organization or authority
backwaters	Areas of slow-moving or stagnant water connected to a river or stream
bioenergetics model	A mathematical model that quantifies the balance between energy intake from food consumption and energy release through metabolism, activity, waste, and reproduction
broadcast	A reproductive method in which eggs and sperm are released freely into the water column for external fertilization
cascades	Steep, high-energy sections of a stream or river characterized by boulder-dominated beds and turbulent flow

critical habitat	Areas officially designated under the Endangered Species Act as essential for the recovery and survival of endangered or threatened species
congeneric	Belonging to the same genus
creel census	Data collected from anglers to estimate catch, harvest, and success rates
debris flow	A fast-moving mass of water-saturated soil, rock, and organic material that travels downslope under the influence of gravity
eddy	Localized area of recirculating flow
deltaic	Anything related to, formed by, or characteristic of a river delta
downlisting	Changing a species' legal status under the Endangered Species Act from "endangered" to "threatened"
endemic	Refers to a species that is native to and restricted within a defined geographic area
extirpated	Describes a species that no longer exists in a localized zone
fecundity	The reproductive capacity of an organism
fidelity	The tendency of an organism to return to or remain in a specific location or habitat type
fry	The early free-swimming life stage of fish that begins after the yolk sac is absorbed and the individual starts active feeding
hydropower operations	The management of reservoir storage and water releases through turbines and spillways at hydroelectric facilities to produce electricity
impoundment	A human-made basin or reservoir created by a dam, berm, or other structure that holds or stores water
inundated	Covered or submerged by water, either seasonally or permanently
Interagency Standardized Monitoring Program (ISMP)	A general description for cooperative monitoring efforts between government agencies, rather than a single program
larval drift	The downstream transport of newly hatched fish by river currents
Lower Colorado River Multi-Species Conservation Program (LCR MSCP)	A comprehensive program for the protection of 27 species and their habitat in the Lower Colorado River Basin
mainstem	The principal or primary channel of a river system
mark-recapture	A population estimation method in which individual organisms are captured, marked, and released, then later recaptured to determine population loss

meristically	Anatomical traits used in describing or identifying species
nursery habitat	Habitat that provides favorable conditions for the survival and growth of juvenile life stages
oxbow pond	A U-shaped or crescent-shaped waterbody formed when a river meander becomes cut off from the main channel
penstock	A pipe that moves water under pressure from a reservoir or intake structure to turbines in a hydroelectric system
piscivory	The feeding behavior of eating fish
PIT-tagged	Describes an organism that has been implanted with a small microchip that contains a detectable code by a specialized scanner
progeny	Offspring or descendants produced by an organism
radio tagged	Describes an organism that has been equipped with a radio transmitter that emits detectable electromagnetic signals
radiotelemetry	A tracking method that uses radio transmitters and receivers to locate and monitor the movement and behavior of organisms
recruitment	The addition of new individuals to a population or to a specific life stage
recurrent channels	Secondary or alternative flow paths within a river or floodplain that periodically carry water during certain flow conditions
redd	A nest created by a female fish where she deposits and buries her eggs in gravel
refugia	Areas that provide shelter or protection for species or communities during periods of environmental stress
ripe fish	A sexually mature fish whose reproductive organs are fully developed and capable of releasing eggs or sperm
rotenone	Naturally derived fish toxin used to eliminate unwanted or invasive fish species from waterbodies
silt-laden	Containing or heavily mixed with fine particles
slack water	Water with little to no current velocity often occurring along channel margins or in backwater areas
slough	A slow-flowing or stagnant side channel, backwater, or wetland area associated with a river, floodplain, or estuary
sonic tagged	Describes an organism equipped with an acoustic transmitter that emits sound pulses detectable by monitories
stocking	Intentional release of fish into a waterbody to supplement natural populations
stratified releases	Controlled discharge of water from specific depths within a reservoir to manage temperature, oxygen levels, or water quality

stressor	Any chemical, physical, or biological factor that can cause adverse effects on an organism, population, or ecosystem
talus	Sloping accumulation of loose rock fragments that collects at the base of a cliff or steep slope due to mass wasting processes
telemetry	The remote detection and transmission of data from tagged organisms or monitoring devices to receivers for analysis
total dissolved solids	A measure of all inorganic and organic substances dissolved in a volume of water, including minerals, salts, and organic matter
translocation	Intentional movement and release of organisms from one location to another

TA 9. Vegetation Including Special Status Species

TA 9.1 Affected Environment

This analysis categorizes vegetation into marsh, woody riparian, and upland habitat types (collectively referred to as terrestrial habitats) throughout the analysis area, which includes Lake Powell, Glen Canyon Dam to Lake Mead, Lake Mead, and Hoover Dam to the Southerly International Boundary (SIB; see **TA 9.2**). Wetlands in the analysis area are typically characterized by marsh habitat, but wetlands could also occur in woody riparian habitats.

Marsh habitats occur in areas that are consistently flooded and are typically found in the transition zone between open water and upland ecosystems. Dominant vegetation in marsh habitat includes graminoids, such as cattails (*Typha* spp.), bulrush (*Schoenoplectus* spp.), and common reed (*Phragmites australis*). Marsh vegetation is sensitive to drought on short timescales, seasonally to annually, and has been found to decrease in cover, species diversity, and productivity when water availability shifts from perennial to intermittent (Stromberg et al. 2005, 2007; Friedman et al. 2022).

Woody riparian habitats occur where water is consistently available and periodic flooding occurs. Dominant vegetation types in woody riparian habitat include woody shrubs and trees, such as cottonwood (*Populus* spp.), mesquite (*Prosopis* spp.), tamarisk (*Tamarix* spp.), arrowweed (*Pluchea* spp.), seep willows (*Baccharis* spp.), and willow (*Salix* spp.). Woody riparian vegetation typically has deeper root systems capable of accessing alluvial groundwater and does not depend on surface water flows (Stromberg et al. 2013). This vegetation type is sensitive to drought on longer timescales, on an annual to decadal scale, depending on the species (Shafroth et al. 2002).

Upland habitats occur in areas without consistent water availability, where vegetation depends on precipitation. Dominant vegetation in the upland habitat is typically desert scrub dominated by various shrub species, such as creosote bush (*Larrea tridentata*) and bursage (*Ambrosia* spp.).

This section also includes special status plant species, defined here as those listed as Bureau of Land Management sensitive species by the overlapping Arizona, California, Utah, and Nevada Bureau of Land Management field offices; species covered in the Lower Colorado River Multi-Species Conservation Program (LCR MSCP); and species listed as threatened or endangered or proposed for listing by the United States (U.S.) Fish and Wildlife Service (FWS; BLM 2017, 2018, 2019, 2023; LCR MSCP 2022; FWS 2025). **TA 9 Attachment 1**, Special Status Plant Species Table, provides a list of the species considered in this document, including their listing status, the river reaches they typically inhabit, and the habitat types they occupy. **TA 9 Attachment 1**, Special Status Plant Species Table, was developed through input from cooperating agencies and local experts.

Culturally important plants are discussed in **TA 13**, Tribal Resources.

TA 9.1.1 Lake Powell

Short-term and long-term fluctuating water elevations influence Lake Powell's shoreline vegetation (**Table TA 9-1**). The median annual water elevation fluctuation between 2008 and 2025, when the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead (2007 Interim Guidelines), were in effect, was 31.45 feet (see **Figure TA 9-1**). The drought-induced drawdown of Lake Powell since 2011 has reduced the lake's perimeter and exposed approximately 59,000 acres of formerly submerged land (Root and Jones 2022).

Table TA 9-1
Approximate Acres of Marsh, Woody Riparian, and Upland Habitat in Each Reach

Reach	Marsh (% of reach)	Woody Riparian (% of reach)	Upland (% of reach)	Total
Lake Powell[1]	1 (<1%)	10,802 (41%)	15,385 (59%)	26,188
Glen Canyon Dam to Lake Mead[2]	96 (3%)	353 (11%)	2,627 (85%)	3,076
Lake Mead[3]	388 (<1%)	6,657 (9%)	64,186 (90%)	71,250
Hoover Dam to the SIB[3]				
Hoover Dam to Davis Dam	36 (5%)	164 (22%)	558 (73%)	758
Davis Dam to Parker Dam	1,069 (20%)	1,990 (38%)	2,195 (42%)	5,254
Parker Dam to Cibola Gage	1,196 (5%)	20,604 (83%)	2,949 (12%)	24,749
Cibola Gage to Imperial Dam	738 (5%)	10,639 (77%)	2,411 (17%)	13,788
Imperial Dam to the Northerly International Boundary	439 (5%)	6,844 (76%)	1,654 (19%)	8,973
Northerly International Boundary to the SIB	10 (<1%)	152 (9%)	1,473 (90%)	1,635
Total	**3,973**	**58,205**	**93,438**	**155,671**

Sources: [1] NPS 2014; [2] Durning et al. 2018; [3] Sound Science 2025
Note: Totals may not equal 100 percent due to rounding.

Historically, marsh and woody riparian vegetation around Lake Powell are restricted due to the natural rocky, desert terrain that extends directly to the water's edge (NPS 2023; Reclamation 2016, 2024). As shown in **Table TA 9-1**, the majority of the reservoir shoreline is upland habitat. Of the 15,385 acres of upland habitat, 7,119 acres were mapped as bare sandstone or slickrock, and 1,044 acres were mapped as sand bar, sand islands, badlands, and other bare dirt areas (NPS 2014). Russian thistle (*Salsola* spp.) is the dominant upland species found along the shores of Lake Powell. Of the 15,385 acres of upland habitat described in **Table TA 9-1**, 1,048 acres were mapped as weedy herbaceous complex, of which Russian thistle is the dominant species (NPS 2014; Tendick et al. 2017). Russian thistle easily takes root on disturbed or bare ground, often establishing before native species (NPS 2023). Recently exposed sites below Lake Powell's full pool showed a higher percentage and cover of nonnative species, with Russian thistle being extremely abundant (Arens 2023).

Long- and short-term fluctuations in reservoir elevations have also had a significant impact on the establishment of marsh and woody riparian vegetation (Reclamation 2016, 2024). Marsh vegetation is extremely limited along Lake Powell, and the 1 acre of marsh vegetation described in **Table TA 9-1** is mapped as spring-supported herbaceous vegetation. Tamarisk is the dominant woody riparian species along the shores of Lake Powell. Of the 10,802 acres of woody riparian habitat described in **Table TA 9-1**, 10,773 acres were mapped as tamarisk shrublands (NPS 2014). Dense stands of tamarisk can displace native plants, degrade wildlife habitat, reduce livestock forage, limit human access, interfere with the natural fluvial processes, alter the ecology and hydrology of riparian systems, and increase the risk of severe wildfires (NPS 2023). Many tamarisk stands were likely established during higher lake elevations and are now showing severe drought stress or mortality as reservoir levels remain low (Arens 2023). The remaining 29 acres of mapped woody riparian habitat were native species vegetation classes, which included coyote willow shrublands, relict spring-supported mixed-deciduous woodlands and shrublands, and Fremont cottonwood (*Populus fremontii*) woodland (NPS 2014). These classes are associated with the major rivers (Colorado, Escalante, and San Juan) and the tributary side canyons (Tendick et al. 2017).

Long-term decreases in water elevations have resulted in standing water and backwater pools in some of the over 90 tributary side canyons of Lake Powell (NPS 2026). Plant surveys were conducted at 20 locations within tributary side canyons along the Escalante River and in exposed areas of Lake Powell bays in 2022 and 2023. At these locations, native shrubs were outcompeting nonnative plants on sites that had been exposed for more than three years, providing diverse ecosystems where natural flow patterns are re-established, including hanging gardens and cryptobiotic crusts (Arens 2023). In these tributary side canyons and along some portions of the major rivers, native woody riparian and marsh vegetation have begun to re-establish. Dominant plants found in areas of canyons include Fremont cottonwood, tamarisk, and cattail (Arens 2023).

In two study areas in the backwaters of Lake Powell, one along the San Juan River and one on the mainstem of the Colorado River, lake water elevations decreased approximately 28 meters between 2009 and 2021 (Kasprak et al. 2026). In these two study areas, a supervised vegetation classification was performed on imagery from 2009, 2014, and 2021, and landcover between these years compared four high-level groupings: water, rock or sand, stressed vegetation, and green vegetation, which included species such as tamarisk, cottonwood, willow, and seepwillow. Green vegetation colonized recently exposed areas, but as water elevations continued to fall, the green vegetation began to show signs of water stress visible in the imagery (such as browning and defoliation).

Two special status plant species are present in the Lake Powell reach and could be affected by operations (**TA 9 Attachment 1**).

TA 9.1.2 Glen Canyon Dam to Lake Mead

Marsh, woody riparian, and upland habitats from Glen Canyon Dam to Lake Mead are influenced by the peak magnitudes, daily fluctuations, and seasonal patterns of river flows. Vegetation composition, structure, distribution, and function are closely tied to ongoing Glen Canyon Dam operations (**Table TA 9-1**; Reclamation 2016; Palmquist et al. 2023).

Hydrologic zone (active channel and active floodplain) was consistently the strongest predictor of vegetation between Glen Canyon Dam and Lake Mead (Palmquist et al. 2023). The active channel, which is inundated by daily fluctuating flows up to 25,000 cubic feet per second (cfs), supports both marsh habitat and woody riparian habitat. Marsh habitat includes species such as bulrushes, rushes (*Juncus* spp.), horsetails (*Equisetum* spp.), and common reed. Woody riparian habitat includes species such as seep willows (*Baccharis* spp.), willow (*Salix* spp.), tamarisk, arrowweed (*Pluchea sericea*), and honey mesquite (*Prosopis glandulosa*). These species occupy the main river margin as well as return-current channels and successional backwaters that are inundated daily for at least part of the year. The active floodplain, inundated by flows up to 45,000 cfs during high-flow experiments (HFEs), supports woody riparian and upland habitat, which includes the woody riparian species as well as upland species, such as mesa dropseed (*Sporobolus flexulosus*), red brome (*Bromus rubens*), and spiny aster (*Chlorocantha spinosa*).

Long-term vegetation monitoring has been conducted since 2014 at two site types: 1) at random locations at sandbars, channel margins, and debris fans and 2) at fixed-site sandbars (Palmquist et al. 2018a). Vegetation dynamics between these two site types vary, including species composition and temporal patterns between years (Palmquist et al. 2023). The fixed-site sandbars are eddy sandbars that have been part of long-term monitoring for geomorphic change and are generally popular camping sites (Palmquist et al. 2018a). At both site types, native species cover and richness were greater than nonnative species cover and richness across all hydrologic zones (Palmquist et al. 2023). The National Park Service has conducted vegetation treatments at a small number of fixed-site sandbars to promote aeolian sand transfer to nearby cultural sites and create campsites for river recreation. These impacts are discussed in **TA 11**, Cultural Resources, and **TA 14,** Recreation.

Marsh and woody riparian vegetation have expanded in this reach since Glen Canyon Dam was completed in 1963 (Sankey et al. 2015). Encroachment of marsh and woody riparian vegetation has decreased the amount of unvegetated areas in the active channel and active floodplain. The greatest area of vegetation expansion between 2002 and 2013 was woody riparian vegetation (tamarisk and seep willow) on sandbars in the active channel (Durning et al. 2021). Encroachment of woody riparian vegetation was most prevalent in the higher elevations of the active channel due to the lower elevation areas being inundated regularly enough to prevent vegetation encroachment. This was despite HFEs in 2004, 2008, and 2012, which aimed to increase unvegetated areas on sandbars for recreation. The effectiveness of HFEs in inhibiting vegetation encroachment is dependent on several factors, including existing vegetation stabilization, geomorphic setting, sandbar elevation, river segment, duration, and flow volume (Mueller et al. 2018; Hazel et al. 2022).

The availability of water at low river elevations (e.g., below 25,000 cfs) from consistent base flows can promote vegetation establishment closer to the river where there were historically bare sand beaches, whereas prolonged periods of peak flow (e.g., above 40,000 cfs during an HFE) may inhibit vegetation establishment closer to the river through scouring action. When inundation frequency increased by five percent or more, vegetation expansion closer to the river was unlikely to occur (Sankey et al. 2015). HFEs may also reduce the narrowing of the riparian zone by inundating the riparian plants that are currently dying back at the upper end of the riparian zone. The Glen Canyon Dam Long-Term Experimental and Management Plan Final Supplemental Environmental Impact Statement (2024 LTEMP SEIS) allows for more spring HFEs to occur in the future, which may

allow more HFEs to occur at the historic timing at which peak flows occurred in this system prior the building of the Glen Canyon Dam (Reclamation 2024) which may have benefits for LTEMP vegetation goals both closer to the river and at the upper end of the riparian zone.

Additional factors related to flow that influence marsh and woody riparian vegetation include characteristics of deposited sediments (e.g., water-holding capacity, aeration, and nutrient levels), depth to groundwater, and anoxia in the root zone. Sand and silt particles are critical for supporting riparian species, and continual erosion may ultimately result in the loss of large stands of riparian plants (Palmquist et al. 2025). The export of sediments (particularly silts, clays, and organic matter) was observed to coarsen substrates, affect nutrient concentrations, and reduce opportunities for subsequent recruitment of tamarisk and native shrubs such as coyote willow (*Salix exigua*) and Emory seep willow (*Baccharis emoryi*; Reclamation 2016).

Twenty special status plant species are present in the Grand Canyon to Lake Mead reach and could be affected by operations (**TA 9 Attachment 1**).

TA 9.1.3 Lake Mead

Similar to Lake Powell, short- and long-term fluctuations in water elevation affect the shoreline vegetation of Lake Mead (**Table TA 9-1**) and are described in detail in Section 3.4 and Section 3.8.1 of the LCR MSCP Habitat Conservation Plan (HCP; Reclamation 2004a) and Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead Final Environmental Impact Statement (2007 Final EIS; Reclamation 2016). The median annual water elevation fluctuation between 2008 and 2025 was approximately 16.19 feet (**Figure TA 9-3**). The drawdown of Lake Mead from 1998 to 2011 reduced the lake's perimeter by more than 400 kilometers (249 miles) and exposed more than 61,776 acres of formerly submerged land (Engel et al. 2014). Water levels have continued to decline since 2012 (see **Figure TA 3-5**, in **TA 3**, Hydrologic Resources), further reducing the lake's perimeter and exposing additional shoreline.

Historically, Lake Mead has undergone large changes in elevation that create and subsequently flood both marsh and woody riparian habitat. From 1990–1996, Lake Mead reservoir levels remained within a relatively narrow range (**Figure TA 3-5, TA 3**, Hydrologic Resources), creating dense stands of willow habitat (approximately 1000 acres; McKernan and Braden 1998). When the water levels rose, then dropped from 2000–2004, a delta at the Virgin River was created that changed habitat conditions, resulting in a subsequent die off of willow (Reclamation 2004b).

Riparian vegetation that does develop within the range of Lake Mead elevation fluctuations is temporary, as fluctuating lake elevations either dewater or inundate these areas through time. Vegetation that develops within the range of short-term (interannual) Lake Mead elevation fluctuations is likely temporary, as frequent inundation and dewatering prevent long-term establishment. Long-term fluctuations allow the establishment of woody riparian vegetation (primarily tamarisk); however, as lake levels continue to fall, tamarisk may begin to show drought stress and mortality when water levels fall below their roots. The decline of tamarisk has been correlated with increased root exposure above the waterline; cover and density of tamarisk were substantially reduced after 6 years of exposure (Engel et al. 2014). Overall, native species cover has

been found to be greatest on surfaces that have been exposed for a longer period of time (Engel et al. 2014).

Sediment deposition and associated vegetation growth at the Lake Mead delta have been ongoing for decades. Historically, both marsh and woody riparian habitats were limited, even along much of the historic Colorado River corridor now inundated by Lake Mead (Engel et al. 2014). The highest concentration of vegetated habitat occurs in the Colorado and Virgin River deltas.

Native vegetation at Lake Mead has also been positively influenced by defoliation from the tamarisk leaf beetle (*Diorhabda* spp.; beetle). Beetles were released along the Virgin River in St. George, Utah, in 2006, and widespread defoliation of tamarisk was first observed in St. George in 2008. The area of tamarisk defoliation on the Virgin River expanded downstream annually, encompassing the entire stretch of the Virgin River to Lake Mead, Nevada, by the end of 2012 (Gonzalez et al. 2020). Arrowweed was found to replace defoliated tamarisk stands as the dominant species along the Virgin River floodplain, increasing native species cover (Gonzalez et al. 2020). Additional control efforts by the National Park Service Lake Mead Inter-Regional Invasive Plant Management team have contributed to controlling tamarisk in the Lake Mead National Recreation Area (NPS 2022).

Twenty-one special status plant species are present in the Lake Mead reach and could be affected by operations (**TA 9 Attachment 1**).

TA 9.1.4 Hoover Dam to SIB

Vegetation in this reach is described in detail in Section 3.4 and Section 3.8.1 of the LCR MSCP HCP and 2007 Final EIS (Reclamation 2004a; Reclamation 2016). The LCR MSCP planning area identifies fourteen land-cover types, including five woody riparian types that are divided into multiple structural types, and the marsh land cover type is divided into seven compositional types based on plant composition and vegetation structure (**Table TA 9-2**). The LCR MSCP HCP further describes the extent of these habitat types by river reach in Table 3-8 and Figures 3-2 through 3-8 (Reclamation 2004a), which are incorporated by reference.

Table TA 9-2
Summary of Vegetation Cover Types from Lake Mead to the SIB

Vegetation Type	Characteristics
Marsh	Cattail/bulrush, little common reed, trees and grasses, and open water
Woody Riparian	Cottonwood-willow, tamarisk, honey mesquite, tamarisk-screwbean mesquite, arrowweed, atriplex
Upland	Desert scrub, agriculture, developed

Source: Reclamation 2004a

Marsh and woody riparian vegetation can be formed through either direct connection to the river and river-dependent groundwater or along reservoirs and impoundments (e.g., Lake Havasu and Mittry Lake). The dams in this reach and their resultant reservoirs and flood control structures, including levees, have altered the extent and quality of marsh and woody riparian vegetation along the river and have converted large areas of riverine habitat to lacustrine habitat behind dams and

diversion facilities (Reclamation 2004a). Habitats at wildlife refuges and management areas, restoration areas, and LCR MSCP conservation areas are dependent on water diversions from the river and existing groundwater levels supported by the river's surface elevation to establish and maintain woody riparian and marsh habitat.

Since the beetle's release in 2006, its range has expanded downstream from Lake Mead along the lower Colorado River, and by 2019, large beetle populations were detected along the Imperial stretch of the lower Colorado River. In 2020, beetles were present, and defoliation was documented in or around all LCR MSCP study areas (Reclamation 2021), and in 2024 beetles have been documented to the SIB (McLeod and Pellegrini 2021; Mahoney et. al 2022; RiversEdge West 2025).

The LCR MSCP HCP and subsequent BOs set habitat creation goals to mitigate for predicted impacts from covered river operations, including flow reductions, water delivery and diversion, changes in point of diversion, generation of hydropower, and operation and maintenance activities in the LCR MSCP planning area (Reclamation 2004a; FWS 2005, 2018, 2022, 2024). A summary of the habitat creation goals and habitat created towards those goals as of 2025 (LCR MSCP 2025) is included as **Table TA 10-1**, in **TA 10**, Terrestrial Wildlife Including Special Status Species. Habitat creation goals assumed the predicted habitat impacts from reductions in flow and changes in points of diversion up to 2.083 maf per year may occur annually until 2055 and would be permanent, even if impacts never actually occur. Habitat would be created to replace it in LCR MSCP conservation areas. This includes a prediction that all existing cottonwood-willow land cover supported by the river and river connected groundwater would be lost due to flow-related covered activities (with the exception of habitat at Topock Marsh and Lake Havasu). Impacts on marsh from flow reductions from 2.083 maf per year to 3 maf per year were predicted to be short term in duration, and the habitat would recover when inundated again (FWS 2024).

Table TA 9-3
Summary of Habitat Creation Goals and Acres Created from Lake Mead to the SIB

Habitat Type	Habitat Creation Goal[1]	Acres Created through 2025[2]
Marsh	568	362
Woody Riparian (cottonwood-willow only)	5,940	4,954
Woody Riparian (honey mesquite only)	1,320	2,046
Woody Riparian (total)	7,260	7,000

Source: [1]Reclamation 2004a; FWS 2005, 2022, 2024; [2]LCR MSCP 2020, 2025

In 2024, the Bureau of Reclamation (Reclamation) contracted RiverRestoration.Org, LLC to map backwater areas (water, marsh, and non-marsh) in the LCR MSCP planning area and to conduct a change analysis between the 2024 effort and a previous 2000 backwater mapping effort. The study found an overall decrease in marsh between Davis Dam and Morelos Dam from 2000 to 2024. The change from marsh to non-marsh was most common and is likely a response to prolonged drought conditions (RiverRestoration.Org 2025). Non-marsh includes woody riparian and upland vegetation types, as well as a broader range of dry and vegetated features that would not typically be considered

"upland" in a geomorphic or ecological sense, such as dry arroyos, cleared ground, and fringe riparian areas.

Nine special status plant species are present in the Hoover Dam to SIB reach and could be influenced by operations (**TA 9 Attachment 1**).

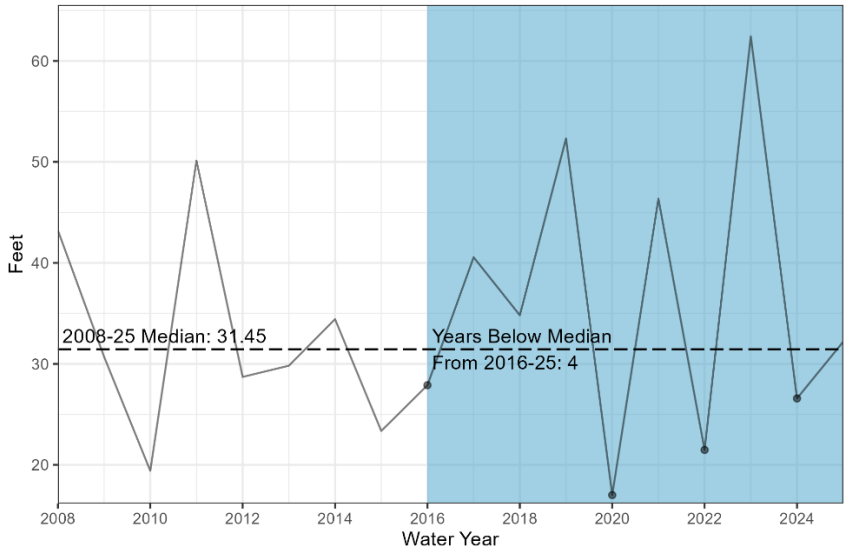
TA 9.2 Environmental Consequences

TA 9.2.1 Methodology

Lake Powell

Ground-based vegetation mapping has not been conducted for all of Lake Powell's shoreline (NPS 2023). To estimate the extent of marsh, woody riparian, and upland habitats within the full pool area of Lake Powell, mapping data from the vegetation classification and mapping project for Glen Canyon National Recreation Area and Rainbow Bridge National Monument was used (NPS 2014; Tendick et al. 2017). This vegetation classification map was created using 1,164 vegetation classification plots, 51 observation points, and aerial photointerpretation using 2009 and 2010 National Agriculture Imagery Program imagery (Tendick et al. 2017). Woody riparian vegetation classes included coyote willow shrublands, Fremont cottonwood woodland, relict spring-supported mixed deciduous woodlands and shrublands, and tamarisk shrublands. The only marsh vegetation class present was spring-supported herbaceous vegetation. As noted in **TA 9.1.1**, since 2011, approximately 59,000 additional acres of formerly submerged land has been exposed in addition to 26,188 acres of terrestrial habitats described in **Table TA 9-2**.

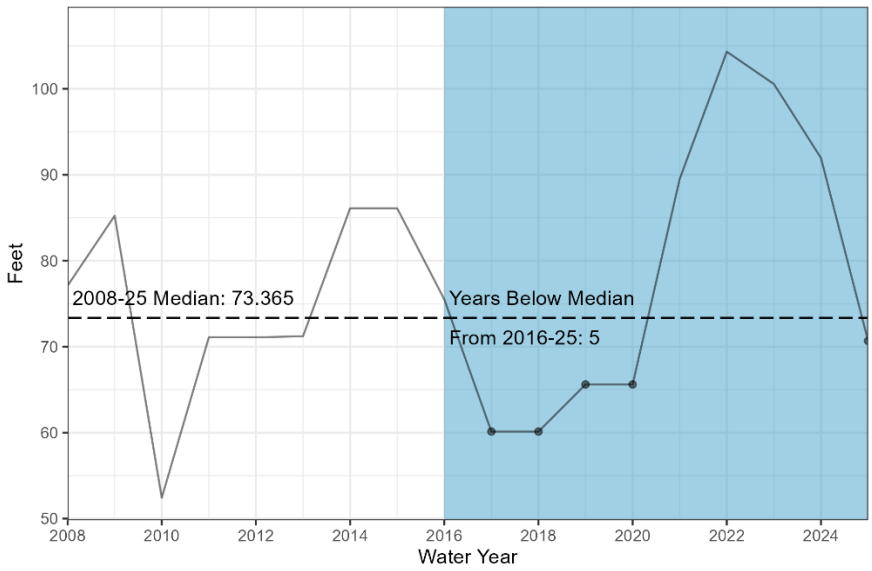
There are no long-term vegetation monitoring datasets available for Lake Powell that would support quantitative habitat modeling for this reach, as was done for the Glen Canyon to Lake Mead section; therefore, a qualitative approach was used to determine the predicted differences in marsh and woody riparian vegetation among the alternatives. As noted in **TA 9.1**, marsh and woody riparian vegetation are affected by water level fluctuations on short (annual) and long (5-year) time scales. Therefore, changes in water elevation over one-year and five-year periods were used as proxies to represent potential changes to marsh and woody riparian vegetation. In the Lake Powell reach, potential changes to marsh and native woody riparian vegetation would be primarily restricted to tributary side canyons and emerging riverine habitats along the major rivers, while non-native woody riparian vegetation (tamarisk) would be expected to continue to establish along the reservoir shoreline.



To determine the changes in water elevation under each alternative, the Colorado River Simulation System model was applied within the Decision Making under Deep Uncertainty (DMDU) framework to show maximum variability within 1 year and over 5 years in robustness heat map figures. A 5-year period was selected to represent longer-term variability in water level fluctuations. The modeled variability from the CRSS model and the DMDU framework were then compared to historic conditions to determine whether variability would remain the same, increase, or decrease for each alternative. For the purposes of this analysis, historic conditions extend from water year (WY) 2008–2025 (the 2007 Interim Guidelines period). Refer to **Section 3.2**, Analysis Methods, for

additional information on DMDU and **Appendix E**, DMDU Overview and Approach, for an overview of how to interpret the DMDU robustness heatmaps.

The DMDU calculations are based on alternatives meeting a preferred minimum performance, defined by a threshold applied to model output values and a frequency over time. If a modeled future meets both the threshold and frequency, it is considered a successful future. For Lake Powell vegetation, the thresholds correspond to the median observed variability in water elevation over 1-year (for marsh vegetation) and 5-year (for woody riparian vegetation), representing historic conditions (**Figure TA 9-1** and **Figure TA 9-2**). The Continued Current Strategies (CCS) Comparative Baseline data displayed on each figure represents the modeled outcome if current management strategies were continued into the future. This information is included for comparative purposes between the alternatives and the modeled future of the analysis area.



Since vegetation can tolerate a range of environmental conditions, failing to meet the threshold criteria once over the full modeling period is not necessarily detrimental to the habitat's establishment or growth over the long-term. Therefore, the analysis focuses on the number of times that the model meets the criteria over a 10-year window for marsh and a rolling 10-year window for woody riparian vegetation.

Figure TA 9-1
Historical Maximum Annual Water Elevation Change in Lake Powell

Note: The median of the maximum annual change was calculated for the 2007 Interim Guidelines period from 2008 to 2025. The number of years in which the maximum annual change was below that median (31.45 feet) in the last 10 years (2016–2025) was counted to determine the historical frequency. The full time period on **Figure TA 9-1** shows the entire 2007 Interim Guidelines period, while the shaded area indicates the last 10 years.

Figure TA 9-2
Historical Maximum 5-year Elevation Change in Lake Powell

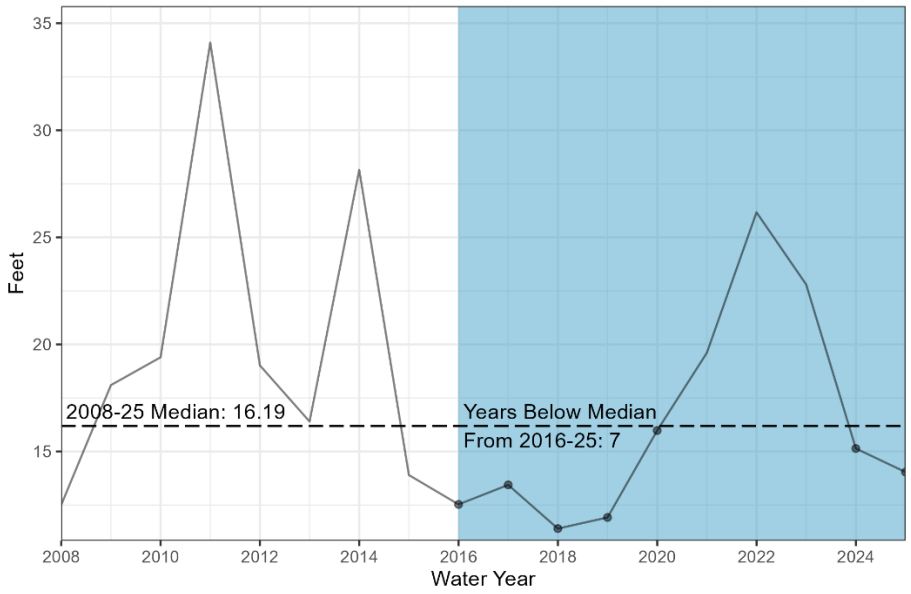
Note: The maximum 5-year elevation change for each year was calculated using the minimum and maximum change from the previous 5 years. For example, the 5-year change for 2021 was calculated by using the minimum and maximums from 2016-2021. The median of the maximum 5-year change was calculated for the 2007 Interim Guidelines period from 2008 to 2025. The number of years in which the maximum 5-year change was below that median (73.365 feet) in the last 10 years (2016–2025) was counted to determine the historical frequency. The full time period on **Figure TA 9-2** shows the entire 2 Interim Guidelines period, while the shaded area indicates the last 10 years.

Glen Canyon Dam to Lake Mead

Riparian species classification data from Durning et al. (2018) was used to quantify existing land cover of marsh, woody riparian, and upland habitats in the analysis area of this reach. Durning et al. used remote sensing to delineate 33 species assemblages, which were consolidated based on the dominant species into marsh, woody riparian, and upland. Using the modeled and estimated 45,000 cfs stage elevation, there are approximately 3,076 acres of terrestrial habitat present in the analysis area (**Table TA 9-1**).

The Grand Canyon Monitoring and Research Center conducted hydrological niche modeling for several species on the fixed site sandbars for each alternative and used these models to estimate the acres of habitat suitability for each species (**Figure TA 9-9** and **Figure TA 9-10**; Butterfield and Palmquist 2026). The data used for this modeling was collected from 2014 to 2019 (Palmquist et al. 2018a) and can be accessed in the associated data release (Palmquist et al. 2022). In addition to habitat suitability, changes to native species richness (**Figure TA 9-12**), proportion native cover (**Figure TA 9-13**), and total vegetation cover (**Figure TA 9-14**) were estimated by combining the modeled habitat suitability. The hydrological niche modeling includes HFEs. For a detailed analysis of frequency and duration of HFEs under each alternative, see **TA 5**, Geomorphology and Sediment Resources.

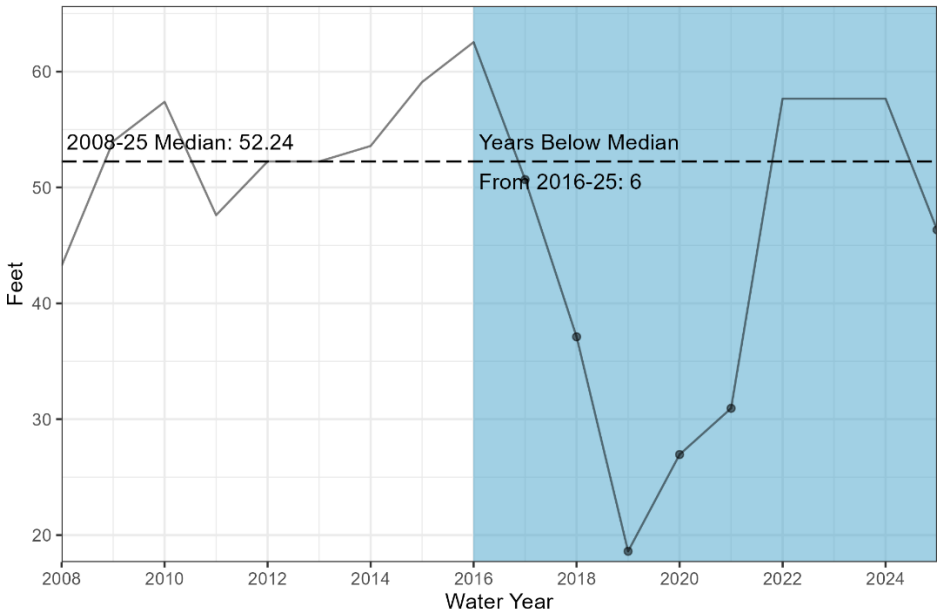
Figures presented for this reach are conditional box plots. Refer to **Section 3.2**, Analysis Methods, for additional information on DMDU and **Appendix E**, DMDU Overview and Approach, for an



overview of how to interpret the DMDU conditional box plots. The hydrological niche modeling results used to create these figures can be accessed in the associated data release (Butterfield and Palmquist 2026). Habitat suitability is modeled in **Figure TA 9-9** and **Figure TA 9-10**, species included were consolidated by marsh (*Schoenoplectus* spp., *Juncu*s spp., *Equisetum arvense*, and *Phragmites australis*; **Figure TA 9-9**) and woody riparian (*Baccharis* spp., *Pluchea sericea*, *Prosopis glandulosa*, and *Salix exigua*; **Figure TA 9-10**). Upland species were not modeled because upland habitat is considered ubiquitous within and surrounding the analysis area (**Table TA 9-1**). Since multiple species can have similar habitat suitability characteristics, the acres presented in **Figure TA 9-9** and **Figure TA 9-10** are likely an overestimate and should be used to compare alternatives relatively in terms of increasing or decreasing habitat rather than as a prediction of actual acres under each alternative. The dashed lines included in **Figure TA 9-9** through **Figure TA 9-14** are reference lines to the 50th percentile of the modeled 'historical' period, which were modeled using 2000-2025 hydrology under CCS Comparative Baseline using a dry-initial condition (see **Section 3.2.6**, Decision Making under Deep Uncertainty for an explanation of initial conditions).

Lake Mead

In 2018, Reclamation contracted Sound Science, LLC, to classify and map riparian vegetation along the lower Colorado River, including Lake Mead (Sound Science 2025). Publicly available aerial imagery and Google Earth Engine were used to classify the imagery into eight classes: Cottonwood/Willow, Tamarisk, Mesquite, Marsh, other (sparsely vegetated), other (densely vegetated), water, and bare ground. Agricultural and developed areas were excluded from this classification. These classes were consolidated into woody riparian (Cottonwood/Willow, Tamarisk, Mesquite, other [densely vegetated]), marsh, and upland (other [sparsely vegetated], bare ground). Within the full pool area of Lake Mead, there are approximately 71,250 acres of terrestrial habitats present (**Table TA 9-1**).



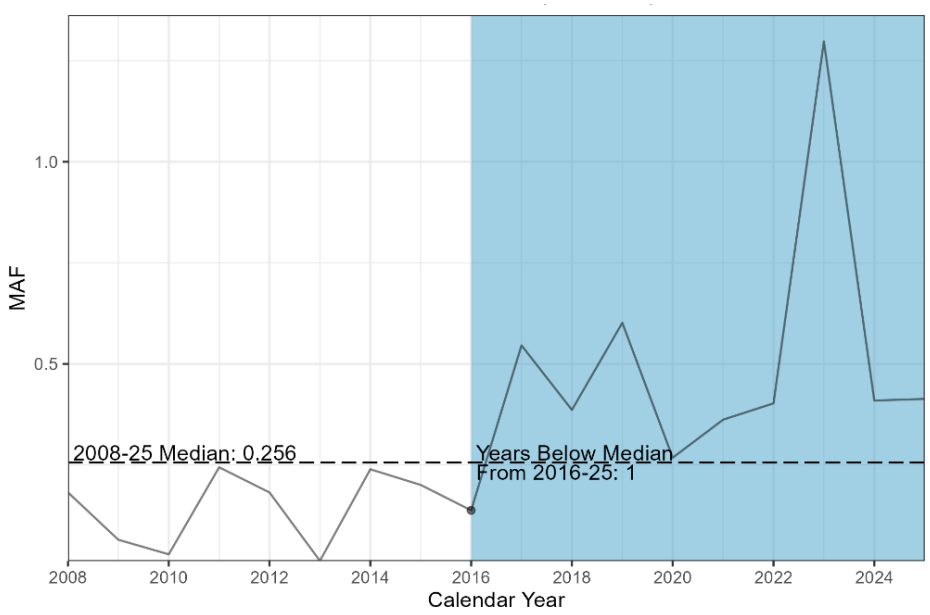
Similar to Lake Powell, changes in water elevation from historical conditions were used as a proxy to determine potential impacts on marsh and woody riparian vegetation under each alternative (**Figure TA 9-3** and **Figure TA 9-4**). The same methods for Lake Mead were used as described for Lake Powell.

Figure TA 9-3
Historical Maximum Annual Water Elevation Change in Lake Mead

Note: The median of the maximum annual change was calculated for the 2007 Interim Guidelines period from 2008 to 2025. The number of years where the max annual change was below that median (16.19 feet) in the last 10 years (2016–2025) was counted to determine the historical frequency. The full time period on **Figure TA 9-3** shows the entire Interim Guidelines period, while the shaded area indicates the last 10 years.

Figure TA 9-4
Historical Maximum 5-year Elevation Change in Lake Mead

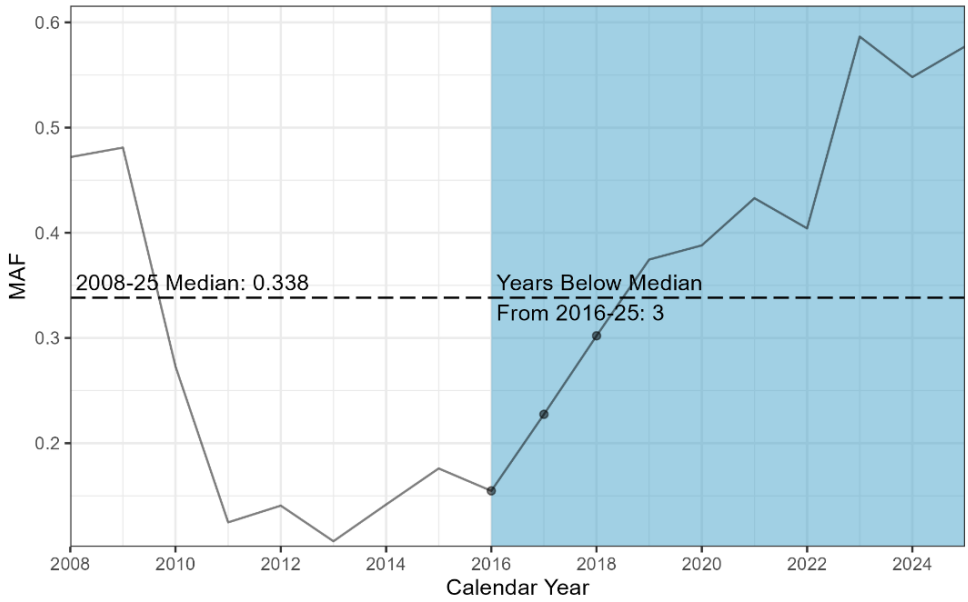
Note: The maximum 5-year elevation change for each year was calculated using the minimum and maximum change from the previous 5 years. For example, the 5-year change for 2021 was calculated by using the minimum and maximums from 2016 to 2021. The median of the maximum 5-year change was calculated for the 2007 Interim Guidelines period from 2008 to 2025. The number of years where the



maximum 5-year change was below that median (52.24 feet) in the last 10 years (2016–2025) was counted to determine the historical frequency. The full time period on **Figure TA 9-4** shows the entire Interim Guidelines period, while the shaded area indicates the last 10 years.

Hoover Dam to Southerly International Boundary

The Sound Science, LLC riparian vegetation mapping effort described above under Lake Mead also includes the analysis areas within the Hoover Dam to SIB reach (Sound Science 2025). Within the full pool of Lake Mohave and Lake Havasu, and the historical floodplain of the Colorado River from Hoover Dam to the SIB, there are approximately 55,121 acres of terrestrial habitat (**Table TA 9-1**).



Similar to Lake Powell and Lake Mead, changes in water elevation were used as a proxy to determine potential impacts on marsh and woody riparian vegetation under each alternative. However, for this reach, water releases were used to represent changes from historic conditions rather than water elevation (**Figure TA 9-5** and **Figure TA 9-6**). Releases from Hoover Dam, Davis Dam, and Parker Dam were modeled, as releases from these dams determine the amount of water available downstream. Davis Dam and Parker Dam were found to have similar trends as Hoover Dam; therefore, only Hoover Dam results are discussed in detail (see **TA 9 Attachment 2** for Davis and Parker Dam results). The impacts as described in the Hoover to SIB section apply to the entire reach.

Figure TA 9-5
Historical Change in Annual Water Releases from Hoover Dam

Note: The median annual change was calculated from 2008 to 2025, whereas the number of years in which the change was below that median was calculated for the prior 10 years (shaded).

Figure TA 9-6
Historical Change in the Average 5-year Water Releases from Hoover Dam

Note: The median 5-year water release was calculated from 2008 to 2025, whereas the number of years in which the change was below that median was calculated for the prior 10 years (shaded).

Impact Analysis Area

Lake Powell

The Lake Powell reach includes Lake Powell up to full pool (water surface elevation 3,700 feet).

Glen Canyon Dam to Lake Mead

The Glen Canyon Dam to Lake Mead reach extends from Glen Canyon Dam (river mile [RM] -15.6) to RM 240. This reach includes the Colorado River through the Grand Canyon and ends where Lake Mead at full pool occurs at RM 240. The analysis area for this reach extends to the 45,000 cfs modeled stage elevation, corresponding to the maximum controlled flood releases under the current HFE protocol, and is considered the active floodplain of the Colorado River in this reach (LTEMP 2016). The modeled 45,000 cfs stage elevation from Magirl et al. (2008) was used for Lees Ferry (RM 0) to Diamond Creek (RM 226) and was estimated using the maximum height of the modeled stage elevation for RM 15.6 to RM 0 and RM 226 to RM 240.

Riparian vegetation composition changes from Glen Canyon Dam to Lake Mead and is related to decreasing elevation, increases in temperature, and shifts in precipitation (Palmquist et al. 2018b). The section from Glen Canyon Dam to Lake Mead is divided into three sub-reaches to account for these vegetation community changes: Marble Canyon (RM -15.6 to RM 60), Eastern Grand Canyon (RM 60 to RM 161), and Western Grand Canyon (RM 161 to RM 240).

Lake Mead

The Lake Mead reach extends from RM 240 in Grand Canyon to Hoover Dam. The analysis area for this reach includes full pool of Lake Mead (water surface elevation 1,229 feet).

Hoover Dam to SIB

The Hoover Dam to SIB reach is aligned with the LCR MSCP planning area. As described in **TA 8**, Biological Resources – Fish and Other Aquatic Species, there are seven reaches within the LCR MSCP planning area. For vegetation analysis, the analysis area includes LCR MSCP reaches 2-7 (Reclamation 2004a). Reach 1 in the LCR MSCP planning area includes Lake Mead up to full pool, which is addressed in the section above under Lake Mead. The analysis area includes the full pool of Lake Mohave and Lake Havasu and the historical floodplain of the Colorado River.

Assumptions

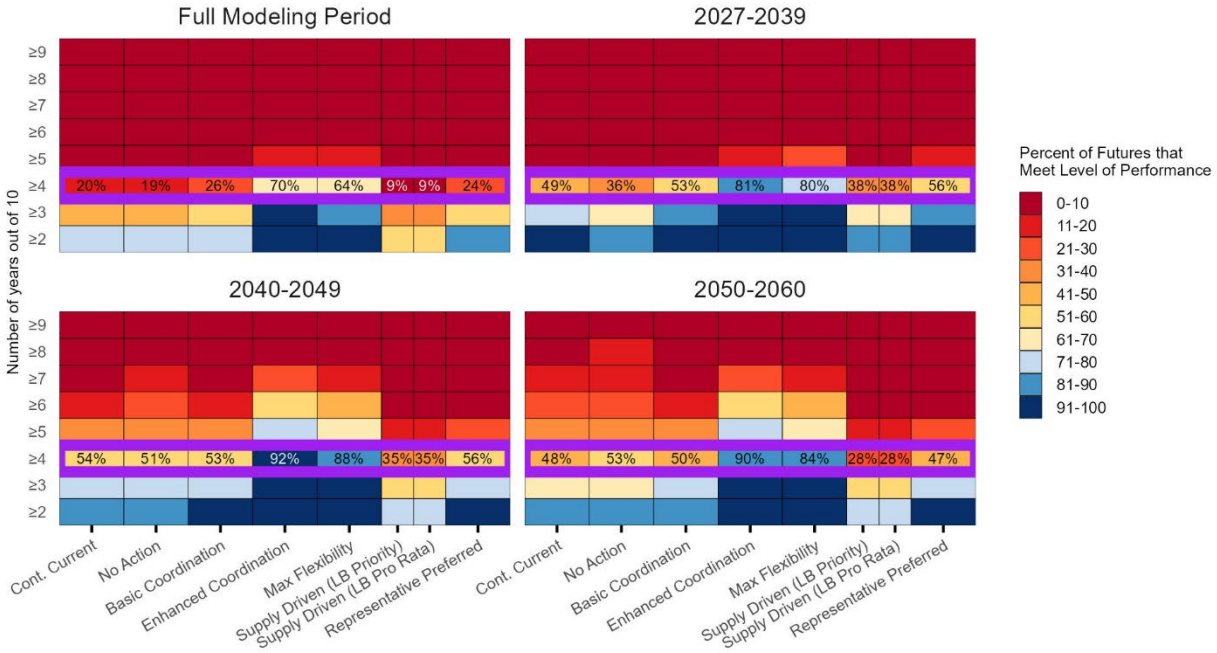
- A change of 10 percent between/among alternatives is considered a notable difference for the DMDU analysis.
- Upland, marsh, and woody riparian vegetation are suitable representatives for the major vegetation types found throughout the analysis area.
- A change in water elevations or releases greater than what has been observed over the past 10 years would result in changes to marsh and woody riparian vegetation compared to existing conditions.

Impact Indicators

- A change in the median and interquartile ranges from modeled historic conditions (Glen Canyon Dam to Lake Mead reach).
- Changes in water fluctuations within a single year compared to historic conditions (Lake Powell, Lake Mead, and Hoover Dam to SIB reaches).
- Changes in water fluctuations in the preceding 5 years compared to historic conditions (Lake Powell, Lake Mead, and Hoover Dam to SIB reaches).

TA 9.2.2 Issue 1: How would changes in the management of the Colorado River impact vegetation, including for special status species

Lake Powell



Marsh Vegetation

As described above in **TA 9.2.1**, there are no long-term vegetation monitoring datasets available for Lake Powell that would support quantitative habitat modeling, therefore, changes in water elevation over one-year and five-year periods were used as proxies to represent potential changes to marsh and woody riparian vegetation. The median of the maximum annual change in water surface elevation from water year (WY) 2008–2025 was 31.45 feet (**Figure TA 9-1**). Over the past 10 years (WY 2016–2025) the maximum annual change in water surface elevation was less than 31.45 feet in 4 of 10 years (**Figure TA 9-1**). These data were used to characterize the existing variability in Lake Powell that has led to the current extent of marsh vegetation in the Lake Powell analysis area and are collectively referred to as historic conditions. As described above in **TA 9.1.1** and **TA 9.2.1**, marsh vegetation in Lake Powell is primarily restricted to tributary side canyons and emerging riverine habitats along the major rivers, so potential changes to marsh vegetation would be expected to be limited to those areas. The minimum level of performance was established based on these historic conditions. Therefore, to meet the minimum level of performance, an alternative must have a

maximum annual change in water surface elevation of less than 31.45 feet in 4 or more years out of 10. The more times an alternative meets that criterion, the higher the percentage in each respective box. The alternative with the highest percentage within the greater than or equal to 4 years row is the alternative most similar to historic conditions. **Figure TA 9-7** compares the similarity of each alternative to the historic maximum annual change in Lake Powell elevation.

The other rows outside the greater than or equal to 4 years row demonstrate how many times the alternative had a maximum annual change in water surface elevation of less than 31.45 feet for X number of years, where the value of X varies by row (displayed on the y-axis). This information demonstrates whether the alternatives would meet the criterion for more or fewer years compared to historic conditions. For comparative purposes, each alternative is compared relative to historic conditions, which are outlined in the greater than or equal to 4 years row for reference. The percentages are provided in the greater than or equal to 4 years row to differentiate between alternatives, with a difference greater than 10 percent considered notable.

Figure TA 9-7
Lake Powell Marsh Riparian Vegetation: Robustness.
Percent of futures in which the maximum annual change in Lake Powell elevation is less than 31.45 feet in the number of years specified by each row during any 10-year period

The maximum annual change in water elevation for marsh over any 10-year period was calculated using historical data for the first 9 years of modeling on a rolling basis. After the 9th year, all data used to calculate the max annual change in water elevation included only modeled outputs. Since the years 2016 through 2019 included 3 years where the elevation change was greater than 31.45 feet (**Figure TA 9-1**), the early years of the first decade (2026–2029) had limited ability to reach the desired level of performance, as they could only fail one more time over the decade before failing to

reach the desired level of performance. Once the years 2016 through 2019 were excluded (2030 and beyond), it became easier for the modeled alternatives to meet the desired level of performance.

For all alternatives except for the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative, increased variability in the first decade (2027–2039; **Figure TA 9-7**) compared to modeled historic conditions, indicated by a lower percentage of futures meeting the level of performance, would result in changes in marsh vegetation. Whether an area experiences an increase or a decrease in marsh habitat in response to changed conditions is mostly dependent on local topography, but generally, an increase in variability is expected to result in a decrease in marsh vegetation due to more frequent dewatering and inundation. In the first decade, the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative are the most robust, meeting the minimum level of performance in 81 percent and 80 percent of futures, respectively. The CCS Comparative Baseline and No Action Alternative meet it in 49 percent and 36 percent of futures, respectively.

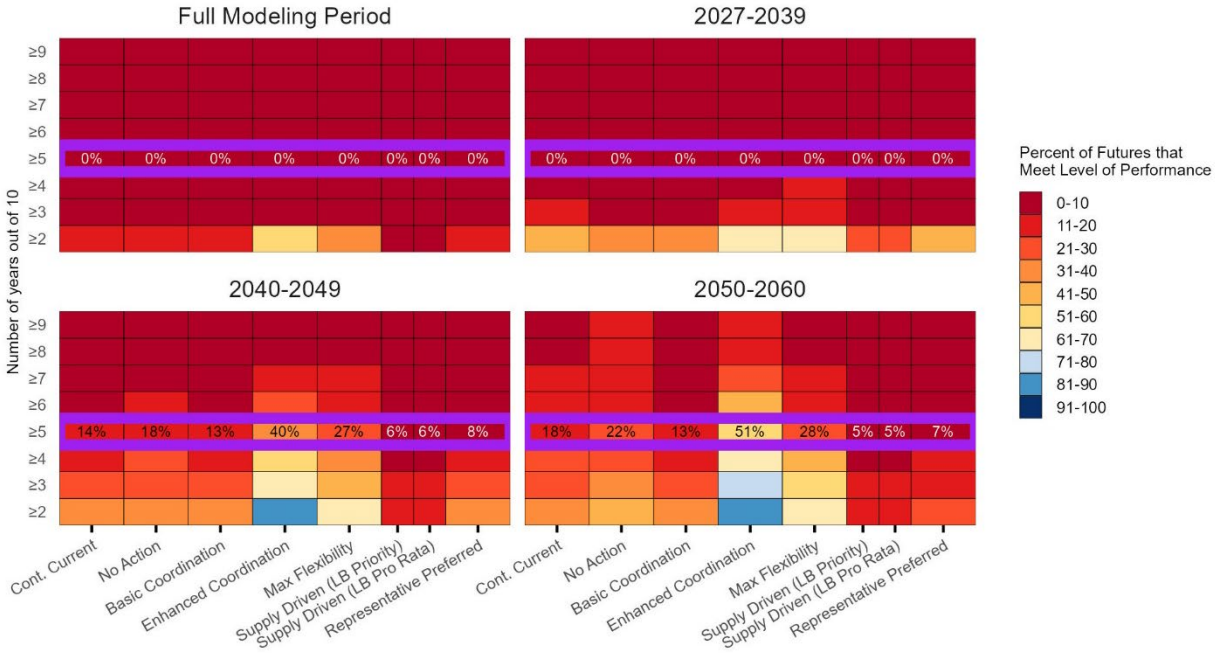
For alternatives with increased variability, in the first decade, cover of prickly Russian thistle may increase due to the increased area of upland habitat created during water elevation fluctuations. Cover of prickly Russian thistle would be expected to decrease in the later decades if variability also decreases, indicated by a higher percentage of futures meeting the level of performance, reducing areas vulnerable to invasive species establishment on an annual basis. Native vegetation can re-establish over time, particularly in areas exposed for more than 3 years (Arens 2023).

In the later decades (2040–2049 and 2050–2060; **Figure TA 9-7**), the Enhanced Coordination Alternative is the most robust, meeting the minimum level of performance in 92 percent and 90 percent of futures, respectively. The CCS Comparative Baseline and No Action Alternative meet it in 54 percent and 48 percent, and 51 percent and 53 percent of futures, respectively. As variability becomes closer to historic conditions for Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative (as indicated by a higher percentage of futures meeting the level of performance), marsh vegetation may re-establish to a similar historical extent under those alternatives.

For the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative under the Critically Dry Flow Category Lake Powell has a modeled WY minimum median elevation of approximately 3,520 feet and 3,512 feet above mean sea level, respectively (see **TA 3**, Hydrologic Resources, **Table TA 3-3**), which are 38 and 46 feet below, respectively, the minimum 2024 water elevation of 3,558 feet (see **TA 3**, Hydrologic Resources, **Figure TA 3-1**). Under the Average Flow Category, Lake Powell has a WY modeled minimum median elevation of approximately 3,613 and 3,605 feet for the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative, respectively (see **TA 3**, Hydrologic Resources, **Table TA 3-4**), which are approximately 55 and 47 feet higher than the minimum 2024 water elevation. This suggests higher modeled elevations under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative under all but the driest hydrologic conditions. If water elevations gradually rise with similar levels of variability to historic conditions (**Figure TA 9-7**), marsh vegetation is expected to continue to re-establish along the new water line over time. If water elevations rise, some of the side

canyons that were exposed as Lake Powell receded may reflood, inundating native plant communities that had reemerged.

If water elevations stay the same or gradually fall with similar variability to historic conditions (**Figure TA 9-7**), marsh vegetation may re-establish to a similar extent along the new water line over time. Under these alternatives, plant communities in side canyons would remain exposed.



Whether water elevations rise, fall, or remain the same, if variability resembles historic conditions under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative in the later decades (**Figure TA 9-7**), marsh vegetation is expected to continue to re-establish along the new water line over time. For alternatives that have more variability than historic conditions (**Figure TA 9-7**), marsh vegetation may re-establish to a smaller extent along the new water line over time. Where variability eliminates or prevents the establishment of marsh habitat, woody riparian or upland habitat may become the dominant habitat type.

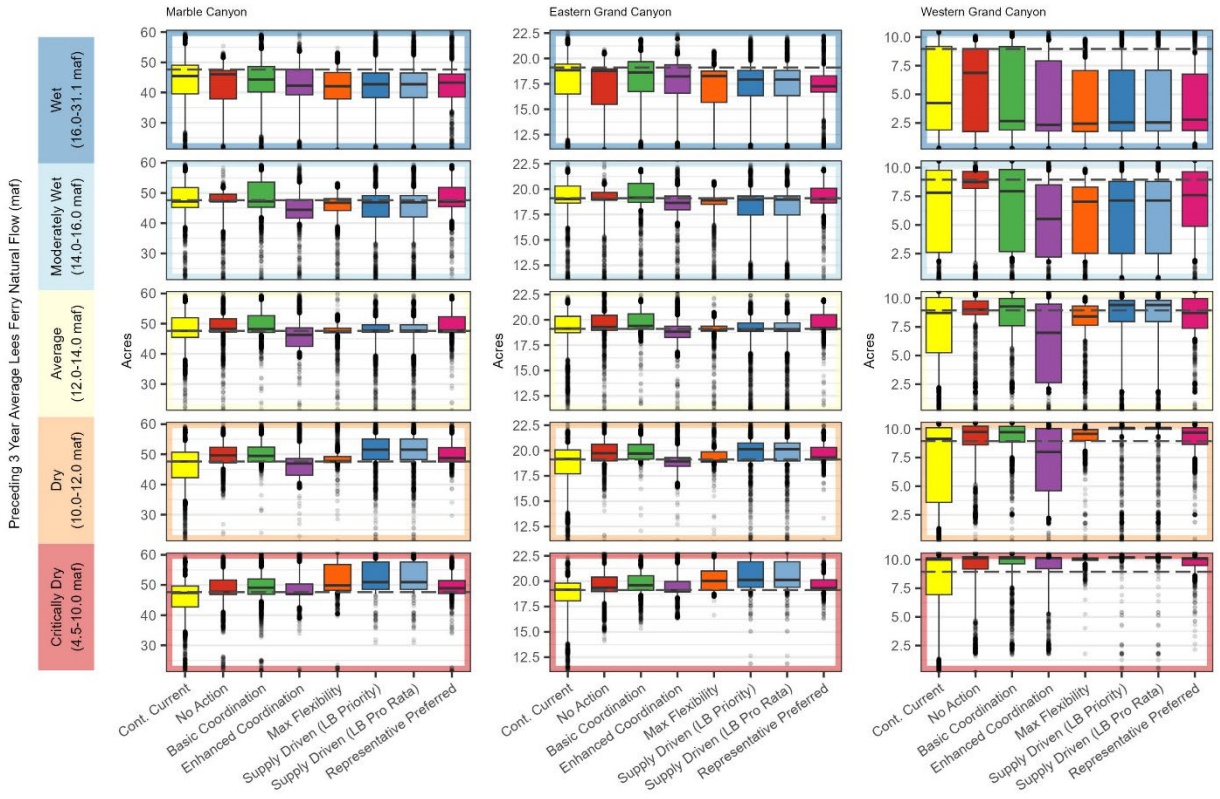
Woody Riparian Vegetation

The median of the maximum 5-year change in water surface elevation from WY 2008–2025 was 73.365 feet (**Figure TA 9-8**). Over the past 10 years (WY 2016–2025), the maximum 5-year change was less than 75.51 feet in 5 of 10 years (**Figure TA 9-8**). These data were used to characterize the existing variability that has led to the current extent of woody riparian vegetation in the Lake Powell analysis area and are collectively referred to as historic conditions. As described above in **TA 9.1.1** and **TA 9.2.1**, native woody riparian vegetation is primarily restricted to tributary side canyons and emerging riverine habitats along the major rivers, while non-native woody riparian vegetation (tamarisk) is abundant in these areas as well as the reservoir shoreline. Potential changes to woody riparian vegetation would be expected to occur in both of these areas, depending on species. The minimum level of performance was established based on these historic conditions. Therefore, to meet the minimum level of performance, an alternative must have a maximum 5-year change in water surface elevation of less than 73.365 feet in 5 or more years during every 10-year period. The more times an alternative meets that criterion, the higher the percentage in each respective box. The alternative with the highest percentage within the greater than or equal to 5 years row is the alternative most similar to historic conditions. **Figure TA 9-8** compares the similarity of each alternative to the historic maximum 5-year change in Lake Powell elevation.

The trends and types of impacts on woody riparian vegetation are the same as those described for marsh vegetation for Lake Powell (**Figure TA 9-7** and **Figure TA 9-8**). Similar to marsh vegetation, the historical trend for the maximum 5-year change includes historical data for the first 9 years, which influenced the ability for the model to reach the level of performance in the first decade (2027–2039). From 2021 to 2024, all 4 years were over the median of 73.365 (**Figure TA 9-8**). Once the years 2021–2024 were no longer a part of the calculation (2034 and beyond), it became easier for the model to hit the desired level of performance, which is reflected in the second and third decades of modeling having higher percentages. In the first decade, all alternatives are equally non-robust, meeting the minimum level of performance in 0 percent of futures.

Figure TA 9-8
Lake Powell Woody Riparian Vegetation: Robustness.
Percent of futures in which the maximum 5-year change in in Lake Powell elevation is less than 73.365 feet in the number of years specified by each row during any 10-year period

In the later decades, the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative are the most robust, meeting the minimum level of performance in 40 percent and 51 percent, and 27 percent and 28 percent of futures, respectively. The CCS Comparative Baseline and No Action Alternative meet the minimum level of performance in 14 percent and 18 percent, and 18 percent and 22 percent of futures, respectively. The Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative would have vegetation most similar to historic conditions in the later decades (2040–2060 and 2050–2060; **Figure TA 9-8**).



Also similar to marsh vegetation, whether water elevations rise, fall, or stay the same, if there are similar levels of variability to historic conditions under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative in the later decades (**Figure TA 9-8**), then woody riparian vegetation is expected to reestablish along the new water line over time. For alternatives that have more variability than historic conditions (**Figure TA 9-8**), woody riparian vegetation may re-establish to a smaller extent along the new water line over time. Where variability eliminates or prevents the establishment of woody riparian habitat, upland habitat may become the dominant habitat type. Whether an area experiences an increase or a decrease in woody riparian habitat in response to changed conditions is largely dependent on local topography, but generally an increase in variability is expected to result in a decrease in woody riparian vegetation.

Glen Canyon Dam to Lake Mead

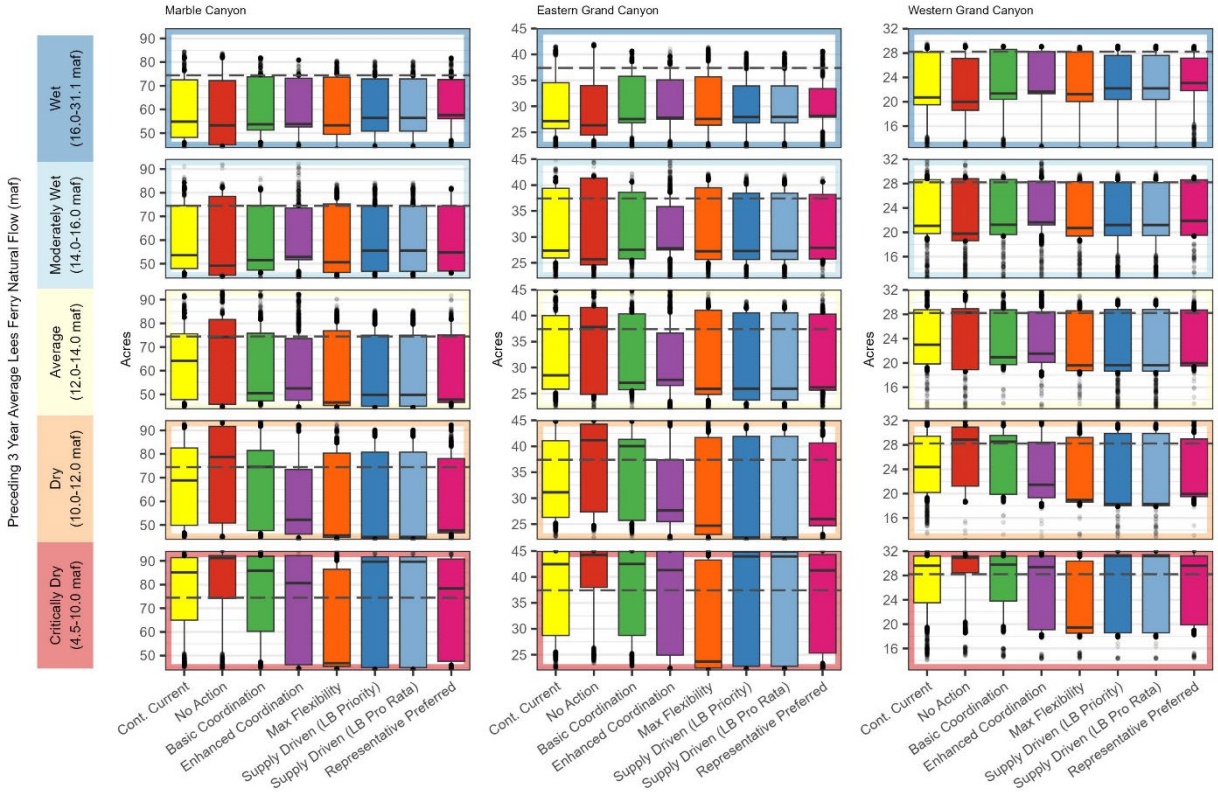
Suitable Habitat Area

Marsh. Figure TA 9-9 compares the amount of modeled marsh habitat for each alternative by Grand Canyon sub-reach. Marsh vegetation includes bulrushes, rushes, field horsetail (*Equisetum arvense*), and common reed. Since multiple marsh vegetation species can have similar habitat suitability characteristics, the acres presented in **Figure TA 9-9** are likely an overestimate and should be used to compare alternatives in terms of relative increases or decreases in suitable habitat area rather than as a prediction of actual acres under each alternative. The hydrological niche modeling data used to create **Figure TA 9-9** can be found in Butterfield and Palmquist (2026).

Figure TA 9-9
Suitable Modeled Marsh Habitat for each Alternative by Sub-reach

In Marble Canyon and Eastern Grand Canyon, under the Average Flow Category, Moderately Wet Flow Category, and Dry Flow Category, the medians are near modeled historic conditions (dashed line) and the interquartile ranges are relatively restricted and overlap the modeled historic conditions (**Figure TA 9-9**) for all alternatives, indicating that the amount of habitat suitable for marsh species would likely be similar to historic conditions under these categories. Under the Critically Dry Flow Category, the Maximum Operational Flexibility Alternative, Supply Driven Alternative (both Lower Basin Priority [LB Priority] and Lower Basin Pro Rata [LB Pro Rata] approaches), and Representative Preferred Alternative medians and interquartile ranges are completely above modeled historic conditions (dashed line), indicating that suitable habitat for marsh species may increase

under the Critically Dry Flow Category for those alternatives. Under the Wet Flow Category, the medians and interquartile ranges are mostly below modeled historic conditions (dashed line) for all alternatives, suggesting there would likely be less suitable marsh habitat under all alternatives.



Further downstream in Western Grand Canyon, wider interquartile ranges suggest greater uncertainty in the amount of modeled suitable marsh habitat. The general trends follow that of Marble Canyon and Eastern Grand Canyon, but with more differentiation in the Moderately Wet and Dry Flow Categories; there would likely be similar levels of marsh habitat under the Average Flow Category, less marsh habitat under the Wet and Moderate Wet Flow Categories, and more marsh habitat under the Dry and Critically Dry Flow Categories. Under the Average, Dry, and Critically Dry Flow Categories, the CCS Comparative Baseline and Enhanced Coordination Alternative have wider interquartile ranges than the other alternatives, suggesting greater uncertainty.

The decrease in suitable habitat for marsh species under the Wet Flow Category for all sub-reaches and all alternatives may be because higher water levels may reduce the overall available terrestrial habitat in the active channel of the river (Sankey et al. 2015). The similarity or increase in suitable habitat for marsh species under the Dry and Critically Dry Flow Categories for all sub-reaches and all alternatives may be because decreasing water levels increase the amount of exposed shoreline habitat.

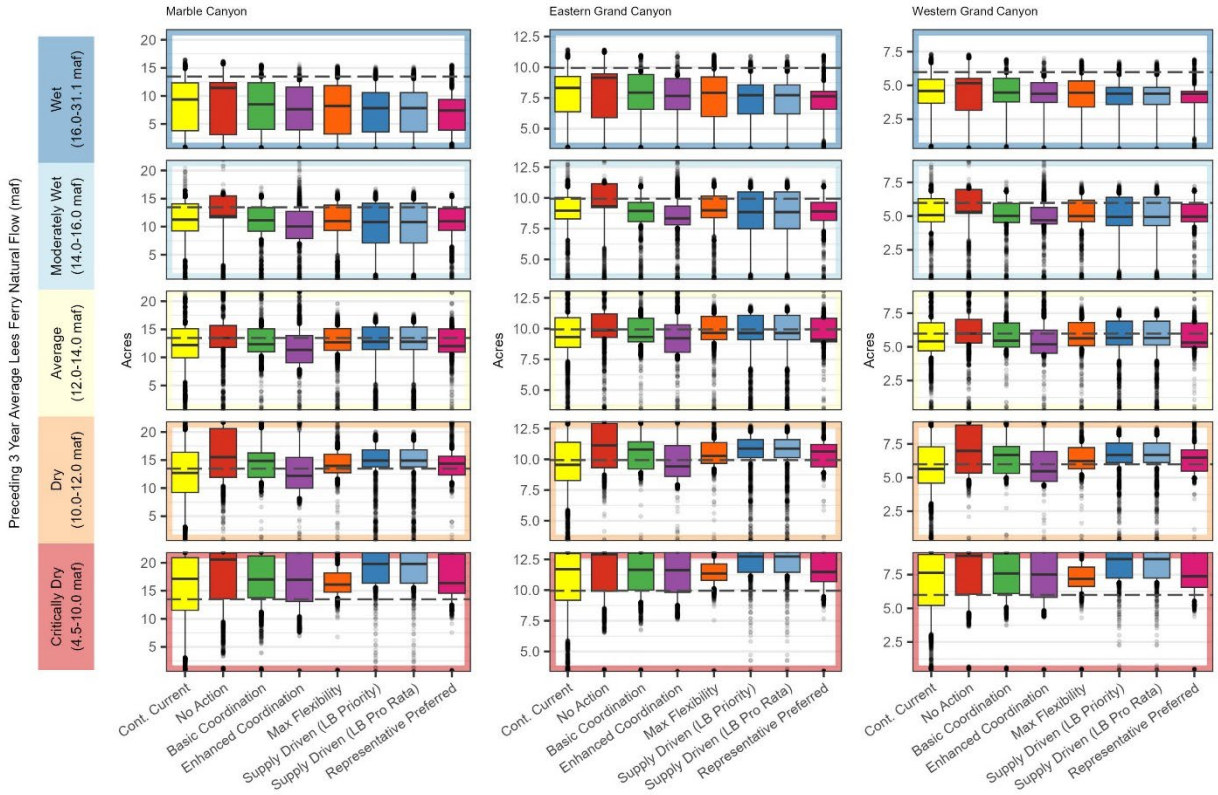
Woody Riparian. Figure TA 9-10 compares the amount of modeled woody riparian habitat for each alternative by Grand Canyon sub-reach. Woody riparian vegetation includes seep willow, arrowweed, honey mesquite, and coyote willow. Since multiple woody riparian species can have similar habitat suitability characteristics, the acres presented in **Figure TA 9-10** are likely an overestimate and should be used to compare alternatives in terms of relative increases or decreases in suitable habitat area rather than as a prediction of actual acres under each alternative. The hydrological niche modeling data used to create **Figure TA 9-10** can be found in Butterfield and Palmquist (2026).

Across all three sub-reaches, similar interquartile ranges would suggest that woody riparian suitable habitat would respond in a similar way across all alternatives under each flow category. However, the wide interquartile ranges suggest a high amount of uncertainty about how vegetation would respond under each of the modeled conditions and alternatives in all three sub-reaches.

Figure TA 9-10
Suitable Modeled Woody Riparian Habitat for each Alternative by Sub-reach

Similar to marsh habitat, under the Average, Moderately Wet Flow, Wet Flow, and Dry Flow Categories, there is less suitable habitat for woody riparian species, as indicated by the median remaining below the modeled historic conditions under all sub-reaches and across all alternatives except for the No Action Alternative and Enhanced Coordination Alternative in the Dry Flow Category. For some alternatives, the interquartile range expands above the modeled historic conditions (dashed line), indicating uncertainty about how vegetation would respond. Under the Critically Dry Flow Category, the medians are typically above the modeled historic conditions (dashed line), indicating a likely increase in suitable habitat for woody riparian vegetation under all alternatives except for the Maximum Flexibility Alternative. However, the large interquartile ranges extend far above as well as below the modeled historic conditions (dashed line) under all reaches and for all alternatives except for the No Action Alternative, indicating the variability is too high to predict whether there would be more or less suitable habitat for woody riparian species under these alternatives. The No Action Alternative remains above the modeled historic conditions for all three sub-reaches. This may be because under the No Action Alternative, there would be less water available compared to the other alternatives, and thus more exposed shoreline that can support woody riparian species.

Similar to marsh habitat, the decrease in suitable habitat for woody riparian species under the Moderately Wet Flow Category and Wet Flow Category for all sub-reaches and all alternatives may be because higher water levels reduce the overall available terrestrial habitat (Sankey et al. 2015).



Whereas suitable habitat for woody riparian species may increase under the Critically Dry Flow Category, this expansion would occur near river level on areas recently exposed by lower water levels. Suitable habitat for both woody riparian and marsh species may overlap in these recently exposed areas, where these habitat types would compete near the river. In areas near the top of the active floodplain, decreasing water levels may provide an opportunity for an increase in upland habitat due to disconnection from the river.

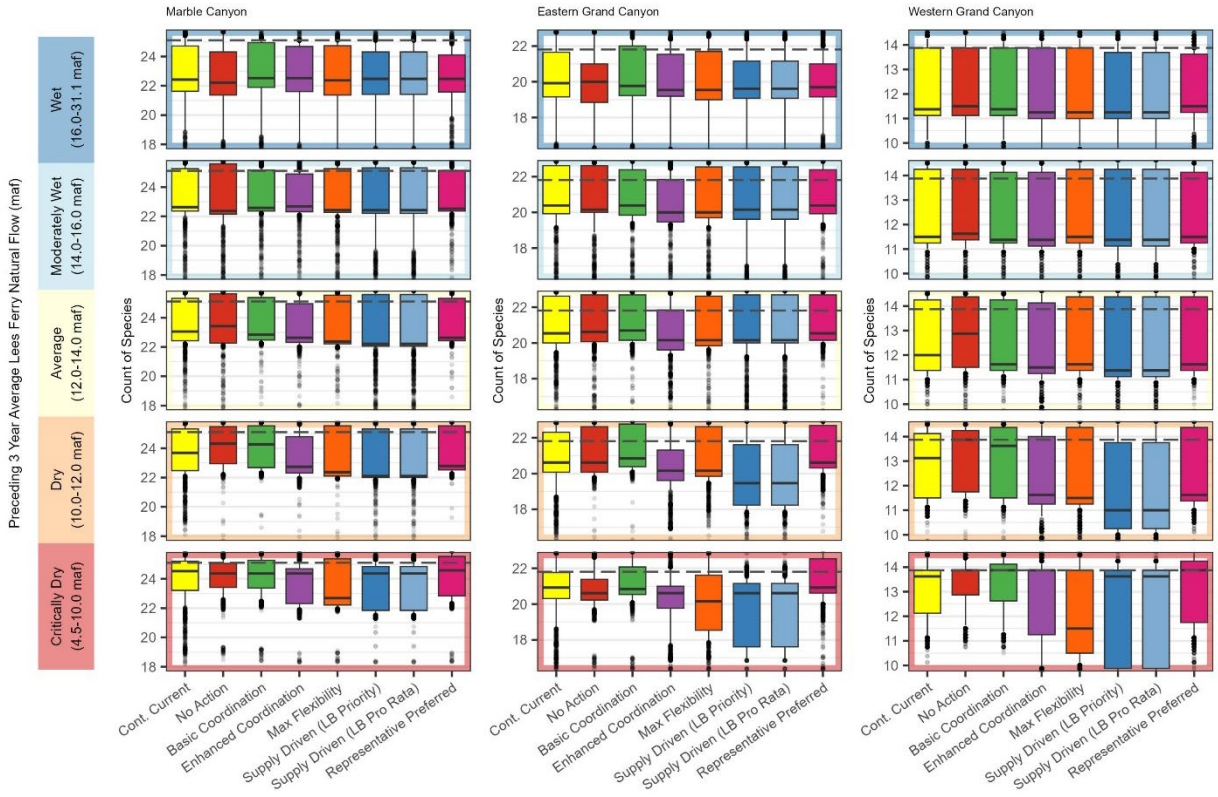
Arrowweed

Figure TA 9-11 compares arrowweed suitable habitat under each alternative by Grand Canyon sub-reach. Across all three reaches, all alternatives show similar trends: the generally similar and overlapping interquartile ranges suggest arrowweed would respond in a similar way across all alternatives. The hydrological niche modeling data used to estimate changes to annual total vegetation cover and create **Figure TA 9-11** can be found in Butterfield and Palmquist (2026).

Under the Average Flow Category, across all three sub-reaches, the median for each alternative overlaps or nearly overlaps the modeled historic conditions (dashed line), and the interquartile ranges are relatively small. This indicates that arrowweed suitable habitat may be similar to historic conditions under the Average Flow Category.

Figure TA 9-11
Suitable Modeled Arrowweed (Pluchea sericea) Habitat for each Alternative by Sub-reach

Across all three sub-reaches, under the Wet Flow Category and Moderately Wet Flow Category, the median and interquartile ranges are below the modeled historic conditions (dashed line) for all alternatives except for the interquartile ranges of the No Action Alternative and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) in the Moderately Wet Flow Category. This suggests that there would be less arrowweed suitable habitat under the Wet and Moderately Wet Flow Categories under all sub-reaches and all alternatives. Under the Dry Flow Category, the median and interquartile ranges are above historic conditions (dashed line), for all alternatives except the CCS Comparative Baseline and Enhanced Coordination Alternatives. Under the Critically Dry Flow Category, the median and interquartile ranges are above the modeled historic conditions (dashed line) for all sub-reaches and all alternatives except for the CCS Comparative Baseline, although the median remains above historic conditions. This indicates that there may be more arrowweed suitable habitat under the Critically Dry Flow Category for all alternatives across all sub-reaches.



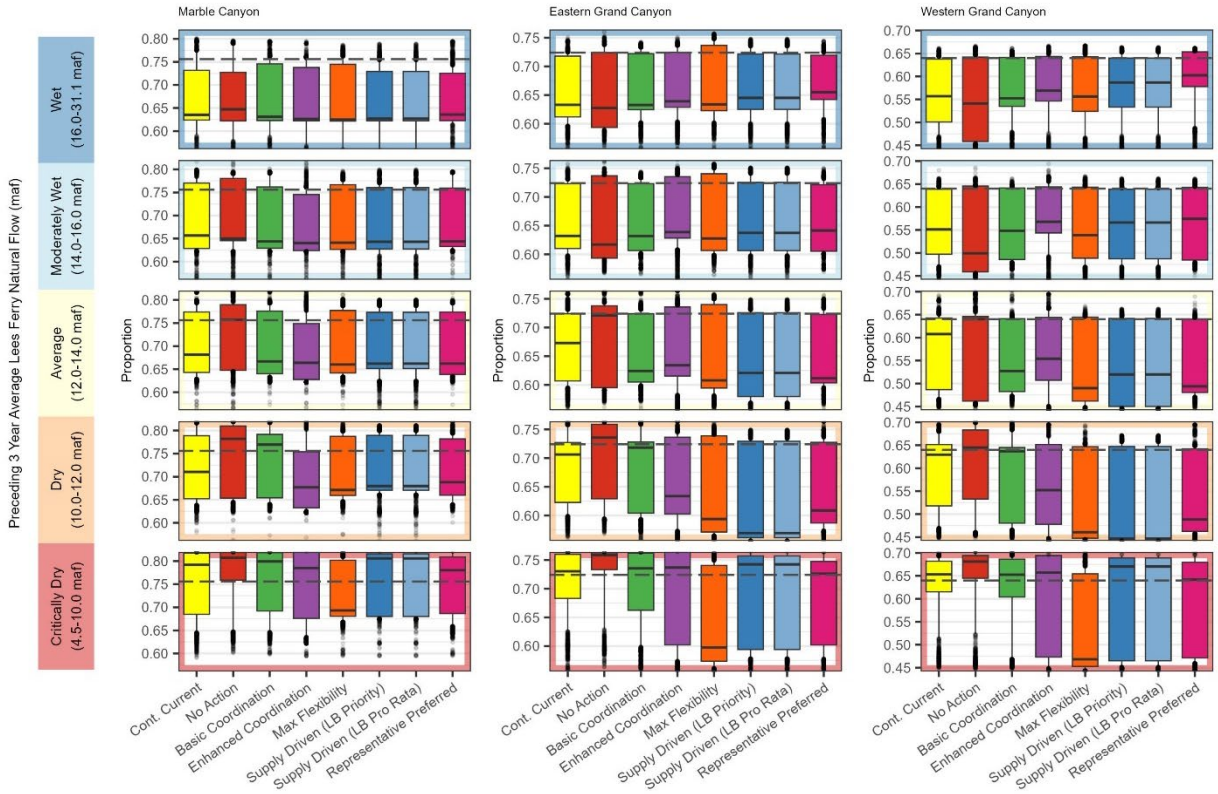
Similar to the discussions under *Marsh* and *Woody Riparian*, the decrease in arrowweed suitable habitat under the Moderately Wet and Wet Flow Categories for all sub-reaches and all alternatives may be because higher water levels reduce the overall available terrestrial habitat (Sankey et al. 2015). HFEs would also have an influence on suitable habitat, with more frequent and longer HFEs impacting vegetation encroachment in various ways depending on geomorphic setting, duration, and flow volume. Conversely, arrowweed suitable habitat may increase under the Dry and Critically Dry Flow Categories, potentially in areas recently exposed by lower water levels. Fewer to no HFEs under the Dry and Critically Dry Flow Categories could also lead to higher vegetation encroachment.

Native Species Richness

Figure TA 9-12 compares the predicted count number of native species (native species richness) under each alternative by Grand Canyon sub-reach. Native species richness includes all habitat types, and does not distinguish between marsh, woody riparian, and upland. Across all three sub-reaches, all alternatives show similar trends: the wide and generally similar interquartile ranges suggest native species richness would respond in a similar way across all alternatives. The hydrological niche modeling data used to estimate changes to native species richness and create **Figure TA 9-12** can be found in Butterfield and Palmquist (2026).

Under all alternatives, sub-reaches, and flow categories, the median is below the modeled historic conditions (dashed line). For some modeled conditions, the interquartile range is above the modeled historic conditions, indicating uncertainty in how vegetation would respond. Since most of the interquartile range is still below the modeled historic conditions, native species richness may decrease under all modeled conditions. However, given the large interquartile ranges, it is difficult to predict how each alternative may respond. Similar to marsh habitat, the Western Grand Canyon reach has larger interquartile ranges than Marble Canyon and Eastern Grand Canyon, indicating greater uncertainty further downstream.

Figure TA 9-12
Native Vegetation Species Richness for each Alternative by Sub-reach



Species richness at the fixed site sandbars declined from 2014-2019, a trend that was driven by low species richness in 2019 (Palmquist et al. 2023). The low species richness in 2019 was likely caused by the HFE that occurred in fall 2018 and the lack of monsoon precipitation in summer 2019. Native species richness may decrease under wet hydrologic conditions as HFEs would be a more frequent occurrence and may decrease under the Critically Dry Flow Category due to a lack of precipitation. Disturbance created by HFEs can also positively impact native species richness, as some species require periodic disturbance. Native species richness may also decrease under the Critically Dry Flow Category due to a lack of HFEs.

Under all conditions, a combination of these hydrological and climatic factors may be driving the variable interquartile ranges.

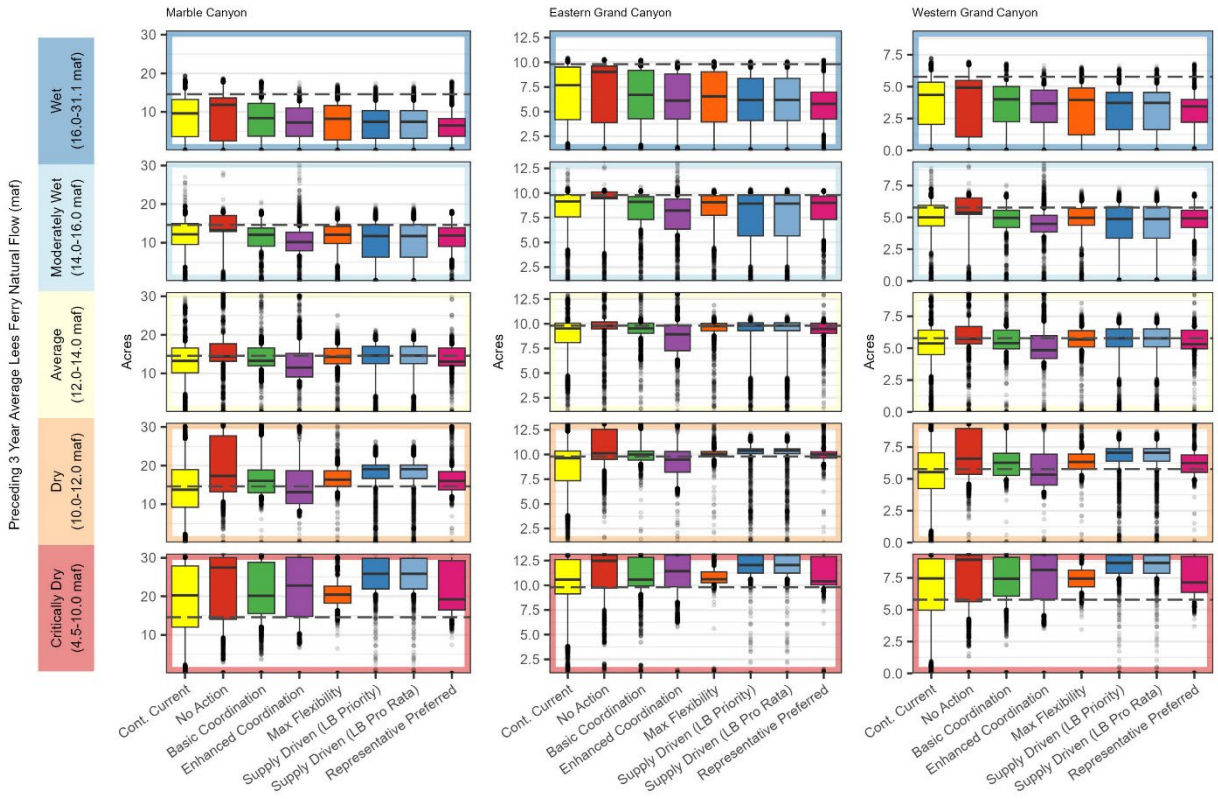
Proportion Native Species Cover

Figure TA 9-13 compares the proportion of native species cover under each alternative by Grand Canyon sub-reach. Proportion of native species cover includes all habitat types and does not distinguish between marsh, woody riparian, and upland. Across all three sub-reaches, all alternatives show similar trends: the generally wide and similar interquartile ranges in each sub-reach suggest that the proportion of native cover would respond in a similar way across all alternatives. The hydrological niche modeling data used to estimate changes to the proportion of native species cover and create **Figure TA 9-13** can be found in Butterfield and Palmquist (2026).

Figure TA 9-13
Proportion of Native Species Cover for each Alternative by Sub-reach

Similar to native species richness, the proportion of native species cover has large interquartile ranges across all modeled conditions and all alternatives. This indicates a large amount of uncertainty in how vegetation would respond under various conditions.

Within all reaches, under the Wet, Moderately Wet, Average, and Dry Flow Categories modeled conditions, the median is below the modeled historic conditions (dashed line) for all alternatives except for the No Action Alternative and Basic Coordination Alternative under Average and Dry Flow Categories. Since most of the interquartile ranges are below the modeled historic conditions, the proportion of native cover may decrease under Wet, Moderately Wet, Average, and Dry Flow Category conditions under all alternatives and all sub-reaches. However, given the large interquartile ranges, it is difficult to predict how vegetation may respond under each of the modeled conditions, alternatives, and sub-reaches.



For all sub-reaches, under the Critically Dry Flow Category modeled conditions, the median and interquartile range is above the modeled historic conditions (dashed line) under all alternatives except for the Maximum Operational Flexibility Alternative. This suggests that under the Critically Dry Flow Category modeled conditions, the proportion of native cover may stay similar to historic conditions or increase under most alternatives. However, given the large interquartile ranges, it is difficult to predict how vegetation may respond under each alternative.

Encroachment of riparian vegetation into the exposed active channel and bare sand of sandbars has been found to be driven by seep willows, which are native species (Durning et al. 2021). The proportion of native species cover may decrease under all conditions except for the Critically Dry Flow Category due to a lack of bare sand available for native species, particularly seep willows, to colonize. Seep willows are also less flood tolerant than other species, so the increase in HFE frequency and duration could decrease their suitable area under the Moderately Wet Flow Category. The proportion of native cover may increase under the Critically Dry Flow Category because of receding water levels and subsequent increase in available sand.

Annual Total Vegetation Cover

Figure TA 9-14 compares the annual total vegetation cover under each alternative by Grand Canyon sub-reach. Annual total vegetation cover includes all habitat types and does not distinguish between marsh, woody riparian, and upland. Across all three reaches, all alternatives show similar trends: the generally similar and overlapping interquartile ranges suggest annual total vegetation cover would respond in a similar way across all alternatives. The hydrological niche modeling data used to estimate changes to annual total vegetation cover and create **Figure TA 9-14** can be found in Butterfield and Palmquist (2026).

Figure TA 9-14
Annual Total Vegetation Cover for each Alternative by Sub-reach

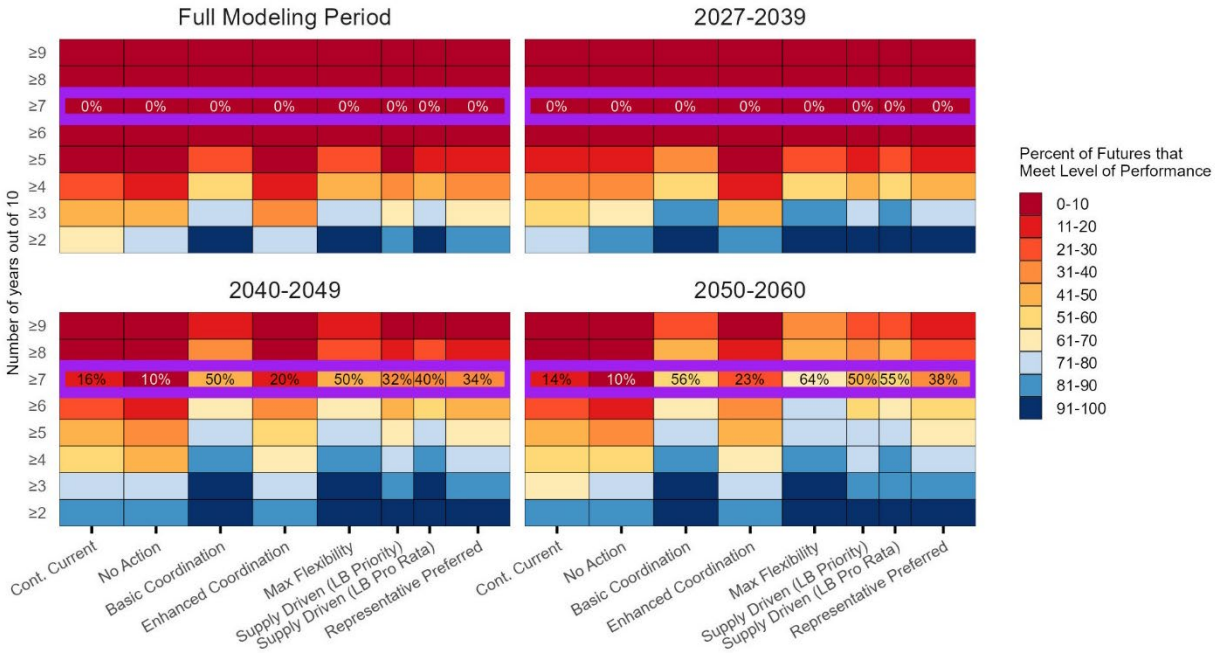
Under the Average Flow Category, across all three sub-reaches, the median for each alternative overlaps or nearly overlaps the modeled historic conditions (dashed line), and the interquartile ranges are relatively small. This indicates that annual total vegetation may be similar to historic conditions under the Average Flow Category.

Across all three sub-reaches, under the Wet Flow Category and Moderately Wet Flow Category, the median and interquartile ranges are at or below the modeled historic conditions (dashed line) for all alternatives except for the interquartile range of the No Action Alternative in the Moderately Wet Flow Category, although the median remains below historic conditions. This suggests that there would be less annual total vegetation cover under the Wet and Moderately Wet Flow Categories under all sub-reaches and all alternatives. Under the Dry Flow Category, the medians are above historic conditions (dashed line) for all alternatives except the CCS Comparative Baseline and Enhanced Coordination Alternative. Under the Critically Dry Flow Category, the median and interquartile ranges are above the modeled historic conditions (dashed line) for all sub-reaches and all alternatives except for the CCS Comparative Baseline. This indicates that there may be more annual total vegetation cover under the Dry and Critically Dry Flow Categories.

Similar to the discussions under *Suitable Habitat Area*, the decrease in annual total vegetation cover under the Moderately Wet and Wet Flow Categories for all sub-reaches and all alternatives may be because higher water levels reduce the overall available terrestrial habitat (Sankey et al. 2015). HFEs would also have an influence on annual total vegetation cover; more frequent and longer HFEs would result in lower vegetation encroachment. Conversely, annual total vegetation cover may increase under the Dry and Critically Dry Flow Categories, potentially on areas recently exposed by lower water levels. Fewer to no HFEs under the Dry and Critically Dry Flow Categories could also lead to higher vegetation encroachment.

High Flow Experiments

HFEs influence vegetation dynamics in this reach depending on geomorphic setting, duration, and flow volume. HFEs are dependent on sufficient storage and sediment conditions at Lake Powell. Alternatives that prioritize retaining higher levels in Lake Powell are more likely to result in HFEs, which could influence modeled vegetation responses in this reach. The role of HFEs in shaping vegetation in this reach is described in greater detail in the 2024 LTEMP SEIS (Reclamation 2024).



Lake Mead

Marsh Vegetation

The median of the maximum annual change in water surface elevation from WY 2008–2025 was 16.19 feet (**Figure TA 9-15**). Over the past 10 years, WY 2016–2025, the maximum annual change was less than 16.19 feet in 7 of 10 years (**Figure TA 9-15**). These data were used to understand the existing variability in Lake Mead that has led to the current extent of marsh vegetation in the Lake Mead analysis area and are collectively referred to as historic conditions. The minimum level of performance was established based on these historic conditions. Therefore, to meet the minimum level of performance, the alternative must have a maximum annual change in water surface elevation of less than 16.19 feet in 7 or more years. The more times an alternative meets that criterion, the higher the percentage in each respective box. The alternative with the highest percentage within the greater than or equal to 7 years row is the alternative most similar to historic conditions. **Figure**

TA 9-15 compares the similarity of each alternative to historic maximum annual change in Lake Mead elevation.

Figure TA 9-15
Lake Mead Marsh Riparian Vegetation: Robustness.
Percent of futures in which the maximum annual change in Lake Mead elevation is less than 16.19 feet in the number of years specified by each row during any 10-year period

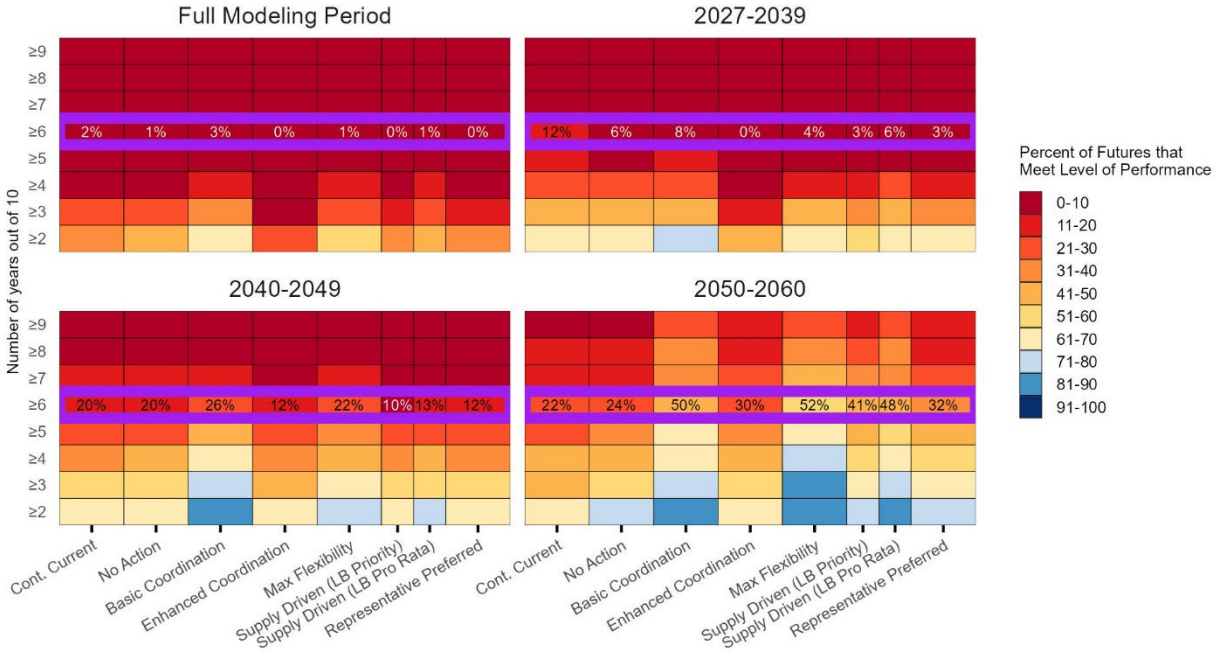
Note: Supply Driven Lower Basin (LB) Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

Similar to Lake Powell, the first decade of modeling for marsh habitat in Lake Mead is influenced by historical data (**Figure TA 9-15**). In the first decade, all alternatives are equally non-robust, meeting the minimum level of performance in 0 percent of futures. For all alternatives, the increased variability from historic conditions in the first decade (2027–2039; **Figure TA 9-15**) of the analysis may result in decreased cover of marsh vegetation.

In later decades (2040–2049 and 2050–2060; **Figure TA 9-15**) when variability becomes closer to historic conditions for the Basic Coordination Alternative and Maximum Operational Flexibility Alternative, marsh vegetation may re-establish to a more similar extent compared to the other alternatives. Both of these alternatives are more robust than the CCS Comparative Baseline and No Action Alternative, which meet the minimum level of performance in 16 percent and 14 percent, and 10 percent and 10 percent of futures, respectively. Similar to Lake Powell, when conditions are more variable, cover of nonnative species such as prickly Russian thistle may increase, and if variability decreases, native cover may reestablish.

As shown in **Figure TA 3-11** (see **TA 3**, Hydrologic Resources), the interquartile ranges for all alternatives for the Average Flow Category are above the 2024 WY minimum of 1,061 feet except for the No Action Alternative. The interquartile ranges under the Dry Flow Category are closer to the 2024 WY minimum compared to the Average Flow Category, and the interquartile ranges overlap with the 2024 WY minimum for all alternatives under the Critically Dry Flow Category. This suggests that Lake Mead is likely to lower under drier conditions. Conversely, under the Moderately Wet and Wet Flow Categories, the interquartile ranges shift to be higher than the 2024 WY minimum of 1,061 feet (**Figure TA 3-11**, see **TA 3**, Hydrologic Resources), suggesting that Lake Mead would rise under wetter conditions.

Similar to Lake Powell, whether water elevations rise, fall, or remain the same, if there are similar levels of variability to historic conditions under the Basic Coordination Alternative, Maximum Operational Flexibility Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) in the later decades (**Figure TA 9-15**), marsh vegetation is expected to continue to reestablish along the new water line over time. For alternatives with greater variability than historic conditions (**Figure TA 9-15**), marsh vegetation may re-establish to a smaller extent along the new water line over time. Where variability eliminates or prevents establishment of marsh habitat, woody riparian or upland habitat may become the dominant habitat type.



Woody Riparian Vegetation

The median 5-year change in water surface elevation from WY 2008–2025 was 52.24 feet (**Figure TA 9-16**). Over the past 10 years, WY 2016–2025, the 5-year change was less than 52.24 feet in 6 years out of 10 (**Figure TA 9-16**). These data were used to understand the existing variability in Lake Mead that has led to the current extent of woody riparian vegetation in the Lake Mead analysis area and are collectively referred to as historic conditions. The minimum level of performance was established based on these historic conditions. Therefore, to meet the minimum level of performance, the alternative must have a maximum 5-year change in water surface elevation of less than 52.24 feet in 6 or more years during every 10-year period. The more times an alternative meets that criterion, the higher the percentage in each respective box. The alternative with the highest percentage within the greater than or equal to 6 years row is the alternative most similar to historic conditions. **Figure TA 9-16** compares the similarity of each alternative to the historic maximum 5-year change in Lake Mead elevation.

Similar to Lake Powell, the first decade of modeling for woody riparian vegetation is influenced by historical data (**Figure TA 9-16**). All alternatives meet the minimum level of performance in 12 percent or less of futures.

The later decades (2040–2049 and 2050–2060; **Figure TA 9-16**) begin to trend towards more similar variability compared to historic conditions, but variability still remains high. The Basic Coordination Alternative and the Maximum Operational Flexibility Alternative are more similar to historic conditions, meeting the minimum level of performance in 26 percent and 50 percent and 22 percent and 52 percent of futures, respectively. Both of these alternatives are more robust than the CCS Comparative Baseline and No Action Alternative, which meet the minimum level of performance in 20 percent and 22 percent, and 20 percent and 24 percent of futures, respectively.

Figure TA 9-16
Lake Mead Woody Riparian Vegetation: Robustness.
Percent of futures in which the maximum 5-year change in Lake Mead elevation is less than 52.24 feet in the number of years specified by each row during any 10-year period

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

In later decades (2040–2049 and 2050–2060; **Figure TA 9-16**), when variability becomes more similar to historic conditions for the Basic Coordination Alternative and Maximum Operational Flexibility Alternative, woody riparian vegetation may re-establish to a more similar extent as existing conditions compared to other alternatives. Where variability eliminates or prevents the establishment of woody riparian habitat, upland habitat may become the dominant habitat type.

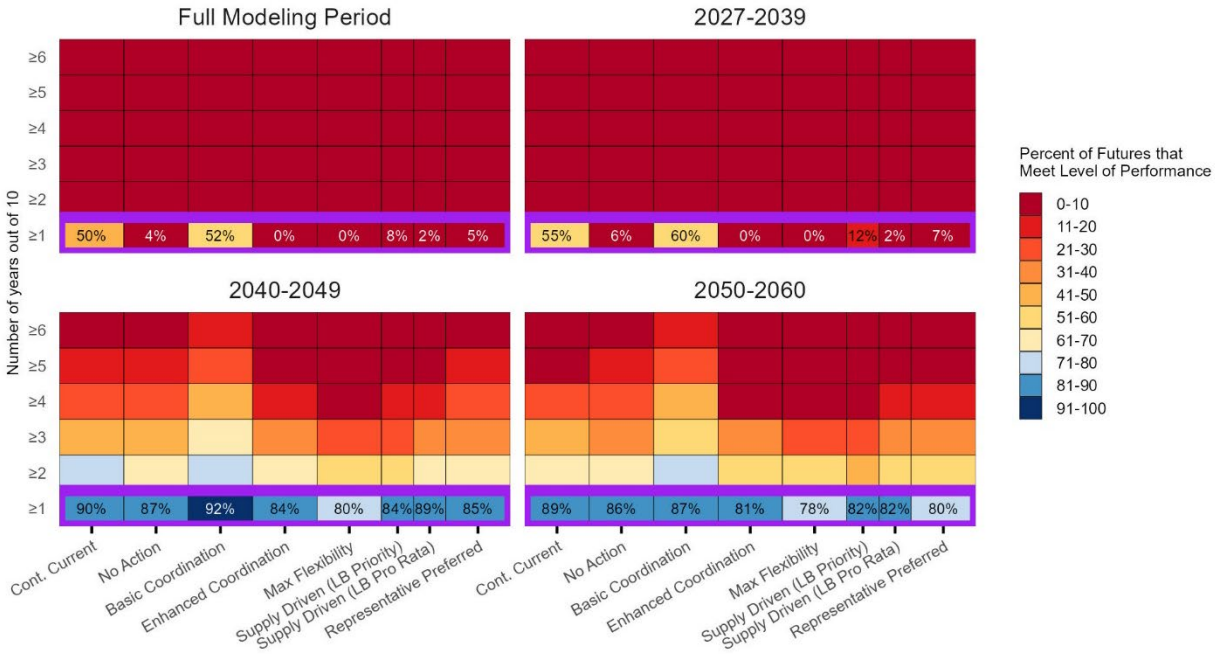


Figure TA 9-15 and **Figure TA 9-16** suggest annual variability in Lake Mead water elevations may be higher, especially in the early decade of the modeling period; however, the variability on a 5-year basis may overall be closer to historic conditions, generally benefiting woody riparian vegetation. As described in **TA 9.1**, historical data indicate that a reduction in variability can create new woody riparian habitat, however, subsequent increases in variability or long term drawdowns can cause vegetation die offs (McKernan and Braden 1998; Reclamation 2004b).

Hoover Dam to SIB

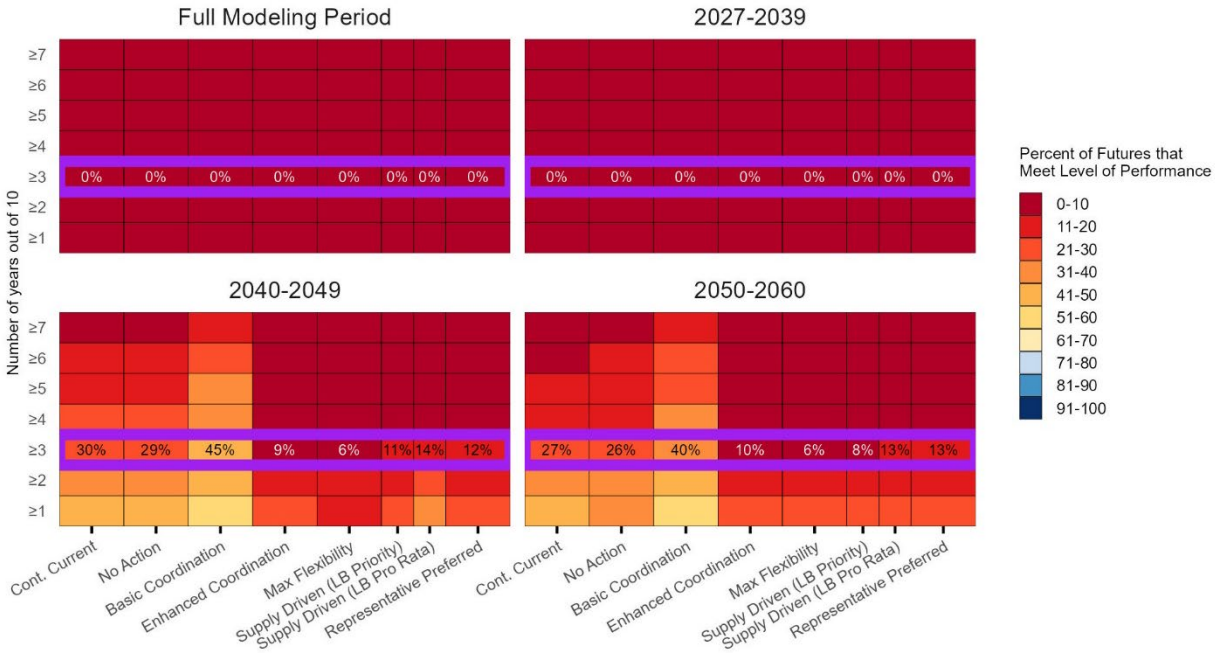
Marsh Vegetation

The median of the maximum annual change in Hoover releases from WY 2008–2025 was 0.256 maf (**Figure TA 9-17**). Over the past 10 years, WY 2016–2025, the maximum annual change was less than 0.256 maf in 1 of 10 years (**Figure TA 9-17**). These data were used to understand the existing variability from Hoover Dam to the SIB, which has led to the current extent of marsh vegetation in the Hoover Dam to the SIB analysis area, and are collectively referred to as historic conditions. The minimum level of performance was established based on these historic conditions. Therefore, to meet the minimum level of performance, an alternative must have a change in releases of water of less than 0.256 maf in 1 or more years. The more times an alternative meets that criterion, the higher the percentage in each respective box. The alternative with the highest percentage within the greater than or equal to 1 year row is the alternative most similar to historic conditions. **Figure TA 9-17** compares the similarity of each alternative to the historic annual year to year change in Hoover Dam annual release.

Figure TA 9-17
Below Hoover Dam Marsh Riparian Vegetation: Robustness.
Percent of futures in which the year-to-year change in Hoover Dam annual release less than 0.256 maf in the number of years specified by each row during any 10-year period

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

Similar to Lake Powell and Lake Mead, the first decade of modeling for marsh vegetation is influenced by historical data (**Figure TA 9-17**). In the first decade, the Basic Coordination Alternative is the most robust, meeting the minimum level of performance in 60 percent of futures. The CCS Comparative Baseline Alternative and No Action Alternative meet it in 55 percent and 6 percent of futures, respectively. For all alternatives, the increased variability from historic conditions in the first decade (2027–2039; **Figure TA 9-17**) may result in decreased marsh vegetation cover.



In later decades (2040–2049 and 2050–2060; **Figure TA 9-17**), all alternatives trend towards more similar variability compared to historic conditions. All alternatives meet the minimum level of performance in 78 percent or more of futures. As variability becomes closer to historic conditions, marsh vegetation may re-establish to a similar extent. Where variability eliminates or prevents the establishment of marsh habitat, woody riparian or upland habitat may become the dominant habitat type.

During the 2007 Interim Guidelines period, the annual volume of the Colorado River below Hoover averaged 9.185 maf (see **Section TA 3.1**, Affected Environment, in **TA 3**, Hydrologic Resources). For all alternatives under Average and Dry Flow Categories, the interquartile ranges of the modeled annual volume are below 9.185 maf (**Table TA 3-21** and **Figure TA 3-27**, in **TA 3**, Hydrologic Resources). This suggests that the annual flow volume below Hoover Dam may decrease under all alternatives in Average and Dry Flow Categories. The 2007 Interim Guidelines reduced average annual releases from Hoover Dam by approximately 1.014 maf from prior operating guidelines (see **Section TA 3.1**, Affected Environment, in **TA 3**, Hydrologic Resources). As described in **TA 9.1**, recent change analysis indicates marsh vegetation has generally decreased from 2000 to 2024 (RiverRestoration.Org 2025). If water releases decrease with higher levels of variability compared to historic conditions (**Figure TA 9-17**), marsh vegetation is expected to continue to decrease over time under Average and Dry Flow Categories. If water releases decrease with similar levels of variability to historic conditions (**Figure TA 9-17**), marsh vegetation is expected to decline at a rate similar to existing conditions under Dry and Critically Dry Flow Categories.

Woody Riparian

The median of the maximum 5-year change in Hoover releases from WY 2008–2025 was 0.338 maf (**Figure TA 9-18**). Over the past 10 years (WY 2016–2025), maximum annual change was less than 0.338 maf feet in 3 of 10 years (**Figure TA 9-18**). These data were used to understand the existing variability in flows from Hoover Dam to the SIB that has led to the current extent of marsh vegetation in the Hoover Dam to the SIB analysis area and are collectively referred to as historic conditions. The minimum level of performance was established based on these historic conditions. Therefore, to meet the minimum level of performance, an alternative must have a change in the 5-year average release of water of less than 0.338 maf in 3 or more years. The more times an alternative meets that criterion, the higher the percentage in each respective box. The alternative with the highest percentage within the greater than or equal to 3 years row is the alternative most similar to historic conditions. **Figure TA 9-18** compares the similarity of each alternative to the historic 5-year average year to year change in Hoover Dam annual release.

Figure TA 9-18
Below Hoover Dam Woody Riparian Vegetation: Robustness.
Percent of futures in which the 5-year average year-to-year change in Hoover Dam annual release is less than 0.338 maf in the number of years specified by each row during any 10-year period

Note: Supply Driven LB Priority and Supply Driven LB Pro Rata results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

Similar to Lake Powell and Lake Mead, the first decade of modeling for woody riparian vegetation is influenced by historical data (**Figure TA 9-18**). In the first decade, all alternatives are equally non-robust, meeting the minimum level of performance in 0 percent of futures. Increased variability from historic conditions in the first decade (2027–2039; **Figure TA 9-18**) may result in decreased woody riparian vegetation cover due to inconsistent water availability.

In later decades (2040–2049 and 2050–2060; **Figure TA 9-18**) all alternatives trend towards variability more similar to historic conditions, but variability still remains high. The Basic Coordination Alternative is the most robust, meeting the minimum level of performance in 45 percent and 40 percent of futures, respectively. The CCS Comparative Baseline and No Action Alternative meet it in 30 percent and 27 percent, and 29 percent and 26 percent of futures, respectively. This increased variability may result in decreased riparian vegetation cover for all alternatives, but to a lesser extent under the Basic Coordination Alternative and No Action Alternative. Where variability eliminates or prevents woody riparian habitat establishment, upland habitat may become the dominant habitat type.

Previous planning efforts, including the LCR MSCP HCP, 2007 Final EIS, 2024 LTEMP SEIS, and their associated Biological Assessments (Reclamation 2004a, 2004c, 2016, 2022, 2023, 2024) assessed and predicted the quantities of habitat impacts from ongoing and future reductions in flow from Hoover Dam, which are here incorporated by reference. The best available information at this time indicates that these analyses are still valid based on predicted operations of Hoover Dam and the dams and diversions between Hoover Dam and SIB. A summary of FWS consultation for this planning effort is included in **Chapter 4**, Consultation and Coordination.

Federal, state, and tribal managed areas, such as Cibola National Wildlife Refuge, depend on water from the Colorado River to ensure woody riparian and marsh habitat. If water in the river drops below the level at which water is able to properly flow through diversion structures or pumps are able to function, there may be impacts on these habitats unless another method is used to transport water to the managed habitat areas. If a prolonged period of dryness occurs, woody riparian and marsh vegetation may begin to desiccate; however, the extent to which this would occur is unknown.

TA 9.2.3 Summary Comparison of Alternatives

Marsh vegetation requires consistent inundation, so when variability increases from historic conditions on an annual scale, marsh vegetation extent is expected to decrease. Woody riparian vegetation is more resilient to water fluctuations, but when variability increases from historic conditions on a 5-year scale, woody riparian vegetation extent is expected to decrease. Similarly, if variability decreases on an annual or 5-year scale, marsh, woody riparian, or upland vegetation may increase in extent.

For Lake Powell marsh and woody riparian vegetation, the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative would result in vegetation most similar to historic conditions (**Table TA 9-4**). The Maximum Operational Flexibility Alternative would also result in vegetation most similar to historic conditions for Lake Mead marsh and woody riparian vegetation. However, for Hoover Dam to the SIB reach, the Maximum Operational Flexibility Alternative and Enhanced Coordination Alternative would result in vegetation least similar to historic conditions, which would result in larger changes in vegetation compared to historic conditions for that reach. Similarly, the Basic Coordination Alternative would result in conditions least similar to historic conditions for Lake Powell woody riparian vegetation, but would be closest to historic conditions for Lake Mead and Hoover Dam to the SIB. This suggests that no single alternative would result in vegetation similar to historic conditions across all reaches. For all reaches, multiple alternatives provide variability more similar to historic conditions than the CCS Comparative Baseline, except for the Hoover Dam to SIB reach, where all alternatives are similarly robust for marsh vegetation. This suggests that a change in management from the current strategies would benefit a large portion of the analysis area.

Table TA 9-4
The Alternatives that Result in the Most Similar or Least Similar Conditions compared to Historic Conditions for All Reaches and Vegetation Types

Reach and Vegetation Type	Most Similar to Historic Conditions	Least Similar to Historic Conditions
Lake Powell Marsh	Enhanced Coordination Alternative, Maximum Operational Flexibility Alternative	Supply Driven Alternative (both LB Priority and LB Pro Rata approaches)
Lake Powell Woody Riparian	Enhanced Coordination Alternative, Maximum Operational Flexibility Alternative	Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), Representative Preferred Alternative, Basic Coordination Alternative
Glen Canyon Dam to Lake Mead Marsh	Variable based on hydrology	Variable based on hydrology
Glen Canyon Dam to Lake Mead Woody Riparian	Variable based on hydrology	Variable based on hydrology
Lake Mead Marsh	Maximum Operational Flexibility Alternative, Basic Coordination Alternative	No Action Alternative, CCS Comparative Baseline
Lake Mead Woody Riparian	Basic Coordination Alternative, Maximum Operational Flexibility Alternative	No Action Alternative, CCS Comparative Baseline, Enhanced Coordination Alternative, Representative Preferred Alternative
Hoover Dam to SIB Marsh	All Alternatives Similarly Robust	All Alternatives Similarly Robust
Hoover Dam to SIB Woody Riparian	Basic Coordination Alternative	Maximum Operational Flexibility Alternative, Enhanced Coordination Alternative, Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), Representative Preferred Alternative

For the Glen Canyon Dam to Lake Mead reach, the alternative that would result in vegetation patterns most similar to historic conditions depends strongly on the flow categories. Under the Dry and Critically Dry Flow Categories, some differences among the alternatives emerge, presumably because there are greater differences in the lowest flows, the median flows, and peak flows under those conditions. However, across all alternatives, all sub-reaches, and all evaluated criteria (suitable habitat area, arrowweed, native species richness, proportion native species cover, and annual total vegetation cover), the interquartile ranges often overlap. When the interquartile ranges overlap, it is difficult to determine whether one alternative is truly different from another. Therefore, no single alternative emerged as the best or worst for retaining vegetation similar to historic conditions. The Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative prioritize protecting elevations in Lake Powell and are therefore most likely to result in HFEs in this reach.

For all alternatives in Lake Powell, Lake Mead, and Hoover Dam to the SIB, the first decade would experience more variability, which would result in a reduction in marsh, woody riparian, and upland habitat compared to historic conditions. All alternatives see conditions return closer to historic conditions in the second and third decades, which may result in vegetation reestablishing to a similar extent. Where variability eliminates or prevents the establishment of marsh, woody riparian, or upland habitat, there may be a shift to one of the other habitat types.

Special Status Plant Species Table

This page intentionally left blank.

TA 9 Attachment 1. Special Status Plant Species

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Alkali mariposa lily *(Calochortus striatus)*	BLM NV	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025a).
Amargosa buckwheat *(Eriogonum contiguum)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025a).
Amargosa niterwort *(Nitrophila mohavensis)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (CDFW 2013).
Antelope Canyon goldenbush *(Ericameria cervina)*	BLM NV	Upland	—	—	—	—	No, this species has been observed upland areas which would not be affected by any alternatives (NatureServe 2025b).
Aravaipa sage *(Salvia amissa)*	BLM AZ	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (Botanical Realm 2024).
Aravaipa woodfern *(Thelypteris puberula var. sonorensis)*	BLM AZ	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025c).
Arizona chalk dudleya *(Dudleya pulverulenta ssp. arizonica)*	BLM NV	Upland	—	X	—	—	Yes, this species has been observed in the analysis area and could be affected by inundation (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025, FNA 2020).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Arizona claret cup (*Echinocereus canyonensis*)	N/A	Upland	—	X	—	—	Yes, this species has been observed in the analysis area and could be affected by inundation (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
Arizona eryngo *(Eryngium sparganophyllum)*	BLM AZ	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (FWS 2025a).
Arizona Sonora rosewood *(Vauquelinia californica ssp. sonorensis)*	BLM AZ	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (Arizona Rare Plant Committee n.d.).
Arizona centaury (*Zeltnera arizonica*)	N/A	Marsh	—	X	—	—	Yes, the species has been documented in the analysis area (Palmquist et al. 2023).
Ash Meadows blazingstar *(Mentzelia leucophylla)*	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025b).
Ash Meadows gumplant *(Grindelia fraxinipratensis)*	BLM NV	Marsh, Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025d).
Ash Meadows ladies tresses *(Spiranthes diluvialis)*	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025e).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Ash Meadows milkvetch *(Astragalus phoenix)*	BLM NV, Threatened	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025f).
Ash Meadows mousetails *(Ivesia kingii* var. *eremica)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025c).
Ash Meadows sunray *(Enceliopsis nudicaulis* var. *corrugata)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025g).
Bartram stonecrop *(Graptopetalum bartramii)*	BLM AZ	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025d).
Bearded screwmoss *(Pseudocrossidium crinitum)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025h).
Beatley's milkvetch *(Astragalus beatleyae)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NNSS 2024a).
Beatley's scorpionflower *(Phacelia beatleyae)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NNSS 2024b).
Beaver dam breadroot *(Pediomelum castoreum)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025i).
Black woollypod *(Astragalus funereus)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025j).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Blue diamond cholla *(Cylindropuntia multigeniculata)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (Baker 2005).
Blue sand lily *(Triteleiopsis palmeri)*	BLM AZ	Upland	—	—	—	X (7)	No, this species grows on sand dunes, which would not be affected by any alternative (NatureServe 2025k).
Bullfrog Hills sweetpea *(Lathyrus hitchcockianus)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025l).
Calico Basin sunflower *(Helianthus devernii)*	BLM NV	Upland	—	—	—	—	No, this species is only found at Red Rock Canyon National Conservation Area (NatureServe 2025m).
California flannelbush *(Fremontodendron californicum)*	BLM AZ	Upland	—	—	—	—	No, the analysis area is outside the range of this species (Abrahamson 2021).
California screw moss *(Tortula californica)*	BLM CA	Upland	—	—	—	—	No, the analysis area is outside the range of this species (Calflora 2025a).
California sawgrass (*Cladium californicum*)	N/A	Marsh	—	X	—	—	Yes, the species has been documented in the analysis area (Palmquist et al. 2023).
Cane Spring suncup *(Chylismia megalantha)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (FNA 2022).
Chaparral sand-verbena *(Abronia villosa var. aurita)*	BLM CA	Upland	—	—	—	—	No, the analysis area is outside the range of this species (UC Berkeley 2025a).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Charleston grounddaisy *(Townsendia jonesii var. tumulosa)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (GBIF 2023).
Charleston Mountain angelica *(Angelica scabrida)*	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025n).
Charleston violet *(Viola charlestonensis)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025o).
Clarke phacelia *(Phacelia filiae)*	BLM NV	Upland	—	—	—	—	No, this species is endemic to a small area in southern Nevada, outside the analysis area (NNSS 2024c).
Clark Mountain agave *(Agave utahensis var. nevadensis)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025p).
Clark Mountain green gentian *(Frasera albomarginata var. induta)*	BLM NV	Upland	—	X	—	—	No, this species is limited to Clark Mountains in Nevada (FNA 2025a).
Clokey buckwheat *(Eriogonum heermannii var. clokeyi)*	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025q).
Clokey Mountain sage *(Salvia dorrii var. clokeyi)*	BLM NV		—	—	—	—	No, this species is found in the Spring Mountains west of Las Vegas and the analysis area is not within its range (NatureServe 2025r).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Cochise sedge *(Carex ultra)*	BLM AZ	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025s).
Coulter's goldfields *(Lasthenia glabrata ssp. coulteri)*	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025t).
Dainty moonwort *(Botrychium crenulatum)*	BLM NV	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025u).
Deane's milkvetch *(Astragalus deanei)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (UC Berkeley 2025b).
Death Valley beardtongue *(Penstemon fruticiformis ssp. amargosae)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (iNaturalist 2025a).
Death Valley sage *(Salvia funerea)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside the areas affected by any alternatives (CNPS 2025b).
Decumbent goldenbush *(Isocoma menziesii var. decumbens)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025v).
Delicate clarkia *(Clarkia delicata)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025w).
Desert mountain thistle *(Cirsium arizonicum)*	BLM NV	Upland	—	X	—	—	Yes, this species has been observed in the analysis area and could be affected by inundation (iNaturalist 2025b).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Dune spurge *(Euphorbia platysperma)*	BLM CA	Upland	—	—	—	X (7)	No, this species occurs in upland desert dune and scrub habitats which would not be affected by any alternative (Arizona Rare Plant Committee n.d.).
Dune sunflower *(Helianthus deserticola)*	BLM NV	Upland	X	—	X	—	Yes, this species has been observed in the analysis area and could be affected by inundation (iNaturalist 2025c).
Dunn's mariposa lily *(Calochortus dunnii)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025c).
Eastern joshua tree *(Yucca jaegeriana)*	BLM NV	Upland	—	—	X	X (2)	Yes, species has been documented within analysis area (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
Entire leaved thelypody (*Thelypodium integrifolium*)	N/A	Upland	—	X	—	—	Yes, species has been documented within analysis area (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
Fish Creek fleabane *(Erigeron piscaticus)*	BLM AZ	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025x).
Felt-leaved monardella *(Monardella hypoleuca ssp. lanata)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025d).
Gander's pitcher sage *(Lepechinia ganderi)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025e).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Gander's ragwort *(Packera ganderi)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025y).
Garret's California fuchsia *(Epilobium canum ssp. garrettii)*	BLM NV	Woody Riparian	—	—	—	—	No, this species has not been observed in the analysis area (iNaturalist 2025d).
Gilman's milkvetch *(Astragalus gilmanii)*	BLM NV	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025z).
Gold butte moss *(Didymodon nevadensis)*	BLM NV	Woody Riparian	—	?	X	—	Yes, this species is found in Gold Butte north of Lake Mead, Arizona and Utah. This species may be present in other locations with gypsum soils (Zander et al. 1995).
Golden crispleaf buckwheat *(Eriogonum corymbosum var. aureum)*	BLM NV	Upland	—	X	—	—	No, this species is present in creosote bush and blackbrush communities which are above analysis area (SEINet 2025a).
Goodding's willow (*Salix gooddingii*)	N/A	Woody Riparian	X	X	X	X	Yes, the species has been documented in the analysis area (Palmquist et al. 2023).
Grand Canyon rose *(Rosa stellata var. abyssa)*	BLM AZ	Upland	—	X	—	—	No, this species grows in upland habitat which would not be affected by any alternative (NatureServe 2025aa).
Gypsum Cave evening primrose *(Oenothera cavernae)*	BLM NV	Woody Riparian	—	X	—	—	Yes, this species is common in Grand Canyon National Park and in canyon washes (NatureServe 2025bb).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Half-ring milkvetch *(Astragalus mohavensis var hemigyrus)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025f).
Harrison's barberry *(Berberis harrisoniana)*	BLM AZ	Upland	—	X	—	—	No, this species grows on talus slopes on and along canyon sides, which would not be affected by any alternative (NatureServe 2025cc).
Harwood's eriastrum *(Eriastrum harwoodii)*	BLM CA	Upland	—	—	—	X (6)	No, this species grows in upland habitat near the Rosevelt Mine, which would not be affected by any alternative (CNPS 2025g).
Newberry's mock yucca (*Hesperoyucca newberryi*)	N/A	Upland	—	X	—	—	No, this species grows on rocky granite slopes in upland habitats, which would not be affected by any alternative (SEINet 2025b).
Hohokam agave *(Agave murpheyi)*	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025dd).
Horn's milk- vetch *(Astragalus hornii var. hornii)*	BLM CA	Marsh	—	—	—	—	No. This species' range is outside of areas affected by any alternatives. (CNPS 2025h)
Huachuca golden aster *(Heterotheca rutteri)*	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025ee).
Hualapai blazingstar (*Mentzelia hualapaiensis*)	N/A	Woody Riparian	—	X	X	—	Yes, species can occur in upland and woody riparian habitats (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Ivory-spined agave *(Agave utahensis var. eborispina)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (iNaturalist 2025e).
Jaeger beardtongue *(Penstemon thompsoniae ssp. jaegeri)*	BLM NV	Upland	—	—	—	—	No, this species has not been observed in the analysis area (iNaturalist 2025f).
Jaeger's ivesia *(Ivesia jaegeri)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025ff).
Johnson's Fishhook Cactus *(Echinomastus johnsonii)*	NPL	Upland			X	X (2)	Yes, this species could be affected by inundation (NatureServe 2025gg).
Kaibab agave (*Agave utahensis ssp. kaibabensis*)	N/A	Upland	—	X	—	—	No, this species grows on rocky outcrops in upland habitats, which would not be affected by any alternative (SEINet 2025c).
Lace-leaved rockdaisy *(Perityle ambrosiifolia)*	BLM AZ	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025hh).
Lakeside ceanothus *(Ceanothus cyaneus)*	BLM CA	Upland	—	—	—	—	No, this species grows in upland habitats, which would not be affected by any alternative (NatureServe 2025ii).
Las Vegas bearpoppy *(Arctomecon californica)*	BLM NV	Marsh	—	—	X	—	Yes, this species is found around Lake Mead in gypsum soils (NatureServe 2025jj).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Las Vegas buckwheat *(Eriogonum corymbosum var. nilesii)*	BLM NV	Upland	—	—	—	—	No, this species grows in upland gypsum soils, which would not be affected by any alternative (NatureServe 2025kk).
Las Vegas catseye *(Oreocarya insolita)*	BLM NV	Upland	—	—	—	—	No, it is suggested this species is currently extinct (NPS 2010).
Latimer's woodland-gilia *(Saltugilia latimeri)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025d).
Limestone monkeyflower *(Erythranthe calcicola)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025e).
Lincoln rockcress *(Boechera lincolnensis)*	BLM CA	Upland	—	—	—	—	No, this species grows in upland habitat, which would not be affected by any alternative (SEINet 2025f).
Littlefield milkvetch *(Astragalus preussii var. laxiflorus)*	BLM NV	Upland	—	—	X	—	Yes, this species has been observed near Lake Mead (SEINet 2025g).
Little San Bernardino Mtns. linanthus *(Linanthus maculatus ssp. maculatus)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025i).
Long-spined spineflower *(Chorizanthe polygonoides var. longispina)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025h).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Longstem evening primrose (*Oenothera longissima ssp. typica*)	N/A	Woody Riparian	—	X	—	—	Yes, species has been documented along Colorado River in Grand Canyon (SEINet 2025i).
Maguire's lewisia *(Lewisia maguirei)*	BLM NV	Upland	—	—	—	—	No, this species is associated with pinyon-juniper woodlands which would not be affected by any alternatives (NatureServe 2025ll).
Marble Canyon milkvetch *(Astragalus cremnophylax var. hevronii)*	BLM AZ	Upland	—	X	—	—	No, this species grows along canyon edges, which would not be affected by any alternative (Arizona Rare Plant Committee n.d.).
Meadow Valley sandwort *(Eremogone stenomeres)*	BLM NV	Upland	—	—	—	—	No, there are no known populations of this species within the areas affected by any alternatives (SEINet 2025j).
Mecca-aster *(Xylorhiza cognata)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025mm).
McDougall's flaveria (*Flaveria mcdougallii*)	N/A	Marsh	—	X	—	—	Yes, this species is found in Grand Canyon and occurs in alkaline seeps and springs (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
Mojave fishhook cactus *(Sclerocactus polyancistrus)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025nn).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Mojave indigo bush *(Psorothamnus arborescens var. pubescens)*	BLM AZ	Upland	—	X	—	—	Yes, this species is found in Grand Canyon and can occur in washes (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
Mojave monarrdella *(Monardella mojavensis)*	BLM NV	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025j).
Mojave tarplant *(Deinandra mohavensis)*	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025k).
Mojave thistle *(Cirsium mohavense)*	BLM NV	Woody Riparian	—	X	—	—	Yes, this species is found in Grand Canyon and occurs in hanging gardens and wet soil in canyons (NatureServe 2025oo). *C. mohavense* populations in Grand Canyon may be a *Cirsium* species new to science (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
Mokiak milkvetch *(Astragalus mokiacensis)*	BLM NV	Upland	—	—	X	—	Yes, this species has been observed within the full pool line of Lake Mead and could be affected by inundation (SEINet 2025l).
Mount Trumbull beardtongue *(Penstemon distans)*	BLM AZ	Upland	—	X	—	—	No, this species grows in upland forest and woodland habitat, which would not be affected by any alternative (NatureServe 2025pp).
Mourning buckwheat *(Eriogonum concinnum)*	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of the species (SEINet 2025m).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Nakestem sunray (*Enceliopsis nudicaulis*)	N/A	Woody Riparian	—	X	X	—	Yes, this species has been documented within full pool of Lake Mead (SEINet 2025n)
Nevada willowherb *(Epilobium nevadense)*	BLM NV	Woody Riparian	—	X	—	—	Yes, this species is found in Grand Canyon and grows on gravelly slopes, canyon walls, and sandy soils (NatureServe 2025qq).
Nuttall's scrub oak *(Quercus dumosa)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (Caliscape 2025).
Nye milkvetch *(Astragalus nyensis)*	BLM NV	Woody Riparian	—	—	X	—	Yes, Lake Mead is within the range of this species (Nature Serve 2025rr).
Oil neststraw *(Stylocline citroleum)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025k).
Orcutt's brodiaea *(Brodiaea orcuttii)*	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025o).
Orocopia Mountains spurge *(Euphorbia jaegeri)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025ss).
Otay manzanita *(Arctostaphylos otayensis)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025tt).
Otay Mountain ceanothus *(Ceanothus otayensis)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025p).
Pahrump silverscale *(Atriplex argentea var. longitrichoma)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025uu).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Pahrump Valley buckwheat *(Eriogonum bifurcatum)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025vv).
Pahute Mesa beardtongue *(Penstemon pahutensis)*	BLM NM	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025ww).
Panamint Spring beauty *(Claytonia panamintensis)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (CNPS 2025l).
Parish's meadowfern *(Limnanthes alba ssp. parishii)*	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025xx).
Parish Onion *(Allium parishii)*	BLM AZ	Upland	—	—	—	X (3 [full pool Lake Havasu])	Yes, this species has been observed in the analysis area (SEINet 2025q).
Parish's phacelia *(Phacelia parryi)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025r).
Parry's spineflower *(Chorizanthe parryi var. parryi)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025yy).
Parry's tetracoccus *(Tetracoccus dioicus)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025zz).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Peach Springs cholla (*Cylindropuntia abyssi*)	N/A	Upland	—	X	X	—	Yes, species has been documented within analysis area (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
Peirson's milk-vetch *(Astragalus magdalenae var. peirsonii)*	BLM CA, Threatened	Upland	—	—	—	—	No, this species occurs in aeolian dunes between the Salton Sea and Colorado River, outside of areas affected by any alternatives (FWS 2022).
Pima Indian mallow *(Abutilon parishii)*	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (Arizona Rare Plant Committee n.d.).
Pintwater rabbitbrush *(Chrysothamnus eremobius)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025aaa).
Planoconvex cordmoss *(Entosthodon planoconvexus)*	BLM NV	Woody Riparian	—	—	—	—	Yes, this species prefers desert washes and canyons which occur in the analysis area (NatureServe 2025bbb).
Polished blazing star *(Mentzelia polita)*	BLM NV	Upland	—	—	—	—	No, this species is restricted to gypsum or mixed gypsum and clay soils in Mohave County at elevations between 1350-1500m (SEINet 2025s).
Rainbow manzanita *(Arctostaphylos rainbowensis)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (Calflora 2025b).
Ramona horkelia *(Horkelia truncata)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025t).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Red Rock Canyon false golden aster *(Ionactis caelestis)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (Nesom and Leary 1992).
Reese River phacelia *(Phacelia glaberrima)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025ccc).
Reveal's buckwheat *(Eriogonum contiguum)*	BLM CA	Woody Riparian	—	—	—	X (2 and 3)	Yes, this species is associated with lower bajadas in California and southern Clark County Nevada (NatureServe 2025ddd).
Robinson's monardella *(Monardella robinsonii)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025eee).
Rock purpusia *(Ivesia arizonica var. saxosa)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025fff).
Rosy twotone beardtongue *(Penstemon bicolor ssp. roseus)*	BLM NV, BLM AZ	Woody Riparian	—	—	X	X (2)	Yes, this species may be found within full pool of Lake Mead (NPS 2004)
Rough dwarf greasebush *(Glossopetalon pungens var. pungens)*	BLM NV	Upland	—	—	—	—	No, there are no known occurrences of this species in the analysis area (iNaturalist 2025g).
Rough fringemoss *(Crossidium seriatum)*	BLM NV	Woody Riparian	—	—	X	—	Yes, this species has been observed in the analysis area (COSEWIC 2014).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Rush lemonweed (*Psoralidium junceum*)	N/A	Woody Riparian	—	X	—	—	Yes, this species is found in Grand Canyon and can occur in washes (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
St. George blue-eyed grass *(Sisyrinchium radicatum)*	BLM NV	Woody Riparian	—	—	X	—	Yes, this species can occupy riparian areas and has been observed in the analysis area (NatureServe 2025ggg).
Salt marsh bird's-beak *(Chloropyron maritimum ssp. maritimum)*	BLM CA	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025hhh).
San Bernadino milk-vetch *(Astragalus bernardinus)*	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025u).
San Diego goldenstar *(Bloomeria clevelandii)*	BLM CA	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025iii).
San Diego gumplant *(Grindelia hallii)*	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025v).
San Diego milk- vetch *(Astragalus oocarpus)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025jjj).
Sandfood *(Pholisma sonorae)*	BLM AZ	Upland	—	—	—	X (7)	No, this species is endemic to sand dunes and would not likely be found in washes (SEINet 2025w).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Sanicle biscuitroot *(Cymopterus ripleyi var. saniculoides)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025kkk).
San Jacinto mariposa-lily *(Calochortus palmeri var. munzii)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025x).
San Luis Obispo sedge *(Carex obispoensis)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025lll).
San Miguel savory *(Clinopodium chandleri)*	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025mmm).
Sanford's arrowhead *(Sagittaria sanfordii)*	BLM CA	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025nnn).
Santa Lucia dwarf rush *(Juncus luciensis)*	BLM CA	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025ooo).
Satin-tail (*Imperata brevifolia*)	N/A	Marsh	—	X	—	—	Yes, the species has been documented in the analysis area (Palmquist et al. 2023).
Scaly sandplant *(Pholisma arenarium)*	BLM AZ	Upland	—	X	X	X (4)	No, this species grows in upland sand and dune habitats, which would not be affected by any alternative (NatureServe 2025ppp).
Screwbean mesquite *(Prosopis pubescens)*	BLM NV	Woody Riparian	—	—	X	X (2, 3, 4, 5, 6, 7)	Yes, this species is present in riparian areas with honey mesquite and cottonwood-willow and has been observed near the Little Colorado River (Meyer 2005).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Scrub lotus *(Lotus argyraeus var. multicaulis)*	BLM NV	Upland	—	—	—	—	No, this species is endemic to desert mountains which would not be affected by any alternatives (NatureServe 2025qqq).
Sheep fleabane *(Erigeron ovinus)*	BLM NV	Upland	—	—	—	—	No, this species is endemic to the Sheep and Groom ranges and on Mt. Irish in Nevada (NatureServe 2025rrr).
Sheep Range milkvetch *(Astragalus amphioxys var. musimonum)*	BLM NV	Upland	—	—	—	—	No, this species variety has not been observed in the analysis area (SEINet 2025y).
Shevock's copper moss *(Mielichhoferia shevockii)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025sss).
Siler fishhook cactus *(Sclerocactus sileri)*	BLM AZ	Upland	—	X	—	—	No, this species grows in upland desert habitats which would not be affected by any alternatives (NatureServe 2025ttt).
Silverleaf sunray *(Enceliopsis argophylla)*	BLM AZ, BLM NV	Upland	—		X	X (2)	Yes, this species can occupy riparian areas and has been observed near the analysis area (SEINet 2025z).
Small wirelettuce *(Stephanomeria exigua ssp. exigua)*	BLM AZ	Upland	—	—	—	—	No, this species has not been documented in areas affected by alternatives (SEINet 2025aa).
Smooth dwarf greasebush *(Glossopetalon pungens var. glabrum)*	BLM NV	Upland	—	—	—	—	No, this species prefers mountain ranges which would not be affected by any alternatives (FNA 2025b).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Snake cholla *(Cylindropuntia californica var. californica)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025bb).
Southwestern ringstem *(Anulocaulis leisolenus var. leisolenus)*	BLM NV	Woody Riparian	—	X	—	—	Yes, species has been collected near Colorado River (personal communication, Wendy Hodgson, Desert Botanical Garden, to Lonnie Pilkington, NPS, October 28, 2025).
Spring-loving century plant *(Zeltnera namophila)*	BLM NV	Marsh	—	—	—	—	No, this species is endemic to Nye County Nevada in Ash Meadows (SEINet 2025cc).
Spring Mountains milkvetch *(Astragalus remotus)*	BLM NV	Upland	—	—	—	—	No, this species grows in upland talus and rocky slopes which would not be affected by any alternative (NatureServe 2025uuu).
Sticky buckwheat *(Eriogonum viscidulum)*	BLM AZ, BLM NV, LCR MSCP	Upland	—	—	X	—	Yes, this species can occupy riparian areas and has been observed near the analysis area (SEINet 2025dd).
Sticky dudleya *(Dudleya viscida)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (SEINet 2025ee).
Sticky ringstem *(Anulocaulis leiosolenus)*	BLM NV	Upland	—	—	X	—	No, this species grows in upland habitats which would not be affected by any alternative (Rees 2007).
Straw milkvetch *(Astragalus lentiginosus var. stramineus)*	BLM NV	Upland	—	—	X	—	Yes, this species has been observed within the analysis area (iNaturalist 2025h).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Summer holly *(Comarostaphylis diversifolia ssp. Diversifolia)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025vvv).
Sweet moustache moss *(Trichostomum sweetii)*	BLM NV	Upland	—	—	X	—	No, this species occurs in upland habitats outside of areas affected by any alternatives (GBIF 2004).
Tecate cypress *(Hesperocyparis forbesii)*	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (UC Berkeley 2025c).
Tecate tarplant *(Deinandra floribunda)*	BLM CA	Upland	—	—	—	—	No, this species grows in upland habitats which would not be affected by any alternative (NatureServe 2025www).
Tecopa salty bird's beak *(Chloropyron tecopense)*	BLM NV	Upland	—	—	—	—	No, this species' range is outside of the analysis area (CNPS 2025m).
Threecorner milkvetch *(Astragalus geyeri var. triquetrus)*	BLM NV, LCR MSCP	Marsh	—	—	X	—	Yes, this species is found along the shores of Lake Mead (D'Ambrosi 2023).
Tumamoc globeberry *(Tumamoca macdougalii)*	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025xxx).
Variegated dudleya *(Dudleya variegata)*	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternatives (NatureServe 2025yyy).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Virgin River thistle *(Cirsium virginense)*	BLM NV	Woody Riparian	—	X	—	—	No, although this species occurs in hanging gardens, its range is along the Virgin River (Arizona Rare Plant Committee n.d.).
White bearpoppy *(Arctomecon merriamii)*	BLM NV	Upland	—	—	—	—	No, this species grows in upland habitat which would not be affected by any alternative (NatureServe 2025zzz).
Whitemargined beardtongue *(Penstemon albomarginatus)*	BLM NV	Upland	—	—	—	—	No, this species grows in upland sand and dune habitats which would not be affected by any alternative (NatureServe 2025aaaa).
White-bracted spineflower *(Chorizanthe xanti var. leucotheca)*	BLM CA	Upland	—	—	—	—	No, this species grows in upland habitat which would not be affected by any alternative (NatureServe 2025bbbb).
Wiggins' croton *(Croton wigginsii)*	BLM CA	Woody Riparian	—	—	—	X (7)	Yes, this species grows in sandy arroyos and has been observed within 200m of the Colorado River (NatureServe 2025cccc).
Yellow twotone beardtongue *(Penstemon bicolor ssp. bicolor)*	BLM NV	Upland	—	—	X	X (2)	Yes, this species may be found within full pool of Lake Mead (NatureServe 2025dddd).
Yucaipa onion *(Allium marvinii)*	BLM CA	Upland	—	—	—	—	No, this species grows in upland habitat which would not be affected by any alternative (SEINet 2025ff).

BLM = Bureau of Land Management; CA = California; NV = Nevada; NPS = National Park Service; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

TA 10. Terrestrial Wildlife Including Special Status Species

TA 10.1 Affected Environment

This section provides an overview of the general terrestrial wildlife typically found within marsh, woody riparian, and upland habitats in the analysis area, as described in **Section TA 9.2** in **TA 9**, Vegetation Including Special Status Species. These general terrestrial wildlife include invertebrates, amphibians, reptiles, birds, and mammals. This section also includes special status species, which are defined here as those listed as Bureau of Land Management (BLM) sensitive species by the overlapping Arizona, California, Utah, and Nevada BLM field offices; species covered under the Lower Colorado River Multi-Species Conservation Program (LCR MSCP); and species listed as threatened or endangered or proposed for listing by the United States (U.S.) Fish and Wildlife Service (FWS; BLM 2017, 2018, 2019, 2023; LCR MSCP 2022; FWS 2025). **Attachment 1** in this technical appendix provides a table of the species considered in this document, including their listing status, the river reaches they typically inhabit, and the habitat types most important to their life histories. **Attachment 1** in this technical appendix was developed with input from cooperating agencies and local experts.

In addition to analyzing the impacts on wildlife in the analysis area as defined in the Vegetation section (see **Section TA 9.2** in **TA 9**, Vegetation Including Special Status Species), impacts are also evaluated for the LCR MSCP conservation areas. These areas were established to provide habitat for species listed under the Endangered Species Act (ESA) or that may become listed under the ESA and that use habitat along the Colorado River from Lake Mead down to the Southerly International Boundary (SIB; LCR MSCP 2025). The Colorado River in this area has been highly modified by several dams and water diversions, which have affected the growth and establishment of marsh and woody riparian habitat (see **Section TA 9.1** in **TA 9**, Vegetation Including Special Status Species).

The LCR MSCP Habitat Conservation Plan (HCP) and subsequent ESA consultations identified the impacts on marsh, woody riparian, upland, and backwater habitats predicted from existing and anticipated future river operations, and the program established the conservation areas and off-river land acquisitions to mitigate for these losses and provide reliable suitable habitat for wildlife (LCR MSCP 2025). There are 18 conservation areas aimed at conserving 27 species, with a goal of creating 5,940 acres of cottonwood and willow, 1,320 acres of honey mesquite, 568 acres of marsh, and 484 acres of backwater habitats. In addition to the conservation areas, several wildlife refuges and lands managed for wildlife are present below Hoover Dam. These include Havasu National Wildlife Refuge, Bill Williams River National Wildlife Refuge, Cibola National Wildlife Refuge, Imperial National Wildlife Refuge, Gooseflats Wildlife Area, Lake Mead National Recreation Area, and Mittry Lake Wildlife Management Area.

TA 9, Vegetation Including Special Status Species, describes the marsh, woody riparian, and upland habitat types, which are used in this section to determine the affected environment and environmental impacts on wildlife, including special status species.

TA 10.1.1 Marsh Habitat

See **TA 9**, Vegetation Including Special Status Species, for a description of marsh habitat. There are approximately 4,327 acres of marsh habitat in the analysis area (**Table TA 9-1** in **TA 9**, Vegetation Including Special Status Species). Marsh habitat can be vulnerable to harmful algal blooms due to increased water temperature and nutrient input. Harmful algal blooms can reduce water quality that can impact marsh vegetation, in turn reducing habitat quality and quantity for wildlife. Harmful algal blooms can also cause toxic water conditions that can be harmful to wildlife that contact or drink the water (CRS 2020). See **TA 6**, Water Quality, for more information on harmful algal blooms.

Invertebrates. Marshes are rich in invertebrate diversity, including mosquitoes (family Culicidae), water beetles (family Hydrophilidae), and midges (family Chironomidae). Many aquatic invertebrates use marsh habitat to lay eggs. These invertebrates are a vital part of the food web, supporting a variety of other wildlife species, including special status species and aquatic species, which are described in further detail in **TA 8**, Biological Resources – Fish and Other Aquatic Resources. Four special status invertebrate species predominantly use marsh habitat (**TA 10, Attachment 1**).

Amphibians and Reptiles. Marsh habitat along the Colorado River provides important resources for amphibian and reptile life stages. Amphibians lay eggs in standing water, where aquatic vegetation offers shelter and protection for eggs and developing larvae. Marshes also serve as important refuges for juvenile amphibians and reptiles, providing abundant food sources like insects and small invertebrates, which are crucial for growth and development. For reptiles, marshes offer both a food-rich environment and opportunities for thermoregulation. These areas are particularly valuable during the breeding season, providing critical hydration and temporary refuges during extreme temperatures.

Ten special status amphibians and reptiles predominantly use marsh habitat, including the northern Mexican gartersnake (*Thamnophis eques megalops*), which is a federally threatened species (**Table TA 9-1**). Northern Mexican gartersnakes use marsh habitat along large rivers and tributaries where they forage for fish, amphibians, lizards, small mammals, and invertebrates (AZGFD 2023). Northern Mexican gartersnakes are difficult to detect, and their occupied range along the Colorado River is unknown, although known occurrences existed within the Lake Havasu National Wildlife Refuge in 2015 and 2019 (LCR MSCP 2020; FWS 2024). It is assumed northern Mexican gartersnakes could be present in the analysis area within the Hoover Dam to the SIB reach (**TA 10, Attachment 1**). Minnow trapping was conducted in 2024 in previously occupied habitat, and ongoing camera trapping surveys are occurring at Topock Marsh. The 2024 and 2025 surveys resulted in no detections of this species (Sabin 2025).

The introduction and spread of aquatic invasive species have affected amphibian populations in the Colorado River system, which can affect species that prey on amphibians, such as the northern Mexican gartersnake (Reclamation 2024, Section 3.8, Aquatics). Nonnative fish prey on native

amphibian eggs, larvae, or adults. Common predatory aquatic invasive species are detailed in **TA 8**, Biological Resources – Fish and Other Aquatic Resources.

Birds. Marshes provide essential nesting sites for waterfowl and other wetland-dependent bird species. These birds depend on dense vegetation to conceal their nests from predators and provide suitable areas for raising their young (Hinojosa-Huerta 2004). Migratory birds use marsh habitat as stopover sites for resting, foraging, breeding, and nesting. Twelve special status species predominantly use marsh habitat, including Yuma Ridgway's rail (*Rallus obsoletus yumanensis*), which is a federally listed endangered species (**TA 10, Attachment 1**). Yuma Ridgway's rails use marsh habitat for both foraging and nesting, typically in areas dominated by cattails (*Typha* sp.) and bulrushes (*Scirpus* spp.; FWS 2009).

Within the analysis area, Yuma Ridgway's rails are found in the Lake Mead to Hoover Dam and Davis Dam to the Northerly International Boundary (NIB) reaches. Most Yuma Ridgway's rails in the analysis area are found in the Davis Dam to NIB reach, which contained between 30 and 58 percent of the U.S. population from 1995 through 2013 (Reclamation 2023). Surveys conducted from 2006 through 2022 detected 120 to 339 Yuma Ridgway's rails annually between Davis and Imperial Dams (Reclamation 2023). Surveys at selected sites in the Davis Dam to NIB reach from 2023 through 2025 detected 43 to 78 Yuma Ridgway's rails annually (Kahl 2024, 2025a, 2025b, 2025c; Ronning 2025).

Yuma Ridgway's rail is a highly mobile species, with a subset of the lower Colorado River population exhibiting migratory movements. Although some rails flew over 900 kilometers (km; 559 miles) to wintering areas in the United Mexican States, the three rails that were documented returning to their breeding grounds all returned to within 32 km (20 miles) of their original capture locations (Harrity and Conway 2020). The readiness with which rails colonize habitats distant from established breeding sites is unclear.

Mammals. Mammals use marsh habitat for shelter, for foraging, and as a critical drinking water resource. This habitat also plays a role in the reproductive cycle of some species, such as beavers (*Castor canadensis*). Other species rely on the aquatic plants and invertebrates in marsh habitats as essential food sources. Three special status mammal species predominantly use marsh habitat (**TA 10, Attachment 1**).

TA 10.1.2 Woody Riparian Habitat

See **TA 9**, Vegetation Including Special Status Species, for a description of woody riparian habitat. There are approximately 48,827 acres of woody riparian habitat within the analysis area (**Table TA 9-1**). Similar to marsh habitat, woody riparian habitat is vulnerable to harmful algal blooms (CRS 2020), which can impact wildlife that use this habitat type.

Invertebrates. Woody riparian habitat supports a variety of common terrestrial invertebrates, including winged (*Pterygota*) and wingless (*Apterygota*) insects. These insects play a crucial role in the terrestrial ecosystem as both pollinators and as a food source for other wildlife, including special status species. Several insect species, such as mayflies (*Leptophlebiidae*), stoneflies (*Plecoptera*), caddisflies (*Limnephilidae*), cicadas (*Hemiptera*), dragonflies (*Anisoptera*), and beetles (*Coleoptera*), breed

in the woody riparian habitat along the Colorado River. These species take advantage of the vegetation, moisture, and organic matter that these environments provide. Woody riparian habitat also supports the adult life stages of aquatic insects that are an important part of the aquatic ecosystem, which is described in further detail in **TA 8**, Biological Resources – Fish and Other Aquatic Resources.

Thirty-two special status invertebrate species predominantly use woody riparian habitat, including the monarch butterfly (*Danaus plexippus*), which is a federally proposed threatened species (**TA 10, Attachment 1**). Monarch butterflies use milkweed (*Asclepias* spp.) that grows in a variety of upland habitat types for breeding habitat as well as other nectar-producing plants while foraging. In Arizona, monarch butterflies are present and seasonally abundant, having been recorded every month of the year when seasonal temperatures are conducive, including documented overwintering at riparian locales. Monarchs often occur near riparian areas or other locations that contain water, including around ciénegas, creeks, washes, roadside ditches, and irrigated gardens. Monarchs favor riparian areas and rivers for migration (Morris et al. 2015). Within the analysis area along the river, there are several known occurrences of monarch butterflies and known locations of milkweed that breeding monarchs could use (Western Monarch Mapper 2025; **TA 10, Attachment 1**).

Amphibians and Reptiles. Woody riparian habitat provides forage and cover for common reptile and amphibian species, such as turtles, snakes, frogs, and salamanders. The thick woody cover provides temperature regulation opportunities and habitat for food sources for reptiles and amphibians; these food sources include plants, small mammals, and invertebrates. Additionally, woody riparian habitat can be used by species that forage in adjacent habitat as cover to avoid predation. Ten special status amphibian or reptile species predominantly use woody riparian habitat (**TA 10, Attachment 1**).

Birds. Birds, including raptors, use woody riparian habitat along the Colorado River for nesting, foraging, and sheltering during migration. Bird species benefit from the rich resources and shelter provided by woody riparian habitats, which are crucial for foraging and nesting activities. Native riparian vegetation, such as cottonwoods and willows, offers nesting sites and cover, which are especially valuable for species that depend on dense canopy structures. This habitat structure is particularly important for raptors that rely on elevated branches for hunting perches and nesting sites. Twenty-three special status bird species predominantly use woody riparian habitat, including southwestern willow flycatcher (*Empidonax traillii extimus*), which is a federally listed endangered species, and western yellow-billed cuckoo (*Coccyzus americanus*), which is a federally listed threatened species (**Table TA 9-1**).

Southwestern willow flycatchers nest in dense riparian habitat near standing or slow-moving water in the Glen Canyon to Lake Mead, Lake Mead to Hoover Dam, and Davis Dam to Parker Dam reaches. Southwestern willow flycatchers are often identified in tamarisk-dominant riparian habitat along the above-mentioned reaches. Generally, the analysis area does not provide extensive stands of dense riparian habitat suitable for breeding southwestern willow flycatchers. Along lake margins, suitable habitats are generally limited to inflow areas. Newly established riparian vegetation can be used as breeding habitat by southwestern willow flycatchers within 3 years of establishment (Paxton et al. 2007).

Two southwestern willow flycatcher breeding sites have been documented within the analysis area in recent years: Lower Las Vegas Wash, in the Lake Mead reach, and Topock Marsh, which is in the Hoover Dam to the SIB reach. A single nesting pair was documented at Lower Las Vegas Wash in 2021 (SWCA 2022). Between two and six southwestern willow flycatcher pairs bred at Topock Marsh each year in 2018 through 2022 (McLeod et al. 2023). No breeding or resident southwestern willow flycatchers were confirmed in the analysis area in 2023 or 2024, although suspected southwestern willow flycatchers were detected at two spring-fed locations in the Glen Canyon Dam to Lake Mead reach in 2023 (McLeod and Pellegrini 2025; McLeod and Pellegrini in prep.; Terwilliger and Whyte 2023). Surveys of these spring-fed locations in 2025 resulted in no southwestern willow flycatcher detections (Robertson 2025).

Migrant and transient southwestern willow flycatchers could use woody riparian habitat throughout the Glen Canyon to Lake Mead and Davis Dam to SIB reaches. Southwestern willow flycatchers readily colonize new suitable habitats that are near established breeding sites, but long-distance movements are relatively rare. Southwestern willow flycatchers exhibit fidelity to local areas, commonly returning from the wintering grounds to breed at the same site where they held a territory in the previous year. Half of adult returns in the lower Colorado River region in 1998 through 2012 resulted in movements of 40 meters (131 feet) or less, and less than 20 percent of movements were greater than 1 km (0.6 miles). Movements between 100 and 259 km (62 and 161 miles) were recorded in approximately 2 percent of cases. Average natal dispersal distances were greater than adult movement distances, although 90 percent of recorded dispersal movements were 75 km (47 miles) or less (McLeod and Pellegrini 2013). Because long-distance movements are uncommon, one southwestern willow flycatcher recovery strategy is to establish habitat close to existing breeding sites to increase the likelihood of colonization (FWS 2002:75).

Western yellow-billed cuckoos nest in riparian woodlands with mature willow and cottonwood from Glen Canyon Dam to Hoover Dam and Davis Dam to NIB. Western yellow-billed cuckoos nest in blocks of riparian woodland that are usually 50 acres or larger (Halterman et al. 2016; *Federal Register* 78:61633). Occupied lowland riparian habitat generally consists of mature willow and cottonwood forest, although other riparian tree species, such as mesquite and tamarisk, may also be present. Breeding habitat generally has both overstory and understory components (*Federal Register* 79:60010–60011), and nest locations typically have high canopy closure (McNeil et al. 2013). Large prey items, such as cicadas, katydids, grasshoppers, and caterpillars, form the bulk of the cuckoos' diet (*Federal Register* 78:61632).

Extensive riparian woodlands suitable for western yellow-billed cuckoo breeding are currently present only in LCR MSCP conservation areas from Davis Dam to the NIB (see LCR MSCP 2022 for a description of the conservation areas), where cuckoos begin using cottonwood-willow habitats after two growing seasons (McNeil et al. 2013). Surveys of the conservation areas in 2018 through 2022 resulted in an estimated 46 to 66 western yellow-billed cuckoo territories annually (Parametrix and Southern Sierra Research Station 2019; Tracy et al. 2023). Since the comprehensive surveys of the conservation areas completed in 2022, the Bureau of Reclamation has surveyed several conservation areas each year and continues to detect the species in suitable habitat. A single possible western yellow-billed cuckoo territory was documented at Lower Las Vegas in 2021 (SWCA 2022).

Migrant and transient yellow-billed cuckoos could use woody riparian habitat throughout the Glen Canyon to Lake Mead and Davis Dam to the SIB reaches. Yellow-billed cuckoo is a highly mobile species and able to move to suitable habitats wherever these habitats are available. Dispersal data from 19 yellow-billed cuckoos along the lower Colorado River indicate that while most between-year returns were to the same or adjacent sites, three movements of approximately 40 km (25 miles) were recorded, and one movement of approximately 75 km (47 miles) was recorded (Tracy et al. 2023). Yellow-billed cuckoos were documented using previous breeding habitat areas and colonizing new habitats at conservation areas along the lower Colorado River from 2008 to 2018 (LCR MSCP 2019). These observations provide evidence that the cuckoos' selection of breeding sites is not restricted to previous breeding areas, and they may be able to use suitable habitat wherever available.

Mammals. Mammals along the Colorado River rely on woody riparian habitat for shelter, food, breeding, young rearing, and movement corridors. These areas provide resources that support a diverse range of species, from small rodents to large herbivores, such as bighorn sheep (*Ovis* spp.), and carnivores. They also support aquatic invertebrates, fish, and small mammals, which serve as prey for carnivores. Bats are particularly dependent on woody riparian habitats, using them as foraging grounds where bats feed on insects attracted to water sources and dense vegetation. Beavers (*Castor canadensis*) play a particularly important role in these ecosystems by using woody riparian vegetation to construct dams and lodges. These structures create ponds that enhance water availability, benefiting many other species. Twenty-seven special status mammals, all bats, predominantly use woody riparian habitat (**TA 10, Attachment 1**).

TA 10.1.3 Upland Habitat

Upland habitat is described in **TA 9**, Vegetation Including Special Status Species, and is predominantly characterized as desert scrub in the analysis area. There are approximately 120,266 acres of upland habitat within the analysis area (**Table TA 9-1**).

Invertebrates. Desert scrub and upland habitat support a variety of invertebrates, including scorpions (*Scorpionidae* spp.), beetles (Coleoptera), and ants (*Formicidae* spp.). These invertebrates are key components of the desert ecosystem, serving as both predators and prey. Thirty-eight special status invertebrate species predominantly use upland habitat (**TA 10, Attachment 1**).

Amphibians and Reptiles. Amphibians and reptiles use upland habitat along the Colorado River for critical life-cycle activities, such as foraging, shelter, and breeding. While many species are closely tied to water sources for reproduction, some spend a significant portion of their lives in the surrounding uplands. The upland habitat along the Colorado River provides essential resources for a variety of reptile species, particularly those that rely on the region's rocky outcrops, sandy soil, and sparse vegetation, such as tortoises and lizards. These species use the sparse vegetation to hide from predators and shelter from extreme temperatures, and the sun-heated rocks provide a surface for basking and regulating body temperature. Fifteen special status amphibians and reptiles predominantly use desert scrub and upland habitat types, including the Mojave desert tortoise (*Gopherus agassizii*), a federally listed threatened species, and the Sonoran desert tortoise (*Gopherus morafkai*), a BLM sensitive species that is also protected under a candidate conservation agreement (FWS 2015; **TA 10, Attachment 1**).

Due to the difficulty in determining whether a tortoise is Mojave or Sonoran based on morphology alone, any tortoises found in the area immediately south and east of the Colorado River in northwest Arizona are listed as similarity of appearance (threatened) under the ESA (FWS 1990). Although the threatened Mojave desert tortoise population's range is defined as north and west of the Colorado River, recent genetic samples collected from tortoises near Lake Mead in Arizona were confirmed to be Mojave desert tortoise rather than Sonoran desert tortoise (FWS 2022). The Mojave and Sonoran desert tortoises are upland-obligate species that use open desert for burrowing and foraging, and they favor creosote bush (*Larrea tridentata*) habitats.

Birds. Desert scrub habitat along the Colorado River provides important nesting sites for several bird species. Additionally, some species actively forage for small mammals, reptiles, and insects within the scrub, often using the terrain's natural features, such as rock outcrops and sandy flats, to hunt and track prey. Desert scrub habitat also serves as habitat for breeding or as seasonal stopovers during migration. Twenty-four special status bird species predominantly use desert scrub and upland habitat; none are federally listed species (**TA 10, Attachment 1**).

Mammals. Small mammals use desert scrub for food and shelter, often using shrubs and low vegetation to hide from predators. The desert scrub also provides a variety of food sources, including grasses, shrubs, and seeds. Mice, rabbits, and other rodents use desert scrub environments to dig burrows to stay cool in the desert heat and for shelter from predators. Large mammals also use desert scrub for foraging and denning. Bats use desert scrub habitats for roosting and reproduction; they roost in rock crevices, abandoned buildings, or beneath the bark of trees found in desert scrub areas. Eleven special status mammal species predominantly use upland habitat; none are federally listed species (**TA 10, Attachment 1**).

TA 10.2 Environmental Consequences

TA 10.2.1 Methodology

This wildlife section relies on the outcomes of the vegetation analysis, the methodology for which is outlined in **Section TA 9.2.1**, Methodology, in **TA 9**, Vegetation Including Special Status Species.

Impact Analysis Area

The analysis area is the same as described in **Section TA 9.2.1**, Impact Analysis Area.

Assumptions

- The impacts analysis does not include upland wildlife species, including special status species, that do not rely directly on the Colorado River or on woody riparian and marsh vegetation influenced by elevation or flows. This is because changes in operations would not impact these species.
- The evaluation of impacts on wildlife, including special status species, is driven by impacts on the vegetation modeling in **Section 3.9** (vegetation analysis based on Decision Making under Deep Uncertainty).

Impact Indicators

These indicators align with the Decision Making under Deep Uncertainty figures in **Section 3.9**.

- For terrestrial wildlife species using marsh habitat, changes in water fluctuations within a single year compared with historical conditions
- For terrestrial wildlife species using woody riparian habitat, changes in water fluctuations in the preceding 5 years compared with historical conditions
- For terrestrial wildlife species using upland habitat, changes in water fluctuations over either the preceding single year or preceding 5 years compared with historical conditions

TA 10.2.2 Issue 1: How would changes in the management of the Colorado River impact terrestrial wildlife species habitat availability, including for special status species?

Lake Powell

As discussed in **TA 9.2** in **TA 9**, Vegetation Including Special Status Species, Lake Powell's surface water elevations fluctuate on a short-term (annual) and long-term (5-year) scale that causes changes in water availability, which results in the establishment, re-establishment, or loss of upland, marsh, and woody riparian habitat over time. Wildlife, including special status species (hereafter referred to as wildlife), that currently use the Lake Powell analysis area have adapted to these changing conditions.

Under all alternatives, modeling indicates a greater range of variability in Lake Powell's surface elevations compared to historic conditions for both marsh and woody riparian habitat in the first decade (2027–2039) (**TA 9**, Vegetation Including Special Status Species, **Figures TA 9-7** and **TA 9-8**). As described in **TA 9.2** in **TA 9**, Vegetation Including Special Status Species, this greater variability would result in changes in the vegetation extent compared to existing conditions, and could decrease vegetation cover. While Lake Powell would continue to support at least some upland, marsh, and woody riparian habitat, the location of where conditions are suitable to support each of these habitat types is likely to change. Areas that currently support marsh, woody riparian, or upland habitat could transition to one of the other habitat types. Side canyons that have been exposed due to lower water levels have had an increase in native vegetation, which likely provides suitable wildlife habitat for a range of wildlife species. An increase in water levels could result in the loss of suitable habitat in these areas.

With increased variability, wildlife would have to adapt to changing habitat availability on a larger scale than under historical conditions. For those species capable of moving long distances, such as large mammals, bats, birds, and some amphibians, reptiles, and invertebrates, this change in habitat availability would likely have less long-term impacts provided that suitable habitat is available within their dispersal or migratory range. This could also result in the range expansion or contraction of some species, including into new reaches, as they adapt to changing habitat availability. For less mobile species, such as some small mammals, amphibians, reptiles, and invertebrates, the transition from one habitat type to another may impact foraging, breeding, or sheltering behaviors, which can impact survival and reproduction. Decreased survival and reproduction on a large-scale can result in a decreased population size. Smaller local populations are more vulnerable to changes in the

environment, which can lead to even greater reductions in population size and an increased risk of the loss of local populations.

During the second (2040–2049) and third (2050–2060) decades, modeling indicates a range of variability more similar to historical conditions for the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative compared to the other alternatives as well as compared to the first decade (2027–2039; **TA 9**, Vegetation Including Special Status Species, **Figures TA 9-7** and **TA 9-8**). This would result in habitat variability similar to what is currently on the landscape; wildlife would need to adapt to changing habitat conditions at the same scale as historical conditions. For all other alternatives, variability would remain high in the second (2040–2049) and third (2050–2060) decades (as indicated by lower percentages of futures meeting the level of performance), and wildlife would continue to need to adapt to changing habitat availability on a larger scale compared to historical conditions.

In addition to the annual and 5-year changes in water elevation, modeling indicates Lake Powell would gradually rise in elevation over time under the Enhanced Coordination and Maximum Operational Flexibility Alternatives in all but the Critically Dry Flow Category (**TA 3.2** in **TA 3**, Hydrologic Resources, **Table TA 3-3 and TA 3.1, Figure TA 3-1s**). This would result in a shift of marsh and woody riparian vegetation along the new shoreline over time. The rise in water elevation would result in a marginal loss of upland habitat, but is not likely to impact wildlife that use marsh or woody riparian habitat, as the shift would be gradual enough for vegetation to continue to re-establish along the new shoreline. Under all other alternatives, modeling indicates water levels would remain the same or decrease in elevation. Similarly, vegetation would re-establish along the lower shoreline as the water elevations change over time. As water elevations lower, the distance to water for upland species would increase. However, given the ability for vegetation to adapt to changing water levels, this change in water elevation, either to a higher elevation under the Enhanced Coordination or Maximum Operational Flexibility Alternatives or to a similar or lower elevation under all other alternatives, is not likely to impact foraging, breeding, or sheltering behaviors for wildlife. Lower water levels can raise the risk of harmful algal blooms. This risk applies to all alternatives except the Enhanced Coordination and Maximum Operational Flexibility Alternatives and under all conditions except for the Critically Dry Flow Category. This could impact wildlife directly through increased toxicity exposure or indirectly through reductions in habitat quality and quantity.

While monarch butterfly primarily use woody riparian habitat for migration, they also use marsh and upland habitat regularly. Given the shifting availability of marsh, woody riparian, and upland habitat, and the ability to use features from all three habitat types, monarch butterflies are likely to be able to find suitable habitat under all alternatives in the Lake Powell analysis area. Species specific impacts will be addressed in future Section 7 ESA biological opinions (BOs).

Glen Canyon Dam to Lake Mead

Similar to Lake Powell, the Glen Canyon Dam to Lake Mead reach experiences fluctuating water levels that cause changes in water availability, which results in the establishment, re-establishment, or loss of upland, marsh, and woody riparian habitat over time. Wildlife in the Glen Canyon Dam to Lake Mead analysis area have had to adapt to these changing conditions in the past.

As shown in **TA 9**, Vegetation Including Special Status Species, **Figures TA 9-9** and **TA 9-10**, the amount of suitable habitat for marsh and woody riparian vegetation across all three sub-reaches of the Glen Canyon Dam to Lake Mead reach is modeled to respond similarly under all alternatives, and the wide interquartile ranges in **TA 9**, Vegetation Including Special Status Species, **Figure TA 9-10** indicates that future acreages of woody riparian habitat are difficult to predict. For marsh and woody vegetation, for all alternatives and sub-reaches, there is less suitable habitat under the Wet and Moderately Wet Flow Categories and more suitable habitat under the Dry and Critically Dry Flow Categories compared to modeled historical conditions. The western Grand Canyon sub-reach has wider interquartile ranges, which suggests greater uncertainty in how vegetation will respond under the various alternatives. Woody vegetation has larger interquartile ranges than marsh vegetation, and therefore greater uncertainty. The amount of habitat available for wildlife species, including southwestern willow flycatcher and yellow-billed cuckoo, is affected primarily by modeled conditions rather than by the alternatives. Species specific impacts will be addressed in future Section 7 ESA BOs.

Similar patterns are apparent for native species richness, proportion of native species cover, and annual total vegetation cover (**TA 9**, Vegetation Including Special Status Species, **Figures TA 9-12**, **TA 9-13**, and **TA 9-14**). Increased species richness, proportion of native species cover, and annual total vegetation cover would be beneficial to wildlife species for foraging and breeding habitat. However, increasing each of these factors is driven by the modeled conditions rather than by the alternatives, with additional habitat available under the Critically Dry Flow Category. This is likely due to encroachment of vegetation into areas exposed by lower water levels.

With potentially decreasing water levels at Lake Powell, the temperature of releases from Glen Canyon Dam could increase, increasing the potential for harmful algal blooms in the Glen Canyon Dam to Lake Mead reach. Harmful algal blooms could impact wildlife directly through increased toxicity exposure or indirectly by reducing habitat quality and quantity (see **TA 6**, Water Quality).

Lake Mead

Similar to Lake Powell, Lake Mead experiences fluctuating water levels on an annual and 5-year time scale that cause changes in water availability, which results in the establishment, re-establishment, or loss of upland, marsh, and woody riparian habitat over time. Wildlife in the Lake Mead analysis area have had to adapt to these changing conditions in the past. As described for Lake Powell, the first decade (2027–2039) exhibits higher variability compared to historical conditions under all alternatives, which would result in changes in habitat availability on a larger scale compared to existing conditions (**TA 9**, Vegetation Including Special Status Species, **Figures TA 9-7** and **TA 9-8**). Marsh and woody riparian vegetation is expected to decrease in response to the increase in variability.

Wildlife species that are capable of moving longer distances would be less likely to be affected by increased variability provided that suitable habitat is available within their dispersal or migratory range. Even for species that are highly mobile, there may be energetic costs to finding suitable habitat in a fragmented landscape if the distance between suitable habitat is outside their typical movement patterns. Increased energetic costs can impact survival and reproduction. Species that are less mobile may experience impacts on foraging, breeding, or sheltering behaviors, which can also

impact survival and reproduction. Decreased survival and reproduction through increased energetic costs while searching for suitable habitat or through impacts on foraging, breeding, or sheltering behaviors can result in a decreased population size. Smaller local populations are more vulnerable to changes in the environment, which can lead to even greater reductions in population size and an increased risk of the loss of local populations.

Unlike Lake Powell, the second (2040–2049) and third (2050–2060) decades exhibit variability similar to historical conditions for the Basic Coordination and Maximum Operational Flexibility Alternatives, rather than the Enhanced Coordination and Maximum Operational Flexibility Alternatives. However, the impacts on wildlife would be the same as described under Lake Powell for the Enhanced Coordination and Maximum Operational Flexibility Alternatives. That is, wildlife would need to adapt to changing habitat conditions at a rate more similar to historical conditions under the Basic Coordination and Maximum Operational Flexibility Alternatives, and would need to adapt to changing habitat conditions on a larger scale for the remaining alternatives.

As described in **TA 9.2** in **TA 9**, Vegetation Including Special Status Species, for all alternatives, Lake Mead elevations could rise, fall, or remain the same compared to existing conditions under all alternatives (**TA 3.2** in **TA 3**, Hydrologic Resources, **Figure TA 3-11**). Similar to Lake Powell, whether the water elevations increase, decrease, or stay the same compared to existing conditions, wildlife would likely be able to adapt to these slower changes and follow the vegetation as it reestablishes along the shoreline. Should water elevations decrease under any of the alternatives, the lowering of the water elevation in Lake Mead could increase the potential for harmful algal blooms, which could impact wildlife directly through increased toxicity exposure or indirectly through reduced habitat quality and quantity.

Listed threatened and endangered species with potential to occur in the Lake Mead analysis area consist of southwestern willow flycatcher, yellow-billed cuckoo, Yuma Ridgway's rail, and Mojave desert tortoise. Impacts have been previously assessed in the LCR MSCP HCP, Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead Final EIS (2007 FEIS; Reclamation 2007), and 2004 SEIS and associated BOs. Additional Section 7 and Section 10 ESA processes are ongoing and additional impacts will be disclosed in future BOs and HCPs. Southwestern willow flycatcher and yellow-billed cuckoo rely on woody riparian habitat, which has modeled increased variability and therefore decreased habitat availability in the first decade (2027–2039) compared to historical conditions. These species are capable of moving long distances to access suitable habitat, although southwestern willow flycatchers exhibit local site fidelity and most readily colonize sites that are near existing breeding sites. The loss of suitable breeding habitat in a river reach could result in southwestern willow flycatchers being slow to recolonize the area even if suitable habitat redevelops. For both species, if water levels fluctuate or rise to the extent that habitat is unavailable, then impacts on nesting may occur. Yuma Ridgway's rails rely on marsh habitat, which may also experience increased variability and therefore decreased habitat availability in the first decade (2027–2039) compared to historical conditions. Yuma Ridgway's rails are also capable of moving long distances to access suitable habitat, although the readiness with which they colonize new areas far from established breeding sites is unclear. For all three species, as variability returns closer to historical conditions in the second (2040–2049) and third (2050–2060) decades for the Basic Coordination and Maximum

Operational Flexibility Alternatives, suitable habitat would likely be available similar to historical conditions.

Mojave desert tortoises rely on upland habitat. While upland habitat availability is modeled to change under all alternatives in each of the decades, Mojave desert tortoises would have suitable habitat available upslope and would be capable of moving away from rising water levels. Survivorship would depend on the quantity and quality of available forage in adjacent areas they would relocate to. As water levels fluctuate, upland habitat loss would be equal to the areas of change unless water fluctuations stabilized and upland vegetation was able to re-establish. Decreased survival and reproduction on a large-scale can result in a decreased population size. Smaller local populations are more vulnerable to changes in the environment, which can lead to even greater reductions in population size and an increased risk of the loss of local populations.

As described for Lake Powell, monarch butterflies are likely to find suitable habitat under each alternative and are unlikely to be affected.

Hoover Dam to the SIB

Similar to Lake Powell and Lake Mead, the Hoover Dam to the SIB reach experiences fluctuating water levels on an annual and 5-year timescale that causes changes in water availability, which results in the establishment, re-establishment, or loss of upland, marsh, and woody riparian habitat over time. Wildlife in the Hoover Dam to SIB analysis area had to adapt to these changing conditions in the past.

The LCR MSCP HCP and subsequent BOs set habitat creation goals to mitigate for predicted impacts from covered river operations including flow reductions, water delivery and diversion, changes in point of diversion, generation of hydropower, and operation and maintenance activities in the LCR MSCP planning area (Reclamation 2004; FWS 2005, 2018, 2022, 2024). A summary of the habitat creation goals and habitat created toward those goals as of 2025 (LCR MSCP 2025) are included as **Table TA 10-1**. Habitat creation goals assumed the predicted habitat impacts from reductions in flow and changes in points of diversion up to 2.083 million acre-feet (maf) per year may occur annually until 2055 and would be permanent, even if impacts never actually occur. Habitat would be created to replace it in LCR MSCP conservation areas. This includes a prediction that all existing cottonwood-willow land cover supported by the river and river connected groundwater would be lost due to flow-related covered activities (with the exception of habitat at Topock Marsh and Lake Havasu). Impacts to marsh from flow reductions from 2.083 maf per year to 3 maf per year were predicted to be short term in duration and the habitat would recover when inundated again (FWS 2024).

These habitat creation goals are the minimum amount of land cover to be created to meet the habitat requirements for the listed and unlisted species covered by the program. Habitat created by the LCR MSCP will be designed in an integrated mosaic and managed for more than one covered species, including habitat elements for each species.

Table TA 10-1
Summary of Habitat Creation Goals and Habitat Acres Created from Lake Mead to the SIB

Habitat Type	Habitat Creation Goal[1]	Acres Created through 2025[2]
Marsh	568	362
Woody Riparian (cottonwood-willow only)	5,940	4,954
Woody Riparian (honey mesquite only)	1,320	2,046
Woody Riparian (total)	7,260	7,000

Source: [1]Reclamation 2004; FWS 2005, 2022, 2024 [2]LCR MSCP 2020, 2025

Table TA 10-2 and **Table TA 10-3** demonstrate the amounts of acres affected, habitat created, and habitat creation commitments. Although it is unknown exactly how many acres of habitat will be affected over the next 30 years, referencing the amounts of acres affected over the last 20 years, the amount of habitat present in the reaches (**TA 9**, Vegetation Including Special Status Species, **Table TA 9-1**), and how those acres were mitigated, allows for a greater understanding of future implications. Future impacts and habitat creation commitments will be included in ESA Section 7 BOs and Section 10 HCPs.

Under all alternatives, all LCR MSCP conservation areas would retain their water entitlements. During shortage conditions, conservation areas with lower priority water rights (4th to 6th level priorities) may not receive their deliveries. Conservation areas are managed for the appropriate habitat type considering their water priority level and historic shortages decisions. During periods of shortage, there may be a reduction in habitat quality for areas with dense overstory and understory. When insufficient water is available, regardless of cause, to maintain established land cover types as habitat for one or more covered species, the Program Manager would coordinate with the FWS to prioritize the distribution of available water among created habitats to ensure that the greatest benefits for covered species would be provided. As water becomes available, the conservation areas would be managed to improve conditions. Currently, the Cibola Valley Conservation Area is the only LCR MSCP conservation area with 4th to 6th level priority water rights. Impacts to habitat quality if 4th to 6th level priority water rights may be minimized if groundwater is available to the roots of some or all of the vegetation. Current depth to groundwater in the Cibola Valley Conservation Area is approximately 10 feet.

As described for Lake Powell and Lake Mead, the first decade (2027–2039) exhibits high levels of variability compared to historical conditions for all alternatives, which would result in changes in habitat availability on a larger scale compared to existing conditions, especially for woody riparian habitat (**TA 9**, Vegetation Including Special Status Species, **Figures TA 9-17** and **TA 9-18**). Marsh and woody riparian habitat are modeled to decrease in the first decade in response to increased variability. Similar to Lake Mead, wildlife species could experience decreased population levels or localized population loss if the increased variability results in increased energy expenditure to find suitable habitat or impacts foraging, breeding, and sheltering behaviors.

Table TA 10-2
Summary of Federal and Nonfederal Flow-Related Affected Acres Included in 2004, 2018, 2022, and 2024 HCPs and BOs

Species	Federal and Nonfederal Flow-Related Impacts (acres) 2004				
Section 7 consultation	2004 BO and HCP[1]	Additional Impacts 2018 BA, BO and HCP[2]	Additional Impacts 2022 BA and BO[3]	Additional Impacts 2024[4] BA and BO	Total
Yuma Ridgway's rail	133	N/A	7	84[5]	224
Southwestern willow flycatcher	1,784	N/A	0[6]	0[7]	1,784
Yellow-billed cuckoo	1,425	N/A	0[8]	0[9]	1,420
Mojave desert tortoise	0	N/A	0[10]	0	0
Northern Mexican gartersnake	N/A	1081	7	84	1,172

[1] 2004 BO Table 2-56
[2] 2018 BO Tables 4-5 and 5-5 (same acres shared by Federal and Non-Federal assessments.
[3] 2022 BA
[4] 2025 BA
[5] The proposed action may have additional, temporary impacts on 16 acres of potential marsh habitat at Topock Marsh due to delayed completion of projects related to full implementation of AMM2, which was designed to avoid impacts of flow-related covered activities on covered species habitats at Topock Marsh (see Section 5.5.1.1 of LCR MSCP 2004b). Implementation of conservation measures, including creation of 41 acres of new marsh habitat and additional avoidance and minimization measures, will offset the effects of reduction in flow.
[6] Almost all existing and potential habitat for the southwestern willow flycatcher that will be affected was previously analyzed, incidental take was issued, and mitigation was established under the LCR MSCP (LCR MSCP 2004a, FWS 2005); therefore, no additional impacts are anticipated beyond those already assessed.
[7] Almost all existing and potential habitat for the southwestern willow flycatcher that will be affected was previously analyzed (see Section 4), incidental take was issued, and mitigation was established under the LCR MSCP (Reclamation 2004, FWS 2005). An exception to this includes Topock Marsh, which was excluded from impacted habitat based on the implementation of AMM2. Increased reduction in flow may temporarily affect 10.9 acres of southwestern willow flycatcher breeding sites at Topock Marsh due to delayed completion of projects related to full implementation of AMM2, which was designed to avoid impacts of flow-related covered activities on covered species habitats at Topock Marsh (see Section 5.5.2.1 of LCR MSCP 2004b). Implementation of avoidance and minimization conservation measures and continued implementation of the LCR MSCP will offset the effects of reduction in flow.
[8] The original LCR MSCP analysis assumed the loss of almost all cottonwood-willow existing and potential habitat for the western yellow-billed cuckoo that will be affected was previously analyzed (see Section 4), incidental take was issued, and mitigation was established under the LCR MSCP (2005); therefore, no additional impacts are anticipated beyond those already assessed.
[9] Almost all cottonwood-willow existing and potential habitat for the western yellow-billed cuckoo that will be affected was previously analyzed (see Section 4), incidental take was issued, and mitigation was established under the LCR MSCP (2005). An exception to this includes Topock Marsh which was excluded from impacted habitat based on the implementation of AMM2. Increased reduction in flow may temporarily affect 133 acres of potential cottonwood-willow habitat at Topock Marsh due to delayed completion of projects related to full implementation of AMM2, which was designed to avoid impacts of flow-related covered activities on covered species habitats at Topock Marsh (see Section 5.5.14.1 of LCR MSCP 2004b). Implementation of avoidance and minimization conservation measures and continued implementation of the LCR MSCP will offset the effects of reduction in flow
[10] Is not affected by flow related covered activities.

Table TA 10-3
ESA Section 7 Habitat Creation Commitments and Habitat Created 2005–Present

Section 7 Habitat Creation Commitments (acres) - Conservation/Mitigation Commitments					LCR MSCP Land Cover Created for the Species (between 2005-2025) (acres)
2004 BO	2018 BO	2022 BO	2024 BO	Total	All[11] (created/creditable)
512	N/A	15	41	568	362
4050	N/A	0	0	4050	945
4050	N/A	0	0	4050	2553
230 acres of existing habitat protection[12]	N/A	0	0	230	230 acres purchased

In the later decades (2040–2049 and 2050–2060), for the Hoover Dam to SIB reach, all alternatives meet the minimum level of performance in 78 percent or more of futures for marsh habitat (**TA 9**, Vegetation Including Special Status Species, **Figure TA 9-17**). For woody riparian habitat, the Basic Coordination Alternative is the most robust. The impacts on wildlife would be the same as described for Lake Powell and Lake Mead; wildlife would need to adapt to changing habitat conditions at a rate more similar to historical conditions under the Basic Coordination Alternative and would need to adapt to changing habitat conditions on a larger scale for the remaining alternatives. This could impact wildlife through changes in foraging, breeding, or sheltering behaviors, which can impact survival and reproductive rates of individuals. Decreased survival and reproduction on a large-scale can have population-level impacts.

Under all alternatives, flows from Hoover Dam to the SIB are modeled to decrease under the Average and Dry Flow Categories (**Table TA 3-21** and **Figure TA 3-27**, **TA 3.2** in **TA 3**, Hydrologic Resources). As described in **TA 9.2** in **TA 9**, Vegetation Including Special Status Species, a recent change analysis found that marsh vegetation decreased from 2000 to 2024 (RiverRestoration.org 2025). With a higher level of variability and decreased releases, marsh vegetation is modeled to continue to decrease over time and be replaced by either upland habitat or woody riparian habitat. Wildlife species that use marsh habitat in the Hoover Dam to SIB reach are modeled to experience greater levels of habitat loss than under historical conditions if future conditions are dry or average. This habitat loss could impact wildlife's ability to forage, breed, nest, and shelter in the area, causing them to relocate or possibly impact survival rates. The potential for decreased water levels in Lake Mead could also result in increased temperatures released from Hoover Dam. This could increase the potential for harmful algal blooms, which impact marsh and woody riparian vegetation, and could impact wildlife directly through increased toxicity exposure or indirectly through reductions in habitat quality and quantity.

[11] Lower Colorado River Multi-Species Conservation Program. 2025. Final Implementation Report, Fiscal Year 2026 Work Plan and Budget, Fiscal Year 2024 Accomplishment Report. Bureau of Reclamation, Boulder City, Nevada. Table 1-8

[12] Net loss in habitat is fully mitigated by protecting 230 acres of desert tortoise habitat in accordance with mitigation requirements in the document entitled "Compensation for Desert Tortoise" (Desert Tortoise Compensation Team 1991).

Federal, state, and tribal managed habitat areas, such as Cibola National Wildlife Refuge, depend on water from the Colorado River to ensure functional habitat for wildlife. If water in the river drops below the level at which water is able to properly flow through diversion structures or pumps are able to function, there may be impacts on habitat unless another method is used to transport water to the managed habitat areas. If a prolonged period of dryness occurs, woody riparian and marsh vegetation may begin to desiccate; however, the extent to which this will occur is unknown.

Listed threatened and endangered wildlife species that have the potential to occur in the Hoover Dam to the SIB analysis area are southwestern willow flycatcher, yellow-billed cuckoo, Yuma Ridgway's rail, northern Mexican gartersnake, and Mojave desert tortoise. Impacts have been previously assessed in the LCR MSCP HCP, 2007 FEIS, and 2004 SEIS and associated BOs. Additional Section 7 and Section 10 ESA processes are ongoing and additional impacts will be disclosed in future BOs and HCPs. Migrant and transient southwestern willow flycatchers and yellow-billed cuckoos could be affected by the general availability of woody riparian vegetation in which they forage and shelter, which is modeled to decrease in the first decade (2027–2039) under all alternatives (**TA 9**, Vegetation Including Special Status Species, **Figures TA 9-17** and **TA 9-18**). In the second (2040–2049) and third (2050–2060) decades, decreased cover of woody riparian vegetation is modeled under all alternatives, but to a lesser extent under the Basic Coordination Alternative, Continued Current Strategies Comparative Baseline, and Representative Preferred Alternative (**TA 9**, Vegetation Including Special Status Species, **Figures TA 9-12** and **TA 9-13**). Breeding southwestern willow flycatchers have been present in recent years at Topock Marsh, while breeding yellow-billed cuckoos are found in LCR MSCP conservation areas and other restored habitat. Woody riparian vegetation in these areas could be affected by the alternatives if they result in shortage allocation reductions of water deliveries. Alternatives that enhance habitat near established populations would benefit species such as the southwestern willow flycatcher that show fidelity to breeding sites. Reductions in water allocations to the conservation areas could reduce the amount of woody riparian habitat available for yellow-billed cuckoo breeding.

Decreased cover of marsh vegetation may occur in the first decade (2027–2039) for all alternatives, which could affect Yuma Ridgway's rail by reducing the amount of habitat available for breeding, feeding, and sheltering. Under all alternatives, marsh vegetation may re-establish in the later decades (2040–2049 and 2050–2059) to an extent similar to recent conditions. However, under dry to average future conditions, water is modeled to decrease over time under all alternatives, which could reduce the amount of habitat available for Yuma Ridgway's rails for breeding, feeding, and sheltering.

The most recent confirmed northern Mexican gartersnake sightings have been in Topock Marsh on the Havasu National Wildlife Refuge. Marsh vegetation at Topock Marsh could be affected by the alternatives if they result in shortage allocation reductions of water deliveries. Northern Mexican gartersnakes are less capable of moving long distances. Should a northern Mexican gartersnake be present in marsh habitat that experiences higher levels of variability that results in the loss of that marsh habitat, as is possible in the first decade (2027–2039) under all alternatives, northern Mexican gartersnakes may not be able to find suitable replacement habitat, which could cause local population loss. In the second (2040–2049) and third (2040–2049) decades, all alternatives would have conditions more similar to historical conditions, which may support northern Mexican

gartersnakes in a condition more similar to existing conditions. Mojave desert tortoise are likely to be able to move to upland habitat as the habitat conditions change over time.

Water levels are modeled to decrease under all alternatives under Average and Dry Flow Categories. This may result in additional upland habitat for Mojave desert tortoise. Similar to Lake Powell and Lake Mead, monarch butterfly is likely to find suitable habitat under each alternative and are unlikely to be affected.

TA 10.2.3 Summary Comparison of Alternatives

Changes in reservoir elevations and flow variability can alter the extent and location of marsh, woody riparian, and upland habitats that support terrestrial wildlife, including special status species. These habitat shifts affect wildlife by changing the availability of areas used for foraging, breeding, sheltering, and migration. While highly mobile species may relocate to suitable habitat, less mobile species may experience reduced survival or reproduction if habitat availability declines or becomes fragmented, which can reduce population sizes or lead to the loss of local wildlife.

For Lake Powell, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would result in wildlife habitat availability most similar to historical conditions (**TA 9**, Vegetation Including Special Status Species, **Table TA 9-1**). The Maximum Operational Flexibility Alternative would also result in wildlife habitat availability most similar to historical conditions for Lake Mead. However, for Hoover Dam to the SIB, the Maximum Operational Flexibility and Enhanced Coordination Alternatives would result in wildlife habitat availability least similar to historical conditions with subsequent impacts on wildlife foraging, breeding, or sheltering behaviors, which can reduce reproduction and survival of individuals. Similarly, the Basic Coordination Alternative would result in wildlife habitat least similar to historical conditions for Lake Powell, but would be closest to historical conditions for Lake Mead and Hoover Dam to the SIB. Therefore, no single alternative would result in wildlife habitat availability similar to historical conditions across all reaches. For all reaches, multiple alternatives provide variability more similar to historical conditions than the Continued Current Strategies Comparative Baseline except for the Hoover Dam to SIB reach, where only the Basic Coordination Alternative would result in variability more similar to historical conditions for woody riparian vegetation. This suggests that a change in management from current strategies would benefit a large portion of the analysis area, but would not benefit woody riparian vegetation in the Hoover Dam to SIB reach unless the Basic Coordination Alternative was selected.

Under all alternatives, the first decade (2027–2039) would experience more variability, which would likely result in a reduction of marsh and woody riparian habitat and therefore impacts on wildlife compared to historical conditions. All alternatives see conditions return to closer to historical conditions in the second (2040–2049) and third (2050–2060) decades, which would likely result in wildlife habitat reestablishing to a similar extent. Where variability eliminates or prevents establishment of marsh, woody riparian, or upland habitat, there may be a shift to one of the other habitat types.

For the Glen Canyon Dam to Lake Mead reach, the alternative that would result in wildlife habitat availability most similar to historic conditions depends strongly on flow categories. Under the Dry

Flow Category and Critically Dry Flow Category, some differences among the alternatives emerge, presumably because there are greater differences in the lowest flows, the median flows, and peak flows under those conditions. However, across all alternatives, all sub-reaches, and all evaluated criteria (suitable habitat area, native species richness, proportion native species cover, and annual total vegetation cover), the interquartile ranges of the alternatives often overlap. When the interquartile ranges overlap, it is difficult to say whether one alternative is truly different from another. Therefore, no single alternative emerged as the best or worst for retaining wildlife habitat similar to historic conditions.

For all reaches, a decrease in water elevation or flow could increase water temperatures, which would increase the potential for harmful algal blooms. Harmful algal blooms can cause direct impacts on wildlife through increased toxicity or indirect impacts through decreases in habitat quality and quantity. The Enhanced Coordination and Maximum Operational Flexibility Alternatives would have increased water levels in Lake Powell in all but the Critically Dry Flow Category, which would result in the lowest potential for a harmful algal bloom. For Lake Mead, all alternatives may result in a lowered elevation, which could increase the potential for a harmful algal bloom in Lake Mead and in the Hoover Dam to SIB reach.

Special Status Wildlife Species List

This page intentionally left blank.

TA 10 Attachment 1. Special Status Wildlife Species

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Birds							
American peregrine falcon (*Falco peregrinus*)	Bureau of Land Management (BLM) Arizona (AZ), BLM Nevada (NV)	Woody Riparian	X	X	X	X	Yes, this species forages along the Colorado River corridor and could be affected by reductions in bat and bird populations associated with loss of riparian and marsh habitat (NDOW 2025a).
American white pelican (*Pelicanus erythrorhynchos*)	BLM Utah (UT)	Marsh	X	X	X	X	No, this species is migratory and does not breed in the analysis area (Van Tatenhove et al. 2025).
Arizona Bell's vireo (*Vireo bellii arizonae*)	BLM California (CA), BLM NV, LCR MSCP	Woody Riparian	X	X	X	X	Yes, the analysis area is within the spring and summer range of this species (LCR MSCP 2016).
Arizona grasshopper sparrow (*Ammodramus savannarum ammolegus*)	BLM AZ	Upland	—	X	X	X	No, this species is a migrant and does not breed within the analysis area. It would not be affected by any alternative (NatureServe 2025a).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Bald eagle (*Haliaeetus leucocephalus*)	BLM AZ, BLM NV, BLM UT	Woody Riparian	X	X	X	X	Yes, this species is present during winter months (November-February) in the Grand Canyon. They are present in winter and spring at Lake Mead, Lake Mohave and Lake Havasu (Buehler 2022).
Bank swallow (*Riparia riparia*)	BLM CA, BLM NV	Marsh	—	X	—	X	No, this species is a migrant that does not breed in the analysis area (Garrison and Turner 2020).
Bendire's thrasher (*Toxostoma bendirei*)	BLM CA, BLM NV, CA Species of Concern (CSC)	Upland	—	—	—	X	Yes, this species forages in riparian habitat (England & Laudenslayer 2020).
Black swift (*Cypseloides niger*)	BLM UT	Upland	X	—	—	—	No, this species forages over diverse habitat types. It nests behind waterfalls, which will not be affected by any alternative (Gunn et al. 2023).
Black-chinned sparrow (*Spizella atrogularis*)	BLM NV	Upland	X	X	—	—	No, this species is found in upland habitats such as desertscrub and pinyon-juniper woodlands, which will not be impacted by any alternative (Pandolfino et al. 2024).
Black-throated gray warbler (*Setophaga nigrescens*)	BLM NV	Woody Riparian	X	X	X	X	Yes, this species overwinters in cottonwood-willow habitat (Guzy and Lowther 2020).
Brewer's sparrow (*Spizella breweri*)	BLM NV	Upland	X	X	X	X	No, this species is found in diverse upland habitats which will not be impacted by any alternative (Rotenberry et al. 2020).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Broad-tailed hummingbird (*Selasphorus platycercus*)	BLM NV	Woody Riparian	—	X	—	—	Yes, this species breeds in riparian corridors in northern Arizona (Camfield et al. 2020).
Brown-crested flycatcher (*Myiarchus tyrannulus*)		Woody Riparian	—	X	X	X	Yes, the analysis area is within the breeding range of this species (Cardiff and Dittmann 2020).
Burrowing owl (*Athene cunicularia*)	BLM UT, BLM NV	Upland	X	—	X	X	Yes, this species utilizes desert habitat for foraging and nesting (Poulin et al. 2020).
Cactus ferruginous pygmy owl (*Glaucidium brasilianum cactorum*)	BLM AZ, threatened	Upland	—	—	—	—	No, the range for this species is outside of areas affected by any alternative (FWS 2025a).
California black rail (*Laterallus jamaicensis coturniculus*)	BLM AZ, BLM CA, LCR MSCP	Marsh	—	—	—	X	Yes, this species nests in marsh areas and the analysis area is within the species' range (Eddleman et al. 2020).
California brown pelican (*Pelecanus occidentalis californicus*)	BLM CA	Marsh	—	X	—	X	No, this species is rarely detected and does not breed in the analysis area (NPS 2022).
California condor (*Gymnogyps californianus*)	BLM AZ, endangered	Upland	X	X	—	—	Yes, this species breeds and nests within the Grand Canyon (FWS 2025b).
Cassin's finch (*Haemorhous cassinii*)	BLM NV	Upland	X	X	—	—	No, this species is found in pinyon-juniper and mixed-conifer forests which will not be affected by any alternative (Hahn 2020).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Clark's grebe (*Aechmophorus clarkii*)	ASC	Marsh	—	—	X	X	Yes, this species breeds in open marshes and forages in open water in reservoirs (LaPorte et al. 2020).
Common nighthawk (*Chordeiles minor*)	BLM NV	Upland	X	X	—	—	No, this species breeds in uplands which will not be affected by any alternative (Cornell 2025).
Crissal thrasher (*Toxostoma crissale*)	BLM CA, BLM NV	Woody Riparian	—	X	—	X	Yes, the analysis area is within the year-round range for this species (Bringham et al. 2020).
Elf owl (*Micrathene whitneyi*)	BLM CA, LCR MSCP	Woody Riparian	—	—	—	X	Yes, this species has been observed along and near Lake Havasu, Bill Williams River Delta, and near Yuma (McKernan and Braden 2002; Wise-Gervais 2005; MSCP 2010; Henry et al. 2020).
Ferruginous hawk (*Buteo regalis*)	BLM UT, BLM NV	Upland	X	X	—	—	No, this species forages over diverse habitat types. It nests on exposed cliffs or solitary trees or infrastructure, which will not be affected by any alternative (Ng et al. 2020).
Flammulated owl (*Psiloscopis flammeolus*)	BLM NV	Upland	—	X	—	—	No, this species is found in conifer forests which will not be affected by any alternative (Linkhart and McCallum 2020).
Gila woodpecker (*Melanerpes* uropygialis)	BLM CA, LCR MSCP	Woody Riparian	—	—	—	X	Yes, the analysis area is in the range of this species (Edwards and Schnell 2020).
Gilded flicker (*Colaptes chrysoides*)	BLM AZ, BLM NV, BLM CA	Woody Riparian	—	—	—	X	Yes, this species will nest in willow or cottonwood which may be affected (Moore et al. 2020).
Golden eagle (*Aquila chrysaetos*)	BLM UT, BLM NV, BLM AZ	Upland	X	X	X	X	Yes, although this species is rarely detected nesting (iNaturalist 2025a).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Grace's warbler (*Setophaga graciae*)	BLM NV	Upland	X	X	—	—	No, this species is found in conifer forests which will not be affected by any alternative (Staicer and Guzy 2020).
Great Basin willow flycatcher (*Empidonax traillii adastus*)	BLM NV	Woody Riparian	—	—	X	X	No, this species does not nest in the analysis area (NDOW 2025b).
Least bittern (*Ixobrychus exilis*)	BLM NV, LCR MSCP	Marsh	—	X	X	X	Yes, this species utilizes marsh habitat and breeds within the analysis area (FWS 2012; Poole et al. 2024).
LeConte's thrasher (*Toxostoma lecontei*)	BLM AZ, BLM NV	Upland	—	—	X	X	No, this species utilizes dry grassland and desert habitat for foraging and nesting, which will not be affected by any alternative (Sheppard 2020)
Lewis's woodpecker (*Melanerpes lewis*)	BLM NV	Woody Riparian	X	X	X	X	Yes, this species is found in riparian areas, and its range is within the analysis area (Vierling 2020).
Loggerhead shrike (*Lanius ludovicianus*)	CSC, BLM NV	Upland	X	X	X	X	No, this species is found in uplands (shrublands, desertscrub, grasslands) which will not be affected by any alternative (Yousef 2020).
Long-billed curlew (*Numenius americanus*)	BLM NV	Marsh	—	—	—	X	Yes, this species breeds in grasslands but migrates and overwinters in riverine marshes including lower Colorado River (Dugger and Dugger 2020).
Long-eared owl (*Asio otus*)	BLM NV	Woody Riparian	X	X	X	X	Yes, this species overwinters in willow and tamarisk which may be affected (Marks et al. 2020).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Lucy's warbler (*Vermivora luciae*)	BLM CA	Woody Riparian	X	X	—	X	Yes, although this species is rare, it has been observed in Lake Mead Recreation area and breeds in tamarisk which may be affected (Johnson et al. 2020).
Mountain plover (*Charadrius montanus*)	BLM CA	Upland	—	—	—	X	Yes, this species is present in the analysis area (FWS 2025c).
Northern goshawk (*Accipiter gentilis*)	BLM AZ	Upland	—	X	—	—	No, this species utilizes upland forested habitat with high canopy cover for foraging and nesting; this habitat will not be affected by any alternative (NDOW 2025c).
Northern harrier (*Circus cyaneus*)	CSC	Marsh		X	X	X	Yes, this species may be found in marshes during nonbreeding season (Smith et al. 2020).
Olive-sided flycatcher (*Contopus cooperi*)	BLM NV	Woody Riparian	X	X	X	X	Yes, this species uses riparian habitat during migration and its range is within the analysis area (Altman and Sallabanks 2020).
Phainopepla (*Phainopepla nitens*)	BLM NV	Woody Riparian	—	X	X	X	Yes, this species uses honey mesquite riparian habitat (Chu and Walsberg 2020).
Pinyon jay (*Gynorhinus cyanocephalus*)	BLM NV	Upland	X	X	—	—	No, this species is found in upland pinyon-juniper habitat which will not be affected by any alternative (Johnson and Sadoti 2023).
Sagebrush sparrow (*Atrtemisiospiza nevadadensis*)	BLM NV	Upland	X	X	X	X	No, this species is found in upland habitat which will not be affected by any alternative (Martin et al. 2025).
Sage thrasher (*Oreoscoptes montanus*)	BLM NV	Upland	X	X	X	X	No, this species is found in upland habitat which will not be affected by any alternative (Reynolds et al. 2020).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Scott's oriole (*Icterus parisorum*)	BLM NV	Upland	X	X	—	—	No, this species is found in upland oak/scrub habitat which will not be affected by any alternative (Flood 2020).
Short-eared owl (*Asio flammeus*)	BLM NV	Marsh	—	—	X	X	Yes, this species winters in marsh habitat which may be affected (Wiggins et al. 2020).
Sonoran yellow warbler (*Dendroica petechia sonorana*)	LCR MSCP	Woody Riparian	—	—	X	X	Yes, this species' breeding range exists in the lower Colorado River valley (Shuford and Gardali 2008).
Southwestern willow flycatcher (*Empidonax traillii extimus*)	BLM AZ, BLM CA, BLM NV, LCR MSCP, Endangered	Woody Riparian	—	X	X	X	Yes, this species is found in riparian areas across the southwest including Lake Mead and the lower Colorado River (FWS 2025d).
Summer tanager (*Piranga rubra*)	LCR MSCP	Woody Riparian	—	X	X	X	Yes, this species is found in the Colorado River area during breeding season (Audubon 2025a).
Swainson's hawk (*Buteo swainsoni*)	BLM CA, BLM NV	Upland	—	X	—	X	No, this species forages over diverse habitat types which will not be affected by any alternative (Bechard et al. 2020).
Tricolored blackbird (*Agelaius tricolor*)	BLM CA	Marsh	—	—	—	—	No, the analysis area is outside of the species' range (Audubon 2025b).
Verdin (*Auriparus flaviceps*)	BLM NV	Woody Riparian	—	—	X	X	Yes, this species nests in honey mesquite in the riparian woodland along the lower Colorado River (Webster 2020).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Vermilion flycatcher (*Pyrocephalus rubinus*)	LCR MSCP, CSC	Woody Riparian	—	—	X	X	Yes, this species utilizes riparian habitat and has been observed in Lake Mead Recreation area (NPSpecies 2011a) and in the Lower Colorado Region, including at Cibola National Wildlife Refuge, Region 5, and Region 12 (LCR MSCP 2021).
Virginia's warbler (*Leiothlypis virginiae*)	BLM NV	Upland	—	X	X	—	No, this species is found in upland pinyon-juniper habitat which will not be affected by any alternative (Audubon 2025c).
Western snowy plover (*Charadrius nivosus nivosus*)	BLM NV	Marsh	—	—	X	—	Yes, this species nested at the Overton Arm of Lake Mead in 2007 and often nests at the Salton Sea (FWS 2025e).
Western yellow-billed cuckoo (*Coccyzus americanus*)	BLM AZ, BLM CA, BLM NV, LCR MSCP, Threatened	Woody Riparian	—	X	X	X	Yes, this species occupies dense thickets along streams and marshes and has been observed along the Little Colorado River (Tracy and Squibb 2022).
White-tailed kite (*Elanus leucurus*)	BLM CA	Marsh	—	—	—	X	Yes, this species is present in the analysis area (CDFW 2025a).
Yellow-breasted chat (*Icteria virens*)	CSC	Woody Riparian	—	X	X	X	Yes, this species is found at Lake Mead, the Salton Sea, the Little Colorado River, and throughout the lower Colorado River region (LCR MSCP 2021; Thompson and Eckerle 2022).
Yuma Ridgway's rail (*Rallus obsoletus yumaniensis*)	BLM AZ, BLM CA, BLM NV, LCR MSCP, Endangered	Marsh	—	Historic	X	X	Yes, this species is a year-round resident of the Colorado and Gila River (Audubon 2025d).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Mammals							
Allen's big-eared bat (*Idionycteris phyllotis*)	BLM AZ, BLM NV, BLM UT	Woody Riparian	X	X	X	—	Yes, this species inhabits riparian areas above 3,000 feet (Carpenter et al. 2021; NDOW 2025d).
Arizona myotis (*Myotis occultus*)	BLM AZ, CSC	Marsh	X	X	X	X	Yes, while typically found at higher elevations (>1830 m), this species has been found in low elevation reaches of the Colorado and Verde rivers in Arizona (Carpenter et al. 2021; USFS 2014).
Big brown bat (*Eptesicus fuscus*)	BLM NV	Woody Riparian	X	X	X	X	Yes, the analysis area is within the range of this species (Carpenter et al. 2021; NPS 2017).
Big free-tailed bat (*Nyctinomops macrotis*)	BLM NV, CSC	Woody Riparian	X	X	X	X	Yes, the analysis area is within the range of this species (Carpenter et al. 2021; NatureServe 2025b).
Bighorn sheep (*Ovis* spp.)	BLM CA, BLM NV	Woody Riparian	X	X	X	X	Yes, these species utilize the Colorado River and associated reservoirs for water (NDOW 2025e).
California leaf-nosed bat (*Macrotus californicus*)	BLM AZ, BLM NV, LCR MSCP	Woody Riparian	—	X	X	X	Yes, this species can be found in the Colorado River valley (iNaturalist 2025b).
California myotis (*Myotis californicus*)	BLM NV	Woody Riparian	X	X	X	X	Yes, the analysis area is within the range of this species (iNaturalist 2025c).
Canyon bat (*Parastrellus hesperus*)	BLM NV	Woody Riparian	X	X	X	X	Yes, the analysis area is within the range of this species (Carpenter et al. 2021, NABat*).
Cave myotis (*Myotis velifer*)	BLM AZ, BLM NV, CSC	Woody Riparian	X	X	X	X	Yes, however, this species has not been confirmed between Glen Canyon Dam and Lake Mead (iNaturalist 2025d).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Colorado River cotton rat (*Sigmodon arizonae plenus*)	LCR MSCP	Marsh	—	—	X	X	Yes, this species is often found near rivers and their floodplains and lakes and ponds (NatureServe 2025c).
Dark kangaroo mouse (*Microdipodops megacephalus*)	BLM NV	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternative (NDOW 2025f).
Desert kangaroo rat (*Dipodomys deserti*)	BLM NV	Woody Riparian	—	—	X	X	No, this species is found in upland desertscrub habitat which will not be affected by any alternative (NatureServe 2025d).
Desert pocket mouse (*Chaetodipus penicillatus sobrinus*)	MSCP, BLM NV	Upland	—	—	X	X	Yes, this species occurs most often in soft alluvian, sandy, or silty soils along stream bottoms, desert washes, and valleys (ADW 2025*).
Fringed myotis (*Myotis thysanodes*)	BLM UT, BLM NV	Woody Riparian	X	X	X	—	Yes, this species has been observed in Lake Mead Recreation area (Carpenter et al. 2021; NPSpecies 2011b).
Greater western mastiff bat (*Eumops perotis californicus*)	CSC, BLM NV	Upland	X	X	—	X	Yes, the analysis area is within the range of this species (Carpenter et al. 2021; NatureServe 2025e).
Hoary bat (*Lasiurus cinereus*)	BLM NV	Upland	X	X	X	X	Yes, the analysis area is within the range of this species (Carpenter et al. 2021; NatureServe 2025f).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Houserock Valley chisel-toothed kangaroo rat (*Dipodomys microps leucotis*)	BLM AZ	Upland	—	—	—	—	No, this species utilizes dry and desert habitat types for foraging; these will not be affected by any alternative (NatureServe 2025g).
Inyo shrew (*Sorex tenellus*)	BLM NV	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternative (NatureServe 2025h).
Kawich pocket gopher (*Thomomys bottae brevidens*)	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (GBIF Secretariat 2024).
Kit fox (*Vulpes macrotis*)	BLM UT	Upland	X	X	X	X	Yes, this species has been observed at Lake Mead (NPSpecies 2011c).
Little brown bat (*Myotis lucifugus*)	BLM NV	Woody Riparian	X	X	X	X	Yes, this species feeds in woody riparian habitats and the analysis area is within its range (Carpenter et al. 2021; Lausen et al. 2008).
Long-eared myotis (*Myotis evotis*)	BLM CA, BLM NV	Woody Riparian	X	X	—	X	Yes, this species is primarily found at higher elevations but has been detected along the Colorado River corridor (Carpenter et al. 2021; NatureServe 2025i).
Long-legged myotis (*Myotis volans*)	BLM NV	Upland	—	—	—	—	No, this species is found in coniferous forests which will not be affected by any alternative (NatureServe 2025j).
Merriam's shrew (*Sorex merriami*)	BLM NV	Upland	—	—	—	—	No, this species inhabits upland grasslands and desertscrub which will not be affected by any alternative (NatureServe 2025k).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Mexican free-tailed bat (*Tadarida brasiliensis*)	BLM NV, CSC	Woody Riparian	X	X	X	X	Yes, this species is present at Lake Mead Recreation Area (Carpenter et al. 2021; NatureServe 2025l).
Mexican long-tongued bat (*Choeronycteris mexicana*)	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (BCI 2025a).
Pallid bat (*Antrozous pallidus*)	BLM NV, CSC	Woody Riparian	X	X	X	X	Yes, the analysis area is within the range of this species (Carpenter et al. 2021; NatureServe 2025m*).
Palm Springs pocket mouse (*Perognathus longimembris bangsi*)	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (NatureServe 2025n).
Palm Springs round-tailed ground squirrel (*Xerospermophilus tereticaudus chlorus*)	BLM CA	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (NatureServe 2025o).
Panamint kangaroo rat (*Dipodomys panamintus*)	BLM NV	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (NatureServe 2025p).
Pocketed freetail bat (*Nyctinomops femorosaccus*)	CSC	Woody Riparian	—	—	—	X	Yes, this species may utilize woody riparian habitats along the Little Colorado River to feed (ADW 2025*).
Silver-haired bat (*Lasionycteris noctivagans*)	BLM NV	Woody Riparian	X	X	X	X	Yes, this species has been documented in Lake Mead and along the Colorado River (Carpenter et al. 2021; NPSpecies 2011d).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Spotted bat (*Euderma maculatum*)	BLM AZ, BLM NV, BLM UT	Woody Riparian	X	X	X	X	Yes, this species has been identified along the Little Colorado River and occurs throughout the river corridor from Glen Canyon to Lake Mead (Carpenter et al. 2021; Luce and Keinath 2007).
Townsend's big-eared bat (*Corynorhinus townsendii*)	BLM AZ, BLM CA, BLM NV, BLM UT, LCR MSCP	Woody Riparian	X	X	X	X	Yes, the analysis area is within the range of this species (Carpenter et al. 2021; NPS 2020). This species uses woody riparian habitats, desert washes, and upland habitats (LCR MSCP 2018a).
Western red bat (*Lasiurus blossevillii*)	BLM NV, BLM UT, LCR MSCP	Woody Riparian	X	X	—	—	Yes, this species has been recorded in riparian habitats dominated by cottonwoods, oaks, sycamores, and walnuts, including riparian restoration sites along the lower Colorado River (Carpenter et al. 2021; Pierson et al. 2026).
Western small-footed myotis (*Myotis ciliolabrum*)	BLM CA, BLM NV	Woody Riparian	X	X	X	X	Yes, this species is present within Grand Canyon (Carpenter et al. 2021; NatureServe 2025q).
Western yellow bat (*Lasiurus xanthinus* = *Dasypterus xanthinus*)	LCR MSCP	Woody Riparian	—	—	X	X	Yes, the analysis area is within the range of this species (BCI 2025b).
Yuma hispid cotton rat (*Sigmodon hispidus eremicus*)	LCR MSCP	Marsh	—	—	—	X	Yes, this species is known to inhabit areas near the Colorado River in the analysis area (NatureServe 2025r).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Yuma puma (*Felis concolor browni*)	ASC, CSC	Woody Riparian	—	—	—	X	No, there are few to no breeding female lions, a lack of prey, and a lack of suitable habitat within the reported range of this population (Kucera 1998).
Yuma myotis (*Myotis yumanensis*)	BLM CA, BLM NV, CSC	Woody Riparian	X	X	X	X	Yes, this species is present throughout the Upper and Lower Colorado River basins (LCR MSCP 2018b; Carpenter et al. 2021; NatureServe 2025s).
Reptiles and Amphibians							
Arizona striped whiptail (*Aspidoscelis arizonae*)	BLM AZ	Upland	—	X	—	—	No, this species is isolated to a small region in southeastern Arizona and prefers upland habitats (Brennan et al. 2023a).
Arizona toad (*Anaxyrus microscaphus*)	BLM UT, BLM NV	Marsh	—	—	X	X (3)	Yes, this species may be present in the analysis area and lays eggs in calm, shallow areas along streams (NDOW 2025g).
Banded Gila monster (*Heloderma suspectum cinctum*)	BLM NV	Woody Riparian	—	—	X	X (2)	Yes, this species has been documented in the Colorado River Basin (Stebbins 2003).
Coast horned lizard (*Phrynosoma blainvillii*)	BLM CA	Upland	—	—	—	—	No, this species range is outside of areas affected by any alternative (Stebbins 2003).
Colorado River toad (*Bufo alvarius=Incilius alvarius*)	LCR MSCP	Woody Riparian	—	—	X	X	Yes, this species is often near permanent water but is also found near temporary water laying eggs in ponds or slow-moving streams (NatureServe 2025t).
Common chuckwalla (*Sauromalus ater*)	BLM NV	Upland	X	X	X	X (2,3)	No, this species is primarily found upland desertscrub habitat which will not be affected by any alternative (Brennan et al. 2023b).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Coronado skink (*Plestiodon skiltonianus interparietalis*)	BLM CA	Woody Riparian	—	—	—	—	No, this species' range is outside of areas affected by any alternative (CA Herps 2025a).
Couch's spadefoot (*Scaphiopus couchii*)	BLM CA	Marsh	—	—	X	X (3, 4)	Yes, this species has been documented in Lake Mead and along the Colorado River (iNaturalist 2025e).
Desert box turtle (*Terrapene ornata luteola*)	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (CA Herps 2025b).
Desert iguana (*Dipsosaurus dorsalis*)	BLM NV	Woody Riparian	—	X	X	X	Yes, this species has been observed at Lake Mead Recreation Area (NPS 2011).
Desert rosy boa (*Lichanura trivirgata gracia*)	CSC	Woody Riparian	—	—	—	X (7)	Yes, this species is attracted to intermittent and permanent water and its range overlaps with the analysis area (SWCHR 2023).
Mojave desert tortoise (*Gopherus agassizii*)	BLM NV, LCR MSCP, Threatened	Upland	—	—	X	X (2, 4)	Yes, the analysis area is within the range of this species (CA Herps 2025c).
Sonoran desert tortoise (*Gopherus morafkai*)	AZ SSS, CCA	Upland	—	—	X	X (4)	Yes, the habitat range for this species includes Lake Mead, Lake Mohave, and the eastern shore of the Colorado River (FWS 2025f).
Flat-tailed horned lizard (*Phrynosoma mcallii*)	BLM AZ, LCR MSCP	Upland	—	—	X	X (7)	Yes, the analysis area is within the range of this species (CDFW 2025b).
Foothill yellow-legged frog (south coast DPS) (*Rana boylii*)	BLM CA	Woody Riparian	—	—	—	—	No, this species range is outside of areas affected by any alternative (FWS 2025g).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Gilbert's skink (*Plestiodon gilberti rubricaudatus*)	BLM NV	Woody Riparian	—	—	—	X (2)	Yes, this species prefers to be near water and makes burrows which could be affected by inundation (Brennan et al. 2023c).
Goode's horned lizard (*Phrynosoma goodei*)	AZGFD	Upland	—	—	—	X (7)	Yes, this species is within the range of areas affected by alternative (AZGFD 2025ra).
Greater short-horned lizard (*Phrynosoma hernandesi*)	BLM NV	Upland	X	X	—	—	No, this species utilizes upland habitat which will not be affected by any alternative (NDOW 2025h).
Great Plains toad (*Anaxyrus cognatus*)	BLM NV	Marsh	—	—	—	X(2, 4, 5)	Yes, this species is within the range of areas affected and is known to use margins of reservoirs (NDOW 2025i).
Lowland burrowing treefrog (*Smilisca fodiens*)	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (AZGFD 2025b).
Lowland leopard frog (*Rana yavapaiensis*)	BLM AZ, BLM CA, LCR MSCP	Marsh	—	X	X	X	Yes, this species has a highly isolated population in one side canyon in western Grand Canyon (AZGFD 2025c).
Mohave fringe-toed lizard (*Uma scoparia*)	BLM AZ, BLM NV	Upland	—	—	—	X(4)	No, this species is primarily found in sand dunes and is not known to occur in riparian habitats (NDOW 2025j).
Northern leopard frog (*Lithobates [=Rana] pipens*)	BLM AZ, BLM NV	Marsh	X	—	—	—	Yes, although functionally extirpated along the river corridor from Glen to Mead (NDOW 2025k).
Northern Mexican gartersnake (*Thamnophis eques megalops*)	LCR MSCP, Threatened	Marsh, Woody Riparian	—	—	—	X(3)	Yes, this species may occur around Havasu National Wildlife Refuge and could be affected by alternative (FWS 2025h).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Relict leopard frog (*Rana onca*)	BLM AZ, BLM NV, LCR MSCP	Marsh	—	—	X	X (2)	Yes, this species has been observed above and below Hoover Dam (Rorabaugh and Brennan 2023).
Resplendent shovel-nosed snake (*Chionactis annulata*)	AZGFD	Upland	—	—	—	X (7)	Yes, the analysis area is within this species' range (CAHerps 2025d).
Ring-necked snake (*Diadophis punctatus*)	BLM NV	Woody Riparian	—	X	—	—	Yes, this species has been observed within Grand Canyon (NDOW 2025l).
Rosy boa (*Lichanura orcuttii*)	BLM NV	Woody Riparian	—	—	—	X(7)	Yes, the analysis area is within the range of this species (AZGFD 2022; CA Herps 2025e).
Sinaloan narrow-mouthed toad (are now known as the Mazatlan narrow-mouthed toad) (*Gastrophryne mazatlanensis*)	BLM AZ	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternative (NatureServe 2025u).
Sonoran green toad (*Bufo retiformis*)	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (NatureServe 2025v).
Two-striped gartersnake (*Thamnophis hammondii*)	BLM CA	Woody Riparian	—	—	—	—	No, this species range is outside of areas affected by any alternative (CA Herps 2025f).
Western pond turtle (*Emys marmorata*)	BLM CA	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternative (CA Herps 2025g).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Western spadefoot (*Spea hammondii*)	BLM CA	Upland	—	—	—	—	No, this species range is outside of areas affected by any alternative (CA Herps 2025h).
Western toad (*Anaxyrus boreas*)	BLM NV	Marsh	—	—	—	—	No, this species' range is outside of areas affected by any alternative (CA Herps 2025i).
Yuman desert fringe-toed lizard (*Uma rufopunctata*)	BLM AZ	Upland	—	—	—	—	No, this species' range is outside of areas affected by any alternative (CA Herps 2025j).
Invertebrates							
Amargosa tryonia (*Tryonia variegata*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the documented range of this species (FWS 2025i).
Amargosa miloderes weevil (*Miloderes amargosensis*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the documented range of this species (NatureServe 2025w).
Amargosa Valley darkling beetle (*Lariversius sp.*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the documented range of this species (NPS 2016).
Apache plume fairy bee (*Perdita fallugiae*)	BLM NV	Upland	—	—	—	—	No, this species is found throughout Clark County, NV in dry mountain washes where Apache Plume exists (Griswold et al. 2004).
Apache springsnail (*Pyrgulopsis arizonae*)	BLM AZ	Marsh	—	X	X	X	No, this species is only known from a few locations that will not be influenced by project operations (FWS 2025j).
Perdita bee (*Perdita stephanomeriae*)	BLM NV	Upland	—	X	X	—	Yes, this species has been documented near Lake Mead (NatureServe 2025x).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Ash Meadows alkali skipper (*Pseudocopaeodes eunus alinea*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025k).
Ash Meadows dune scorpion (*Paruroctonus arenicola arenicola*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025y).
Ash Meadows naucorid (*Ambrysus amargosus*)	BLM NV, Threatened	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025l).
Ash Meadows pebblesnail (*Pyrgulopsis erythropoma*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025m).
Atomic tarantula (*Aphonopelma atomicum*)	BLM NV	Upland	—	—	—	—	No, this species is limited to Death Valley National Park and Amargosa Desert (NatureServe 2025z).
Big-headed perdita (*Perdita cephalotes*)	BLM NV	Upland	X	—	—	X (1)	Yes, this species specializes on *Chrysothamnus spp.* which is present in the analysis area. This species is presumed to nest in the soil and could be affected by alternative (Griswold et al. 2004).
Carole's fritillary (*Argynnis coronis ssp. carolae*)	BLM NV	Upland	X	X	X	X	No, the analysis area is outside of the range of this species and does not contain suitable habitat (NatureServe 2025aa).
Crystal springsnail (*Pyrgulopsis crystalis*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025n).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Death Valley june beetle (*Polyphylla erratica*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025o).
Devils Hole warm spring riffle beetle (*Stenelmis calida calida*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025bb).
Distal-gland springsnail (*Pyrgulopsis nanus*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025p).
Dune honey ant (*Myrmecocystus arenarius*)	BLM NV	Upland	—	X	X	X	Yes, this species is found within the Mojave and Sonoran deserts and utilizes washes (NatureServe 2025cc).
Eastern desert snail (*Eremarionata rowelli*)	BLM NV	Woody Riparian	—	—	—	—	No, this species is isolated to springs in the Amargosa River Basin (NatureServe 2025dd).
Elongate-gland springsnail (*Pyrgulopsis isolata*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025q).
Fairbanks springsnail (*Pyrgulopsis fairbanksensis*)	BLM NV	Woody Riparian	—	—	—	—	No, this species is endemic to Fairbanks Spring in Ash Meadows, located within Amargosa Valley (FWS 2025r).
Gila tyronia (*Tryonia gilae*)	BLM AZ	Marsh	—	X	X	X	No, this species is only known from a few locations that will not be influenced by project operations (FWS 2025s).
Giuliani's dune scarab (*Pseudocotalpa giulianii*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025ee).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Grand wash springsnail (*Pyrgulopsis bacchus*)	BLM NV	Upland	—	X	X	X	No, this species is only found in a watershed feeding Lake Mead; this watershed will not be influenced by project operations (AZGFD 2025d).
Grated tryonia (*Tryonia clathrata*)	BLM NV	Woody Riparian	—	—	—	—	No, this species occurs in spring-fed habitats and there is no observational data of this species occurring south of Moapa, NV (FWS 2025t).
Gypsum booklouse (*Speleketor flocki*)	BLM NV	Upland	—	—	—	—	No, this species is only known to occur within Ash Medows, NV, Big Gypsum Valley, CO, and the Tucson Mountains, AZ (NatureServe 2025ff).
Interior tiger beetle (*Parvindela terricola continua*)	BLM NV	Marsh	—	—	—	—	Yes, this species is known to occur within Southern California along alkaline or saline soils and salt lake margins (NatureServe 2025gg).
Inyo Mountains blue (*Euphilotes bernardina inyomontana*)	BLM NV	Upland	—	—	—	—	No, this species is only known to occur within Inyo and eastern Kern Counties (Davenport 2018).
Kingman springsnail (*Pyrgulopsis conica*)	BLM AZ	Woody Riparian	—	X	X	X (2, 3, 4, 5)	Yes, this species is found in the Colorado River (AZGFD 2025e).
Knight's aegialian scarab (*Aegialia knighti*)	BLM NV	Upland	—	—	—	—	No, this species occurs in sandy substrates and records indicate presence within Moapa and north of Moapa, NV (NatureServe 2025hh).
Large aegialian scarab (*Aegialia magnifica*)	BLM NV	Upland	—	—	—	—	No, this species is only known to occur in Nye County, NV (NatureServe 2025ii).
Las Vegas fairy bee (*Perdita cracens*)	BLM NV	Upland	—	—	X	—	No, little is known about this species and its range (Griswold et al. 2004).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Leaf beetle sp. (*Trirhabda gurneyi*)	BLM NV	Upland	—	—	—	—	No, this species inhabits upland weedy fields and brushy areas (Iowa State University 2025).
MacNeill's sooty-winged skipper (*Hesperopsis gracielae*)	BLM NV, LCR MSCP	Upland	—	—	X	X (4, 5)	Yes, this species occurs along the Colorado River from southwest Utah through southern Nevada, western Arizona, and California (LCR MSCP 2017, 2018c; NatureServe 2025).
May beetle sp. (*Phyllophaga benwaneri*)	BLM NV	Woody Riparian	—	—	—	—	No, this species is adapted to sand dune habitats (Warner 2021)
Median-gland springsnail (*Pyrgulopsis pisteri*)	BLM NV	Woody Riparian	—	—	—	—	No, this species is found within thermal systems and spring-fed streams and has only been observed within Ash Meadows and Amargosa Valley (FWS 2025u).
Mercury miloderes weevil (*Miloderes mercuryensis*)	BLM NV	Upland	—	—	—	—	No, this species is limited to the Amargosa Valley, NV (NatureServe 2025jj).
Moapa fairy bee (*Perdita fulvescens*)	BLM NV	Upland	—	—	—	—	No, this species is endemic to the Moapa, NV area (Griswold et al. 2004).
Moapa mydas fly (*Rhaphiomidas moapa*)	BLM NV	Woody Riparian	—	—	—	—	No, this species has only been recorded in one wash in Clark County, NV (NatureServe 2025kk).
Moapa pebblesnail (*Pyrgulopsis avernalis*)	BLM NV	Woody Riparian	—	—	—	—	No, this species is endemic to springs in Moapa Valley (FWS 2025v).
Moapa Valley pyrg (*Pyrgulopsis carinifera*)	BLM NV	Woody Riparian	—	—	—	—	No, this species is endemic to springs in Moapa Valley (FWS 2025w).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Moapa warm spring riffle beetle (*Stenelmis moapa*)	BLM NV	Woody Riparian	—	—	—	—	No, this species prefers habitats with warm springs (83-96 deg F) and is endemic to the Moapa Valley (FWS 2025x).
Mojave gypsum bee (*Andrena balsamorhizae*)	BLM NV	Marsh	—	—	X	—	Yes, this species is associated with rare plant species in gypsum soils around Lake Mead and could be affected by inundation to full pool if vegetation expands into the lake during lower elevation years (NatureServe 2025ll).
Mojave Mountain fairy bee (*Perdita vicina*)	BLM NV	Woody Riparian	—	—	X	—	Yes, this species is endemic to Clark County, NV and is a specialist on Apache Plume which could be affected by inundation (NatureServe 2025mm).
Mojave poppy bee (*Perdita meconis*)	BLM NV	Upland	—	—	X	—	Yes, this species is associated with rare plant species in gypsum soils around Lake Mead and could be affected by inundation to full pool if vegetation expands into the lake during lower elevation years (Griswold et al. 2004).
Mojave twilight bee (*Perdita celadona*)	BLM NV	Upland	—	—	X	—	Yes, this species makes burrows which could be affected by full inundation (NatureServe 2025nn).
Monarch butterfly (*Danaus plexippus plexippus*)	BLM NV, Proposed Threatened	All	X	X	X	X (2, 3, 4, 5, 6, 7)	Yes, this species is present during migration and over wintering along the Little Colorado River. It has been documented in cottonwood-willow, and mesquite and marsh habitats (NatureServe 2025oo).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Nearctic riffle beetle (*Stenelmis occidentalis*)	BLM NV	Woody Riparian	—	—	—	—	No, this species has not been observed near the analysis area (iNaturalist 2025f).
Nevada admiral (*Limenitis weidemeyerii nevadae*)	BLM NV	Woody Riparian	—	—	—	—	No, the only known population of this subspecies is west of Las Vegas near Charleston Peak (NatureServe 2025pp).
Northern Mojave blue (*Euphilotes mojave virginensis*)	BLM NV	Upland	—	X	X	X	Yes, this species is associated with buckwheat which is present in the analysis area (NatureServe 2025qq).
Nye County army ant (*Neivamyrmex nyensis*)	BLM NV	Upland	—	X	—	—	No, verry little is known about this species (NatureServe 2025rr).
Nye County pyrg (*Pyrgulopsis licina*)	BLM NV	Upland	—	—	—	—	No, this species is endemic to Ash Meadows (NatureServe 2025ss).
Pahranagat naucorid bug (*Pelocoris biimpressus shoshone*)	BLM NV	Woody Riparin	—	—	—	—	No, the subspecies *shoshone* has not been observed near the Colorado River (NatureServe 2025tt).
Point of Rocks tryonia (*Tryonia elata*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species. Only known species locations are in springs near Nye and Clark County, west of Mercury, NV (FWS 2025y).
Prodigious fairy bee (*Perdita prodigiosa*)	BLM NV	Upland	—	—	—	—	No, the habitat for this species is unknown (NatureServe 2025uu).
Red-tailed blazing star bee (*Megandrena mentzeliae*)	BLM NV	Upland	—	—	X	—	Yes, this species is ground nesting and has been observed within the analysis area (iNaturalist 2025g).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Robber fly sp. (*Stackelberginia cerberus*)	BLM NV	Upland	—	—	—	—	No, this species has only been observed in the Amargosa desert (iNaturalist 2025h)
Sanchez pyrg (*Pyrgulopsis sanchezi*)	BLM NV	Woody Riparian	—	—	—	—	No, this species is endemic to the Amargosa River basin (NatureServe 2025vv).
Sin City scorpion (*Pseudouroctonus peccatum*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (Tate et al. 2013).
Sonoran talussnail (*Sonorella magdalenensis*)	BLM AZ	Upland	—	X	—	—	No, this species occurs in upland habitats and will not be affected by any alternative (NatureServe 2025ww).
Southwest Nevada pyrg (*Pyrgulopsis turbatrix*)	BLM NV	Woody Riparian	—	—	—	—	No, this species has not been observed within the analysis area (NatureServe 2025xx).
Southwest viceroy butterfly (*Limenitis archippus obsoleta*)	BLM NV	Woody Riparian	—	X	—	—	Yes, this species feeds on trees in the willow family which may be affected by alternative (NatureServe 2025yy).
Sportinggoods tryonia (*Tryonia angulata*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (FWS 2025z).
Spring Mountains dark blue early form (*Euphilotes ancilla purpura*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025zz).
Spring Mountains dark blue late form (*Euphilotes ancilla cryptica*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025aaa).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Spring Mountains forestfly (*Malenka murvoshi*)	BLM NV	Upland	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025bbb).
Spring Mountains sagebrush checkerspot (*Chlosyne acastus robusta*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (NatureServe 2025ccc).
Spring Mountains springsnail (*Pyrgulopsis deaconi*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (McKelvy et al. 2020).
Spring Mountains undescribed pyrg 1 (*Pyrgulopsis sp. 1*)	BLM NV	Woody Riparian	—	—	—	—	No, the analysis area is outside the range of this species (McKelvy et al. 2020).
Spurge-loving perdita (*Perdita euphorbiae*)	BLM NV	Upland	—	—	—	—	No, no known populations exist within the areas affected by any alternative (NatureServe 2025ddd).
Thorne's hairstreak (*Callophrys thornei*)	BLM CA	Woody Riparian	—	—	—	—	No, this species relies on Tecate cypress, which will not be affected by any alternative (NatureServe 2025eee).
Tiquilia fairy bee (*Perdita exusta*)	BLM NV	Woody Riparian	—	X	X	—	Yes, this species relies on *Tiquilia hispidissima*, which has been observed along the Colorado River (Griswold et al. 2004).
Two-tone fairy bee (*Perdita bipicta*)	BLM NV	Unkn	—	—	—	—	No, the habitat for this species is unknown habitat (Griswold et al. 2004).
Virgin River perdita (*Perdita crotonis caerula*)	BLM NV	Unkn	—	—	—	—	No, the analysis area is outside the range of this species (Griswold et al. 2004).

Common Name (Scientific Name)	Listing Status	Habitat	Lake Powell	Glen Canyon Dam to Lake Mead	Lake Mead	Hoover Dam to SIB	Potential Impact
Virgin River tiger beetle (*Eunota praetextata pallidofemora*)	BLM NV	Woody Riparian	—	—	X	—	No, this species has not been observed in the analysis area (iNaturalist 2025i).
Virgin River twilight bee (*Perdina vespertina*)	BLM NV	Upland	—	—	—	—	No, this species is found within sandy washes, dunes, and creosote dominated basins in the Mohave Desert (NatureServe 2025fff).

BLM = Bureau of Land Management; CA = California; NV = Nevada; CSC = California Species of Concern; LCR MSCP = Lower Colorado River Multi-Species Conservation Program; AZ = Arizona.

WAPA	Western Area Power Administration
WY	water year

TA 11. Cultural Resources

TA 11.1 Affected Environment

Cultural resources are the physical evidence of past or present cultures, including archaeological sites, historic-era buildings and structures, objects, trails, landforms, and other places of traditional, cultural, or religious importance. Cultural resources can be human-made or natural features and are, for the most part, unique, finite, and nonrenewable.

Of the many laws, regulations, executive orders, and policies concerning cultural resources, the most pertinent to this project is Section 106 of the National Historic Preservation Act (NHPA; 54 United States [U.S.] Code 306108), as amended, and its implementing regulations (36 Code of Federal Regulations [CFR] 800). The NHPA and its implementing regulations require federal agencies to take into account the effects of their undertakings (federal undertakings or federally permitted or funded undertakings) on historic properties. Historic properties are defined as any district, site, building, structure, or object included in or eligible for inclusion in the National Register of Historic Places (NRHP); these include properties of traditional religious and cultural importance to an Indian tribe or Native Hawaiian organization that meet the NRHP criteria (36 CFR 800.16(l)(1)). As such, they are a subset of cultural resources.

Management and ownership of the land through which the Colorado River runs is multifaceted. Bureau of Reclamation (Reclamation) manages river water operations. In southern Utah, northern Arizona, and southeastern Nevada, the river runs through Grand Canyon National Park (GCNP), the Lake Mead National Recreation Area (NRA), and the Glen Canyon NRA, which are managed by the National Park Service (NPS). In western Arizona and eastern California south of Nevada, the river runs through Bureau of Land Management (BLM), Reclamation, U.S. Fish and Wildlife Service (FWS), state, tribal, municipal, and private lands.

Reclamation is consulting with the Arizona, California, Nevada, and Utah State Historic Preservation Officers (SHPOs), land managing agencies, affected tribes, and other consulting parties to develop a project-specific programmatic agreement under Section 106 of the NHPA and its implementing regulations (36 CFR 800.14). As part of the development of the programmatic agreement, Reclamation, the SHPOs, the land managing agencies, the affected tribes, and other consulting parties have defined the area of potential effect (APE). For this analysis, the NEPA study area coincides with the APE, which also mirrors the Class I search area.

The study area for the analysis runs from the northern extent of Lake Powell to the Southerly International Boundary (SIB), and consists of the Colorado River channel from bank to bank except from Glen Canyon Dam to Lake Mead, where it stretches from canyon rim to canyon rim, as well as a 0.5-mile buffer on either side of the riverbank or canyon rim. The study area coincides with the search area used for the Class I records search conducted for this analysis (Tremblay et al. 2024a,

2024b; Eddy et al. 2024; Winslow et al. 2024; Eskenazi 2024). The study area covers a total of 2,735,066 acres in Arizona, California, Nevada, and Utah.

TA 11.1.1 Identification Efforts

A Class I cultural resources record search was conducted for the study area in Arizona, California, Nevada, and Utah (Tremblay et al. 2024a, 2024b; Eddy et al. 2024; Winslow et al. 2024; Eskenazi 2024). Data were collected on archaeological sites, built environment resources, historic-era trails, special designations (National Historic Landmarks [NHLs]), congressionally designated areas (National Heritage Areas [NHAs] and National Historic Trails [NHTs]), traditional cultural places (TCPs), and resources of traditional cultural and religious importance to Native American peoples. Data were provided by the NPS (GCNP, Glen Canyon NRA, Lake Mead NRA, and NPS-managed portions of Grand Canyon-Parashant National Monument [NM]), National and State Registers of Historic Places, NHL and state landmark records, SHPO records, and the NPS Heritage Documentation Programs of the Historic American Building Survey, the Historic American Engineering Record, and the Historic American Landscapes Survey archives. Additionally, historical maps and aerials were checked for all states.

In Arizona, data were obtained from state databases and sources, such as AZSITE, Arizona State Museum Archaeological Records Office, and Arizona Department of Transportation; the Forest Service (Kaibab National Forest); and records searches conducted at BLM field offices or data provided by the BLM (Arizona Strip District Office, including BLM-managed portions of Grand Canyon-Parashant NM, Kingman Field Office, Lake Havasu Field Office, and Yuma Field Office).

In California, data were obtained from the California Historical Resources Information System at three different Information Centers (South Coastal Information Center, South Central Coastal Information Center, and Eastern Information Center). Cultural resource data were also obtained from the California Points of Historical Interest list, the California Historical Landmarks list, the Archaeological Determinations of Eligibility list, and the California State Historic Resources Inventory list.

In Nevada, cultural resources were identified through the Nevada Cultural Resources Inventory System (NVCRIS), Southern Nevada Archaeological Archive, and BLM records. In Utah, Utah Division of State History's (now known as the Utah Historical Society) Sego database and Historic Utah Building database were searched.

Information on TCPs and resources of traditional and religious concern to Native American peoples were gathered through ethnographic research and data provided by Reclamation and NPS. Historic General Land Office and topographic maps were also checked for potential cultural resources. Data on sites on tribal lands was not collected for this effort. Data about ancestral sites located on tribal lands is sensitive and confidential. Reclamation concluded that data collected from state and federal sources would be sufficient to characterize the overall numbers and types of resources that may be affected.

The Class I records search shows that much of the study area has not been surveyed for cultural resources. This is particularly true in the vicinity of Lake Mead and less for Lake Powell, as neither

of these reservoirs were fully surveyed before inundation began behind Hoover Dam in 1934 and behind Glen Canyon Dam in 1963. Because survey coverage for both Lake Powell and Lake Mead is very low, there is high potential for additional yet-to-be identified (that is, undiscovered) sites to exist in the study area. The following discussion concerns only previously recorded archaeological sites and built environment resources, as well as built environment resources found on aerial photographs. Additional resources may be, and are likely to be, present in the areas not covered by previous surveys.

Data were compiled in August 2023, and the 2023 datasets were incorporated into the analysis. Additionally, the NPS provided updated archaeological site counts for Lake Powell and Lake Mead (including Grand Canyon-Parashant NM) in March 2026, which supplemented the August 2023 dataset for the reservoirs. Therefore, the site counts used in the analysis do not reflect later agency database updates in the study area outside the reservoirs.

TA 11.1.2 Section 106 of the National Historic Preservation Act and Tribal Consultation

Per Section 106 of the NHPA and its implementing regulations (36 CFR 800), Reclamation is consulting with the Arizona, California, Nevada, and Utah SHPOs; Tribal Historic Preservation Officers (THPOs); affected tribes without THPOs; and consulting parties regarding the effects of the undertaking on historic properties. Reclamation is developing a project-specific programmatic agreement, in consultation with the SHPOs, THPOs, tribes without THPOs, cooperating agencies, and other consulting parties per 36 CFR 800.14 to outline a process to resolve any adverse effect on historic properties from Reclamation's operation of the Glen Canyon and Hoover dams under the new operating guidelines for annual releases.

TA 11.1.3 Cultural Background

The Colorado River and its surrounding landscape holds significance for many peoples today and has for thousands of years. Indigenous peoples have a strong connection to the river, which plays an important role in their histories and lives. Indigenous peoples' relationship and kinship with the Colorado River is complex and is discussed further in the Tribal Resources (see **TA 13**, Tribal Resources). The following presentation of cultural resources data is from a Western viewpoint and Reclamation acknowledges that this is a partial picture and stems from the viewpoint of Western archaeologists and federal regulations largely promulgated by non-Indigenous peoples. For many Indigenous peoples, archaeological sites are sacred places inhabited in the past and today by ancestors.

Western archaeologists view the human history of the Colorado River and its surrounding landscape in terms of three general temporal components: precontact (including the Paleoindian, Archaic, and Formative cultural periods), ethnohistoric, and postcontact (historic-era). Indigenous concepts of time are also different from Western ideas. For example, the Zuni provided text describing the Zuni concept of time, beginning with their emergence in the Grand Canyon (see **TA 13**, Tribal Resources).

TA 11.1.4 Class I Results

Arizona

Overall, 870 cultural resource investigations (projects) have been conducted in the study area for an overall survey coverage of approximately 4 percent (Tremblay et al. 2024b). This number includes both the non-NPS and NPS datasets and accounts for duplicate records between the datasets. The Class I records search of non-NPS data sources showed that 363 projects have been conducted in the study area in Arizona; however, these projects only cover approximately 2 percent of the study area, and the majority of those projects are over 10 years old. Projects include block and linear surveys, data recovery, and monitoring projects associated with gas pipelines, fiber-optic lines, transmission lines, road and highway construction, mining operations, and numerous development projects, and land transfers. The Class I records search of NPS data sources demonstrated that 521 projects had been conducted resulting in coverage of approximately 3 percent of the study area. Like projects outside the parks, the projects consist of block and linear intensive archaeological surveys, monitoring, and data recovery treatments associated with recreational development, vegetation management, post-fire assessments, land and timber transfers, graffiti removal, and a number of "documentation as preservation" surveys.

California

Within the study area in California, 216 archaeological projects have been conducted (Eddy et al. 2024). Previously conducted projects include survey, data recovery, monitoring, literature reviews, and planning documents. Of the 216 previously conducted archaeological investigations, 161 were surface surveys, covering approximately 11 percent of the study area in California. Projects were conducted in support of a variety of projects including but not limited to transmission lines, water infrastructure, fiber optics installation, pipelines, residential and commercial development, highway projects, prescribed burns and fuel breaks, and agricultural projects.

Nevada

Within the Nevada study area, 605 archaeological projects have been conducted; 408 of the surveys are from the NPS dataset (Winslow et al. 2024). Most of these projects were surveys in support of improvements at Lake Mead NRA, other recreational projects, utility installation, and road improvements. Previous survey covers approximately 5 percent of the study area in Nevada.

Utah

In total, 135 previous survey projects have been conducted within the Utah study area covering 37 percent of the Utah study area (Eskenazi 2024). These surveys were conducted in support of research and improvements to facilities in the Glen Canyon NRA, road improvements, transmission lines, land exchanges, and movie sets.

Archaeological Sites

As discussed above, survey coverage of the study area is variable by state but is overall very low, ranging from 2 or 3 percent in Arizona, 5 percent in Nevada, 11 percent in California, and 37 percent in Utah. Because of the low coverage, the numbers of archaeological sites presented below do not reflect the total number of sites in the study area and are likely only a small fraction of the sites that are present. However, the sites that have been recorded give an overall picture of resources

that may be found in the study area and are used in the analysis as a representative dataset for what may be present in unsurveyed areas.

Arizona

A total of 4,246 archaeological sites were identified in the study area in Arizona based on the 2023 Class I records search (Tremblay et al. 2024b). This number includes both non-NPS and NPS data accounting for duplicates between the two datasets. **Table TA 11-1** summarizes the NRHP status and temporal components of all archaeological sites within the study area in Arizona.

Table TA 11-1
Summary Counts of Previously Recorded Sites in the Study Area in Arizona

		Overall Study Area
Count (Sites)		**4,246**
NRHP	NRHP Listed	13
	Determined Eligible	3,059
	Recommended Eligible	41
	Determined Ineligible	144
	Recommended Ineligible	92
	Unevaluated	897
Temporal Component	Precontact	3,231
	Ethnohistoric	50
	Postcontact	458
	Multicomponent	282
	Unknown	225

Source: Tremblay et al. 2024b
Note: The information presented in this table incorporates NPS and non-NPS data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.

Non-NPS Dataset

The 2023 record search of non-NPS data identified 1,246 archaeological sites in the study area (Tremblay et al. 2024b). Seventeen sites in the study area are listed in the NRHP; 12 of the 17 listed sites are within the Ripley Intaglio Complex Historic District. Of the 1,246 sites, 345 are determined and recommended eligible for the NRHP and 126 are determined or recommended not eligible. The remaining 758 sites are unevaluated for the NRHP or of unknown NRHP status.

Of the 1,246 sites, 985 are precontact sites, 107 are postcontact (historic-era) sites, two are ethnohistoric sites, and 56 are multicomponent sites (i.e., used during more than one temporal period). The temporal affiliations of the remaining 96 sites are unknown. Precontact sites or site components could be attributed to the Paleoindian and Archaic period cultures, as well as the Basketmaker and Ancestral Puebloan cultures. Ethnohistoric sites or site components are affiliated with Mohave, Southern Paiute, Hopi, Diné (Navajo), and indeterminate Indigenous peoples. Postcontact (historic-era) component sites are overwhelmingly associated with Euro-American

culture; however, a few historic-era sites are attributed to Havasupai, Mohave, Diné (Navajo), Pai, Southern Paiute, Ute, and indeterminate Indigenous peoples.

Table TA 11-2 presents a summary of site function for sites in the non-NPS dataset. For precontact sites and site components, limited activity artifact scatters were the most abundant, but both long- and short-term habitation sites, resource procurement and processing sites, lithic reduction sites, and petroglyph/pictograph sites were well-represented. Although in smaller numbers, agricultural and water management sites, storage sites or caches, ceremonial or special-use sites, and trails were also present. Site functions for ethnohistoric sites or site components are similar to those from precontact component sites and include limited activity sites, an agricultural site, temporary camps, long-term habitations, resource processing sites, special-use sites, and a trail. The most common function of historic sites and site components is waste management (refuse piles). Other functions include mining, ranching, agriculture, permanent habitations, temporary camps, public utilities, and water management, as well as numerous transportation features, including roads, trails, and ferry crossings.

Table TA 11-2
Summary of Site Functions within the Study Area in Arizona (Non-NPS Data Only) by Temporal Component

Site Function	Count	Temporal Component		
		Precontact	Ethnohistoric	Postcontact
Limited Activity (Artifact Scatters)	236	233	3	0
Habitation	206	186	2	18
Temporary Habitations/Camps	155	133	2	20

Source: Tremblay et al. 2024b
Notes:

- Some sites have multiple functions identified for individual components, such that total site function counts in this table will exceed the total number of individual sites/components within each temporal category.
- The table does not include sites/components where temporal affiliations were not available. The information presented in this table incorporates non-NPS data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current databases.

NPS Dataset

As stated above, data provided by the NPS will be presented separately where applicable. This means that some sites are found in both the non-NPS and NPS databases. Counts of NPS sites presented below are based on the complete NPS dataset consisting of data acquired in August 2023 and updated in March 2026. Duplicate sites are accounted for above in **Table TA 11-1**.

A total of 4,135 previously recorded archaeological sites are found in the NPS dataset for the study area based on the March 2026 update. Sixteen sites are listed in the NRHP, another 3,315 sites have been determined or recommended eligible, 80 sites have been determined or recommended not eligible, and 678 are unevaluated. There are 46 sites in the Glen Canyon NRA dataset where no NRHP eligibility was given. See **Table TA 11-3** for eligibility by park unit.

Table TA 11-3
Summary Counts of Previously Recorded Sites for NPS Data by Park Unit in Arizona

		Park Unit			Total
		GCNP	Lake Mead NRA	Glen Canyon NRA	
Total Count (Sites)		**3,175**	**790**	**170**	**4,135**

	Recommended Ineligible	6	30	11	**47**
	Unevaluated	42	587	49	**678**
	Unknown/No Status	0	0	46	**46**

Source: NPS (including GCNP, Glen Canyon NRA, and Lake Mead NRA staff)
Notes: The information presented in this table incorporates NPS data acquired in March 2026 from current park databases; therefore, the number of sites and/or their corresponding information do not reflect information presented in other tables that rely on the August 2023 Class I records search. Total site counts for Lake Mead NRA also include sites from the NPS-managed portions of Grand Canyon-Parashant NM in Arizona.

Precontact sites or site components from the NPS dataset are attributed to time periods that archaeologists identify as Paleoindian and Archaic period, Basketmaker, Ancestral Puebloan, Cohonina, Patayan, and Cerbat cultures and peoples (**Table TA 11-4**). Ancestral Puebloan sites are most common, and indeterminate Indigenous peoples are second-most common. Ethnohistoric sites or site components are attributed to the Havasupai, Hopi, Diné (Navajo), Pai, and Southern Paiute peoples. For postcontact (historic-era) sites or site components, sites attributed to Euro-American sites are most common; however, several sites are attributed to Havasupai, Hopi, Diné (Navajo), Pai, Southern Paiute peoples, or unspecified Indigenous native cultures.

Note: The information presented in this table incorporates NPS data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current park unit databases.

Precontact site functions include agricultural, ceremonial/religious/special use, habitation, temporary habitation/camp, limited activity, lithic reduction, resource procurement/processing, petroglyphs/pictographs, storage/cache, transportation (trails), and water management sites (**Table TA 11-5**). Among these, longer-term habitations, resource processing sites, and temporary habitations were the most common. Ethnohistoric site and site component functions are similar to those of precontact sites and include agriculture, habitation, temporary habitation/camp, ceremonial/religious/special use, limited activity, lithic reduction, resources procurement/processing, storage/cache, and petroglyphs/pictographs. Historic site or site component functions consist of temporary habitations/camps, mining, ranching, agriculture, utilities, and water management, as well as numerous sites associated with transportation, such as ferry crossings.

California

A total of 551 previously recorded archaeological resources were identified within the study area in California as a result of the Class I records search. Of the 551 previously recorded archaeological resources, 493 are classified as archaeological sites, and 58 are classified as isolated occurrences. For the previously recorded archaeological resources (both sites and isolated occurrences), 4 are listed in the NRHP, 22 are recommended or determined eligible for the NRHP, 13 are recommended or determined ineligible or non-significant, and 512 are unevaluated or of unknown NRHP status. Of the 493 archaeological sites, 372 are precontact sites, 78 are postcontact (historic-era) sites, 31 are multicomponent sites with both precontact and postcontact (historic-era) resources, one is a multicomponent site with both precontact and ethnohistoric resources, and 11 sites are unknown.

Site or site component functions within the study area are shown in **Table TA 11-6**. The most common function is lithic reduction followed by transportation (trail). Other common functions include habitation; waste management; ceremonial, religious, and special use; and camps. Some sites or site components are of indeterminate function and are listed in **Table TA 11-6** according to their site type (i.e., potter scatter or rock feature).

Note: The information presented in this table incorporates data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.

Nevada

In the Nevada study area, 664 archaeological sites were identified in the non-NPS and NPS datasets (99 non-NPS [NVCRIS only] and 565 NPS) based on the Class I records search. Four sites are listed in the NRHP (including the B-29 Heavy Bomber Superfortress and the Pueblo Grande de Nevada: Main Ridge Locality); all are in the Lake Mead NRA. Additionally, a total of 29 sites are eligible or contributing for the NRHP (13 non-NPS and 16 NPS), including the St. Thomas historic townsite (ca. 1865). Fifty-five are ineligible (18 non-NPS and 37 NPS), and the remaining 576 resources are either unevaluated or unknown (68 non-NPS and 508 NPS). See **Table TA 11-7** and **Table TA 11-8** for non-NPS and NPS site eligibility, respectively.

Total site counts presented here include both Lake Mead NRA and NPS-managed portions of Grand Canyon-Parashant NM in Nevada.

Precontact sites include habitation sites, rock shelters, campsites, artifact scatters, tool stone procurement localities, and rock features. Euro-American sites include roads, utility lines, house foundations, mines, recreation facilities, and sites associated with the construction and operation of Hoover and Davis Dams (**Table TA 11-9**).

Utah

The Class I records search identified 1,384 sites (366 non-NPS and 1,018 NPS) within the Utah study area. Of the 1,384 sites, 2 are listed in the NRHP (non-NPS), 194 are eligible for the NRHP (56 non-NPS and 138 NPS), 143 are not eligible (20 non-NPS and 123 NPS), and 1,045 are unevaluated, undetermined, or have an unknown NRHP eligibility status (288 non-NPS and 757 NPS). See **Table TA 11-10** and **Table TA 11-11** for non-NPS and NPS site eligibility, respectively.

Built Environment Resources

Built environment resources are those human-made and/or intentionally modified components of our world that are shaped by the way we live, work, and play. For the purposes of this analysis, this includes buildings, structures, sites, objects, and districts that are historic in age (at least 50 years old since first constructed) and retain their basic structural elements, configurations, alignments, or patterns of organization (i.e., that are not in ruins and thus categorized as archaeological resources).

It is important to note that the state-specific lists of built environment resources discussed in this section do not include every individual resource or property type of historic age and, collectively, are not intended to represent a comprehensive inventory within the overall study area. Each state has different requirements when it comes to documenting built environment resources, as some state agencies manage such records in continuously maintained databases, while others do not. Arizona does not have a process to track built environment surveys conducted within the state, and at present, such resources are not assigned to any type of unique identifier like archaeological sites. California allocates project numbers to cultural resource investigations and assigns primary numbers to all cultural resources documented during those inventories, but the state's database system (California Historical Resources Information System) does not distinguish between archaeological and built environment (architectural) surveys and/or resources. Nevada maintains its own statewide inventory database where both archaeological and built environment inventories are registered by NVCRIS number and resources documented under the latter are currently assigned state-specific built environment numbers. Lastly, Utah manages information pertaining to previously recorded built environment resources (The HUB) where individual property record numbers are assigned.

Because Arizona, California, Nevada, and Utah each approach the management of built environment resource data in various ways, the types of information presented in this section are specific to each of the four states in the study area. For Arizona, built environment resources have not been documented consistently in the past, and currently, there is no systematic tracking or database managed for these resources. For this reason, the only sources of data that were readily available for historic-era built environment resources in Arizona were the NRHP and Arizona Register of Historic Places; lists encompassing designated NHLs, NHAs, and NHTs; NPS Heritage Documentation Programs (Historic American Building Survey, Historic American Engineering Record, and Historic American Landscapes Survey) databases; and historical aerial imagery. Because of this, only the most important built environment resources (as demonstrated by research) associated with the historic setting of the study area are included for analysis.

The datasets acquired from federal and state agencies were also examined to identify any additional properties that qualified as built environment resources, which were then culled from the archaeological site data; none of the datasets provided included information pertaining to NRHP-ineligible and/or unevaluated built environment resources. For California, all documented cultural resources are assigned a state-specific primary number and built environment resources documented in the study area were identified by their primary numbers from the comprehensive datasets obtained from the California Historical Resources Information System and other registers and lists. Conversely, because Nevada and Utah have (at least to some degree) state-maintained databases for built environment resources, those that are eligible, ineligible, and unevaluated for the NRHP are considered for analysis; however, this is limited to only those resources that have officially been assigned state resource numbers.

Additional details pertaining to identification efforts performed for resources in Arizona, California, Nevada, and Utah are presented in the data-gathering methods summaries in each state-specific volume (Tremblay et al. 2024b; Eddy et al. 2024; Winslow et al. 2024; Eskenazi 2024).

Finally, there is a substantial degree of overlap between designations, particularly involving NHLs and NRHP-listed historic properties, because NHLs are also listed in the NRHP when designated, if they have not been already. For this reason, where historic properties were listed in the NRHP before they were later designated as NHLs (in some cases, many years later), they are included for analysis as NRHP-listed built environment resources and NHLs. NHLs in the study area are discussed in a separate section below (see NHLs, NHAs, and NHTs).

Arizona

In all, a total of 49 previously evaluated built environment resources were identified as part of the Class I records search in the Arizona portion of the study area (Tremblay et al. 2024b). Of these, 43 are NRHP-listed (non-NHL) historic properties (8 districts, 26 buildings, 6 structures, 1 object, and 2 sites) and 6 are NRHP-eligible historic properties (all districts). **Table TA 11-13** provides a summary of NRHP-listed and NRHP-eligible built environment resources identified in the Arizona study area.

Table TA 11-13
NRHP-Listed and NRHP-Eligible Historic Properties in the Study Area in Arizona

DISTRICTS					
Name[a]	**NRHP Status**	**Year**	**Eligibility Criteria**	**Jurisdiction/ Ownership[b]**	**Administering Agency**
Lee's Ferry and Lonely Dell Ranch	Listed	1976, 1978 1997 (combined)	A, C	NPS	Glen Canyon NRA
*North Rim Entrance Road Corridor	Eligible	2011	A, C	NPS	GCNP
*Grand Canyon Inn and Campground	Listed	1982	A, C	NPS	GCNP

DISTRICTS

Name[a]	NRHP Status	Year	Eligibility Criteria	Jurisdiction/ Ownership[b]	Administering Agency
*Grand Canyon North Rim Headquarters	Listed	1982	A, C	NPS	GCNP
*El Tovar Stables	Listed	1974	A	NPS	GCNP
*Grand Canyon National Park Trail System	Eligible	N/A	A	NPS	GCNP
*Transcanyon Water Distribution Pipeline (including Silver Bridge)	Eligible	2016	A, C	NPS	GCNP
*Cross Canyon Corridor	Eligible	2015	A, C	NPS	GCNP
*Grand Canyon Railway	Listed	2000	A	NPS, U.S. Forest Service, Private	GCNP, Kaibab National Forest (federal lands only)
*Horace M. Albright Training Center	Listed	2013	A, C	NPS	GCNP
Temple Bar Developed Area	Eligible	2020	A	NPS	Lake Mead NRA
Katherine's Landing Developed Area	Eligible	2021	A	NPS	Lake Mead NRA
Parker Dam	Eligible	N/A	A, C	Reclamation	Lower Colorado River Office (LCRO)
Brinley Avenue	Listed	1982	A, C	Municipal, Private	City of Yuma (city lands only)
Yuma Main Street	Listed	1994	A	Municipal, Private	City of Yuma (city lands only)

BUILDINGS

Name[a]	NRHP Status	Year	Eligibility Criteria	Jurisdiction/ Ownership[b]	Administering Agency
*Buckey O'Neill Cabin	Listed	1975	A	NPS	GCNP
*Ranger's Dormitory	Listed	1975	A, C	NPS	GCNP
*Superintendent's Residence (First Administration Building)	Listed	1974	A	NPS	GCNP
San Carlos Hotel	Listed	1984	C	Private	N/A
Yuma County Courthouse	Listed	1982	A, C	County	Yuma County

BUILDINGS

Name[a]	NRHP Status	Year	Eligibility Criteria	Jurisdiction/ Ownership[b]	Administering Agency
Yuma Main Post Office	Listed	1985	A, C	Private	N/A
Cactus Press-Plaza Paint Building	Listed	1987	C	Private	N/A
Pauley Apartments	Listed	1982	C	Private	N/A
Methodist Parsonage	Listed	1982	A	Private	N/A
Methodist Episcopal Church	Listed	1982	A, C	Private	N/A
Masonic Temple	Listed	1984	C	Private	N/A
Hotel del Ming	Listed	1982	A, C	Private	N/A
Lee Hotel	Listed	1984	C	Private	N/A
Old Yuma City Hall	Listed	1982	A, C	Municipal	City of Yuma
Dressing Apartments	Listed	1982	C	Private	N/A
Power Apartments	Listed	1982	C	Private	N/A
Named private residences (n=10)	Listed	1982	B and/or C	Private	N/A

STRUCTURES

Name[a]	NRHP Status	Year	Eligibility Criteria	Jurisdiction/ Ownership[b]	Administering Agency
*Navajo Steel Arch Highway Bridge (Navajo Bridge)	Listed	1981	A, C	ADOT	ADOT
*Trans-Canyon Telephone Line	Listed	1986	A, C	NPS	GCNP
Old Trails Bridge (Topock Bridge)	Listed	1988	A, C	FWS, Private	FWS Southwest Region, EPNG
Historic U.S. Route 66 in Arizona	Listed	1989	A, C	FWS, State, County	FWS Southwest Region, ADOT, Mohave County
Ocean-to-Ocean Highway Bridge	Listed	1979	A, C	County	Yuma County
Southern Pacific Passenger Coach Car	Listed	2000	A, C	State	ASPT

Notes:

- Resources are listed in order from north to south by type (district, building, structure, site, object).
- The information presented in this table incorporates data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.
- The Grand Canyon Inn and Campground and the Grand Canyon North Rim Headquarters historic districts are on the North Rim within GCNP, which recently suffered extensive damage from the 2025 Dragon Bravo Fire; therefore, the NRHP status for district components may have changed as a result of wildfire impacts. The Buckey O'Neill Cabin, Ranger's Dormitory, and Superintendent's Residence (First Administration Building) also contribute to the Grand Canyon Village NHL. The Grand Canyon Pioneer Cemetery is listed as part of the Grand Canyon Village Historic District but is not part of the Grand Canyon Village NHL. Parker Dam has not been evaluated as a district in Arizona but was subject to a preliminary assessment in California in 1997, concluding the dam and its components likely qualified as an NRHP-eligible historic district; a formal NRHP nomination is currently in progress for listing.

[a] Properties marked with an asterisk (*) are resources in the study area (or portions thereof in terms of linear resources like trails) that are spatially separated from the river corridor because of substantial vertical distance and/or intervening canyon terrain (by several thousand feet in elevation in some instances).

[b] Jurisdiction and ownership are given only for the study area, as follows: ADOT = Arizona Department of Transportation; EPNG = El Paso Natural Gas Company; ASPT = Arizona State Parks and Trails; and FWS.

Additionally, 16 unevaluated but notable built environment resources (five districts, one building, nine structures, one site) were also identified as important resources that may be eligible for the NRHP based on extensive research. **Table TA 11-14** summarizes these resources identified in the Arizona portion of the study area.

Table TA 11-14
Unevaluated But Notable Built Environment Resources in the Study Area in Arizona Listed from North to South

Name[a]	Property Type	Location/Vicinity[b]
Glen Canyon Dam	District	Glen Canyon NRA
*Glen Canyon Dam Bridge	Structure	Glen Canyon NRA
*Greenland Lake Salt Cabin	Building	GCNP

Name[a]	Property Type	Location/Vicinity[b]
Black Suspension Bridge (Kaibab Suspension Bridge)	Structure	GCNP
Davis Dam	District	Laguna
London Bridge	Structure	Lake Havasu City
Ehrenberg Pioneer Cemetery	Site	Ehrenberg
Palo Verde Diversion Dam	Structure	Yuma
Yuma Levee System (Yuma Project)	District	Yuma
Fisher's Landing	District	Yuma
Imperial Dam	Structure	Yuma
Gila Project	District	Yuma
Laguna Dam	Structure	Yuma
Southern Pacific Railroad[c]	Structure	Yuma
Southern Pacific Railroad Bridge (Colorado River)[c]	Structure	Yuma
Morelos Dam	Structure	Northerly International Boundary

Source: Tremblay et al. 2024b

Note: The information presented in this table incorporates data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.

[a] Properties marked with an asterisk (*) are resources in the study area (or portions thereof in terms of linear resources) that are spatially separated from the river corridor because of substantial vertical distance and/or intervening canyon terrain (by several thousand feet in elevation in some instances).

[b] Location and vicinity do not imply jurisdiction, ownership, or administrative responsibilities.

[c] The Southern Pacific Railroad has been recorded in other locations in Arizona, but the route as aligned through Yuma has not yet been documented and/or evaluated for the NRHP, nor has the Southern Pacific Railroad Bridge across the river.

California

A total of nine built environment investigations have been conducted within the California portion of the study area based on the Class I records search, which involved inventory and evaluation for components of the All-American Canal, the Imperial Dam, the Imperial Irrigation District, land ports of entry, and masonry arch bridges. In all, 63 historic-era built environment properties were identified from archival records searches, including three districts (Picacho Squatters Settlement District, Topock Compressor Station District, and Parker Dam), a regional park (Moabi Regional Park), and various buildings, structures, roads, and transmission lines (Eddy et al. 2024). **Table TA 11-15** summarizes the general categories of built environment resources (based on function and/or use) established for the literature review.

Table TA 11-15
Built Environment Resource Categories in the Study Area in California

Category	Number of Resources
Bridge	3
Building	12
District	3
Historic/Survey Marker	3
Other Structure	8

Category	Number of Resources
Park	1
Railroad	2
Road	21
Single Family Dwelling	2
Transmission	3
Water Conveyance/Management	5
Totals	**63**

Source: Eddy et al. 2024

Notes:

- Sixteen individual resources are within the Topock Compressor Station District, which is counted as one of three districts in this table.
- The information presented in this table incorporates data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.

For the 63 built environment resources identified in the study area, two are listed in the NRHP (the Old Trails Bridge near Topock and the Ocean-to-Ocean Highway Bridge in Yuma), six were recommended as eligible for the NRHP, 17 were recommended/determined ineligible (including the Topock Compressor Station District and Moapi Regional Park), while 38 have either not yet been evaluated (including the Picacho Squatters Settlement District), or NRHP status was not reported (Eddy et al. 2024). Parker Dam and its associated facilities were subject to a 1997 preliminary evaluation that concluded the dam complex is likely eligible as a district, therefore it is considered an NRHP-eligible historic district for the purposes of this Final Environmental Impact Statement (see Arizona above). The eight NRHP-listed/-eligible historic properties are summarized in **Table TA 11-16**.

Table TA 11-16
NRHP-Listed/-Eligible Historic Properties in the Study Area in California Listed from North to South

Resource Name/Type	Category	Property Type	NRHP Status	Criteria
National Trails Highway (Bat Cave Wash)	Transportation	Structure	Eligible	A
Historic U.S. Route 66	Transportation	Structure	Eligible	A
Old Trails Bridge (Topock Bridge)	Transportation	Structure	Listed	A, C
Parker Dam[a]	Water conveyance/ management	District	Eligible	A, C
All-American Canal	Water conveyance/ management	Structure	Eligible	A, C
Transmission Line (near Fort Yuma Riviera)	Electric Power	Structure	Eligible	D
Southern Pacific Railroad	Transportation	Structure	Eligible	D

Resource Name/Type	Category	Property Type	NRHP Status	Criteria
Ocean-to-Ocean Highway Bridge	Transportation	Structure	Listed	A, C

Source: Eddy et al. 2024
Note: The information presented in this table incorporates data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.
[a] As previously mentioned, Parker Dam was subject to a preliminary assessment in California in 1997; a formal NRHP nomination is currently in progress for listing; therefore, the dam complex is included here as an NRHP-eligible district.

Nevada

In all, the Class I records search identified 22 built environment inventories that have been completed within the Nevada portion of the study area; these inventories were undertaken for several Lake Mead NRA improvements, transmission line construction, roadway improvements, resource evaluations, and NRHP eligibility determinations. Research identified 159 previously documented built environment resources, consisting mostly of properties (districts [i.e., groupings of resources], along with individual buildings, structures, sites, and objects) associated with the construction and ongoing operation of Hoover Dam on the Nevada side of the Colorado River (Winslow et al. 2024). As previously mentioned, the Hoover Dam Historic District was listed in the NRHP in 1981 and later designated an NHL in 1985. Because of the substantial number of district resources present on the Nevada side of the Colorado River, nearly all of which were given individual state-specific numbers, Hoover Dam is discussed in detail in this section as an NRHP-listed historic district.

In all, 98 individual built environment resources were documented as part of Hoover Dam, of which 66 are contributing (eligible), and 29 are noncontributing (ineligible) components of the NRHP-listed historic district, with the remaining 3 having no information pertaining to NRHP status. These include dam operational components (diverter towers, spillways, intakes, tunnels, penstocks, diversion channels, concrete support structures, and anchor foundations), cableway components (hoist house, crane towers, tower bases, and cable lines), electric power-related components (power plants, switchyards, transformers, and transmission lines), visitor services components (modern visitor facilities [not housed in operational buildings], parking lots and structures, food/beverage/gift shop facilities, historical monuments and interpretive installations, walking trail systems, and scenic overlooks), transportation components (access roads, gates, railroads and associated features, and bridges), and other components (unique and unclassifiable resources like spoils piles, survey markers, and memorials).

In addition to the Hoover Dam Historic District, there is one additional NRHP-listed historic property within the boundaries of Lake Mead NRA in the study area: Willow Beach Gauging Station (listed in the NRHP in 1986). Elsewhere in the Nevada study area, a total of 26 built environment resources associated with the development of recreation around Lake Mead and Lake Mohave within Lake Mead NRA have been given state-specific built environment resource numbers, consisting of 10 NRHP-eligible properties (including Echo Bay Developed Area, Cottonwood Cove Developed Area, and the Las Vegas Wash Developed Area) and 16 ineligible properties (including Boulder Beach Developed Area District, Callville Bay Developed Area, and Overton Beach

Developed Area District). At the south end of Lake Mohave is Davis Dam, and because most of the dam complex is on the Arizona side of the river, only three components of the dam have been documented and given inventory numbers, and all are eligible for the NRHP (Winslow et al. 2024).

Furthermore, 23 built environment resources identified in the Nevada study area were documented on an individual basis (apart from Hoover and Davis Dams and established recreation areas in Lake Mead NRA), including 11 NRHP-eligible properties and five NRHP-ineligible properties, leaving eight properties where NRHP status information was absent in the archival record (Winslow et al. 2024). Half of these resources represent individual overhead powerlines that are owned and maintained by various utility entities (federal, state, municipal, private), bringing electricity generated at both Hoover and Davis Dams to their respective service areas primarily in Southern California. The other half consists of transportation (road segments), non-electric power utility (the Boulder City water supply line, a telephone line), science and research (U.S. Geological Survey [USGS] monitoring facilities), resources that have been given state-specific built environment numbers. Lastly, there are six built environment resources for which no information (e.g., resource category, property type, NRHP status, and jurisdiction/ownership) was available from corresponding archives. **Table TA 11-17** summarizes the built environment resources by category (i.e., function and/or use) along with corresponding property types and NRHP status as identified in the Nevada portion of the study area.

Table TA 11-17

Source: Winslow et al. 2024
Notes:

- Jurisdiction is given only for the study area and is based on ownership information in NVCRIS; WAPA (Western Area Power Administration) is under the DOE (Department of Energy); the Southern Nevada Fish and Wildlife Office is part of the FWS. Other administering entities include MWD (Metropolitan Water District of Southern California), LADWP (Los Angeles Department of Water and Power), SWGC (Southwest Gas Corporation), SCE (Southern California Edison), and Nevada Department of Wildlife. For transmission lines, shared jurisdictional responsibility is not uncommon; however, this is not reflected in this table. For components of the Hoover Dam Historic District, resources noted as eligible are contributing components of the district, while ineligible resources are noncontributing components. For Lake Mead and Lake Mohave—two districts (Boulder Beach [ineligible] and Las Vegas Wash Campground [eligible]), each encompasses a share of the buildings, structures, and sites listed separately.
- The information presented in this table incorporates data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.

Utah

The Class I records search identified one built environment resource within the Utah portion of the study area—Hite Crossing Bridge—which was previously documented and recommended as eligible for the NRHP under Criterion C (Eskenazi 2024). Also known as the Colorado River Arch Bridge, it spans the river connecting Utah State Route 95 near Hite Marina within the boundaries of Glen Canyon NRA. Part of the Trail of the Ancients National Scenic Byway and the Utah Bicentennial Highway Scenic Byway, the Hite Crossing Bridge is under the management of the Utah Division of Transportation.

Specially Designated Cultural Resources

As previously mentioned, there are three different types of special designations identified in the study area—that of the NHL, as well as the congressionally designated NHA and the NHT. NHLs are historic properties that illustrate U.S. heritage, while NHAs are nationally important landscapes encompassing unique natural, cultural, and scenic values. NHAs are not managed by the federal government, rather, they are managed by state governments, non-profit organizations, or private entities. Lastly, NHTs follow past routes of exploration, migration, trade, struggle, and/or military action representing historic corridors of national significance, which may or may not have a present physical manifestation. With some exceptions, administration of an NHT is generally assigned to a single federal agency (NPS, BLM, or U.S. Forest Service), with on-site jurisdiction belonging to various governmental agencies or private entities that own or manage the lands along each NHT.

The specially designated areas intersecting the study area are briefly summarized below by state, with more detailed discussions presented in the respective state volumes prepared to support this Final Environmental Impact Statement (Eddy et al. 2024; Eskenazi 2024; Tremblay et al. 2024b; Winslow et al. 2024). It should be noted that there are five specially designated areas crossing the study area in

more than one state including two NHLs and three NHTs—Hoover Dam NHL (Arizona and Nevada within Lake Mead NRA), Yuma Crossing NHL (Arizona and California), the Armijo Route (Arizona and Utah within Glen Canyon NRA) and the Mojave Road route (Nevada within Lake Mead NRA) of the Old Spanish NHT, as well as the Juan Bautista de Anza NHT and the recently designated Butterfield Overland NHT (Arizona and California).

Arizona

The Class I records search identified nine NHLs that intersect the Arizona portion of the study area—five districts and four individual buildings (Tremblay et al. 2024b). Most of the NHLs in the study area are within GCNP, including two districts and four buildings on the South Rim and one on the North Rim, all of which are administered by the NPS. The remaining two NHLs outside of GCNP are Hoover Dam and Yuma Crossing. Hoover Dam is under the jurisdiction of Reclamation and is situated within the boundaries of Lake Mead NRA but is not part of the NPS-administered park. The NHL designation encompasses infrastructure in both Arizona and Nevada, with the majority of components on the latter side of the river. Yuma Crossing NHL is unique in that it is composed of five distinct individual areas (including two state parks) that are collectively also designated as an NHA. The NHL designation encompasses portions of the study area in both Arizona and California while the NHA boundary only includes Arizona. The NHA is managed by a non-profit organization.

For the Arizona study area, the Armijo Route of the Old Spanish NHT crosses portions of Lake Powell within Glen Canyon NRA, while both the Juan Bautista de Anza NHT and the recently designated Butterfield Overland NHT traverse the river corridor in the Yuma area. There are no known physical remnants of the Old Spanish NHT in Arizona and if present, such evidence would be under the waters of Lake Powell. The routes of the Juan Bautista de Anza NHT and the Butterfield Overland NHT are approximate through the study area and, likewise, there is no known physical evidence of any original trail sections for either NHT. Therefore, there are no known NRHP-eligible segments of any of the three NHTs (Tremblay et al. 2024b).
Table TA 11-18 summarizes the specially designated areas (NHLs, NHAs, and NHTs) in the Arizona study area.

Table TA 11-18
National Historic Landmarks, National Heritage Areas, and National Historic Trails in the Study Area in Arizona

NATIONAL HISTORIC LANDMARKS

Name	Year Designated	Property Type	Jurisdiction/Ownership	Administering Agency

Source: Tremblay et al. 2024b

Notes:

- Jurisdiction and ownership are given only for the study area.
- NHLs, when designated, are automatically listed in the NRHP if not already. NHLs in this table that also contribute to other NRHP-listed historic districts are indicated with an asterisk (*) and may also be repeated in subsequent applicable table(s). The M.E.J. Colter Buildings NHL consists of four isolated buildings on the South Rim (Lookout Studio, Hopi House, Desert View Watchtower, and Hermit's Rest), of which two (Lookout Studio and Hopi House) contribute to the significance of the Grand Canyon Village NHL. NHLs in GCNP are spatially separated from the river corridor because of substantial vertical distance and intervening terrain in Grand Canyon. Yuma Crossing NHA encompasses Yuma Territorial Prison State Park, Colorado River State Park, Yuma East Wetlands, Yuma West Wetlands, and Pivot Point Plaza. The Grand Canyon (North Rim) Lodge was designated as an NHL in 1987 along with its associated cabins; however, the main lodge was recently lost during the 2025 Dragon Bravo Fire, along with several cabins. While it is still designated as an NHL, it has been mostly destroyed by wildfire and its status is likely to change; therefore, this NHL has been removed from consideration.
- The information presented in this table incorporates data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.

California

The Class I records search identified one NHL—Yuma Crossing—which extends across the Colorado River into California to encompass the site of Fort Yuma, a former nineteenth century U.S. military post now on the Fort Yuma-Quechan Reservation (Eddy et al. 2024). There are no NHAs in the California portion of the study area because the Yuma Crossing NHA designation only

includes the portion of the NHL on the Arizona side of the river. For the portions of the Juan Bautista de Anza NHT and Butterfield Overland NHT that cross the study area in California, there is no physical evidence of original trail segments known to exist.

Nevada

The Class I records search identified two specially designated cultural resources intersecting the study area—Hoover Dam NHL and the Mojave Road route of the Old Spanish NHT (Winslow et al. 2024). Hoover Dam NHL was designated in 1985, spanning two states, encompassing half the dam along with extensive electrical infrastructure on the Nevada side of the river, including primary visitor services. The Old Spanish NHT corridor enters the Nevada study area along the Virgin River and is submerged under the Overton Arm of Lake Mead. It exits the study area near Boulder Wash Cove and reenters at Callville Bay before exiting again at Las Vegas Bay. There are no known original segments of the Old Spanish NHT within the Nevada portion of the study area, and if remnants do exist, they were submerged when Lake Mead was impounded and would be underwater.

Utah

Based on the Class I records search, there is only one congressionally designated area in the Utah portion of the study area—the Armijo Route of the Old Spanish NHT—which crosses into the study area within Glen Canyon NRA (Eskenazi 2024). There are no known segments of the original trail documented within the Utah portion of the study area. Like Lake Mead, if such do exist, they are inundated under the waters of Lake Powell.

Cultural Landscapes

There are different definitions for what constitutes a cultural landscape, however, at its basic level, a cultural landscape is a geographic area, encompassing both cultural and natural resources, that illustrates evidence of human interaction with the physical environment. The only defined cultural landscapes in the study area are within GCNP, where NPS has identified 16 cultural landscape areas in the park, representing historically or culturally significant designed, vernacular, and ethnographic landscapes, which allows land managers to assess how these landscapes should be managed and interpreted (NPS 2024). Most of the cultural landscapes identified in GCNP are spatially separated from the river corridor because of vertical distance and/or intervening canyon terrain. The Colorado River and its associated uplands represent a cultural landscape with both tangible and intangible attributes for many Indigenous peoples. Natural resources, such as animals, plants, springs, rivers, land formations, and human-made elements, such as ancestral homes and trails, fields, prayer objects enshrined in travertine and salt, are all important aspects of a cultural landscape. Tribal perspectives on cultural landscapes are summarized in **TA 13**, Tribal Resources.

The historic landscape at Lees Ferry, a recreation site at the confluence of the Colorado and Paria rivers in Glen Canyon NRA, is an example of a managed cultural landscape encompassing the NRHP-listed Lee's Ferry and Lonely Dell Ranch Historic District, which represents over 60 years of non-Indigenous cultural use of the Colorado River beginning with the establishment of the first ferry crossing by John D. Lee in 1871 up to 1909 when the Church of Jesus Christ of Latter-day Saints divested itself from both the ferry and farmstead. Lee's Ferry was the only ferry crossing of the Colorado River within 700 miles because, here, the river was not bound by steep canyon walls,

allowing wagons to be driven to the river's edge. Historically, Lee's Ferry operated as a ferry crossing and farmstead with an extensive irrigation system, which today are represented by several historic-era buildings, a cemetery, an orchard, trails, and fields. The Lee's Ferry and Lonely Dell landscape is an interpretative site that is still used today by day visitors, river runners, campers, and the USGS for their river gauging stations.

Traditional Cultural Places

A TCP, which is a type of historic property, is "a building, structure, object, site, or district that may be eligible for inclusion in the National Register for its significance to a living community because of its association with cultural beliefs, customs, or practices that are rooted in the community's history and that are important in maintaining the community's cultural identity" (NPS 2024). Because the TCPs of concern are those of Indigenous peoples, the analysis of impacts on TCPs is found in **TA 13**, Tribal Resources.

TA 11.2 Environmental Consequences

TA 11.2.1 Methodology

Direct and indirect impacts on cultural resources could result from changes in lake levels or river flows from the annual releases. Of greatest concern are effects on historic properties (i.e., resources eligible for or listed in the NRHP) that alter the characteristics of the properties in a way that would diminish the integrity of its location, design, setting, materials, workmanship, feeling, or association (36 CFR 800.5). Direct impacts may be from processes such as wave action and wet-dry cycling, but include any impact that is immediate in place and time, including visual, auditory, and atmospheric impacts; indirect impacts, such as from increased ease of access to previously inundated sites, are those that occur farther away in distance and/or later in time.

Impacts on cultural resources analyzed in this section only include those impacts resulting from Reclamation's management of annual releases from Glen Canyon and Hoover dams. The analysis emphasizes cultural resources within 20 meters (66 feet) of the river corridor because they are the most likely to be affected by changes in river flows.

Archaeological Sites

Three types of analyses are used to discuss potential impacts on archaeological resources: known site counts by elevation and modeled lake elevations/known sites counts within 20 meters (66 feet) of the river corridor, preservation risk modeling developed by the USGS and NPS, and aeolian transport modeling also developed by the USGS. Elevations for sites identified in the Class I records search at Lake Powell and Lake Mead were calculated and used to identify those sites that are at elevations subject to changes in water levels. However, due to the low Class III survey coverage, there are doubtless more sites to be found. Archaeological data over broad areas are, by virtue of how and when the data were collected, variable in coverage and documentation. For example, areas around Lake Powell have a higher cultural resource survey coverage and therefore, more archaeological data are available, while areas around Lake Mead do not. Also, there is very limited data on archaeological sites below the water line due to a lack of studies prior to inundation in Lake Mead NRA.

Along the river corridor, the analysis focuses on sites identified within 20 meters (66 feet) of the river corridor (bank to bank). A 20-meter (66-foot) distance is used because the variability of elevation along the river corridor is too great to efficiently sort thousands of sites by elevation; this distance corresponds to the most likely impacted zone from the Class I report (Tremblay et al. 2024b; Winslow et al. 2024).

Inundated Resources and Water Levels

Fluctuating water levels at Lake Powell and Lake Mead can impact the preservation of archaeological sites, especially for those that are currently or previously inundated. The NPS prepared an initial study of how inundation and fluctuating water levels at Lake Powell affect resources (Morgan and Conlin 2023), which generally parallel the findings of earlier archaeological inundation studies (e.g., Lenihan et al. 1981a, 1981b; Ware 1989). Archaeological resources are more vulnerable to disturbance and degradation when water levels fluctuate. Fluctuating water levels can result in increased wave impacts, wet-dry cycling, freeze-thaw cycling, and erosion.

Differences in topography and elevation in the lake reservoirs, as well as the length of exposure, affect the impact on sites. The reservoirs, in the cross section, are wide at the higher elevations and narrow at the lower elevations, where the lake fills what were steep-sided and deep canyons. In areas where the topography is flatter, at higher elevations, changes in lake elevation take longer, and the reservoir volume fluctuation exposes more horizontal area, while in the steeper areas, like canyons, changes in lake elevation may be faster and reservoir volume fluctuation occurs in a much more volatile fashion. In the lower reaches of the narrow canyons, removal or addition of a small amount of water will raise or lower the lake significantly; this may occur multiple times due to normal reservoir operations and will be relatively rapid. Higher in the canyons, removal or addition of water will raise or lower the lake by a smaller amount, leading to more extended periods of impacts due to wave actions and freezing and thawing.

Changes in temperature, water chemistry, pH, salinity, and sedimentation as water levels rise and fall can also be detrimental to the preservation of resources. While inundation is also not ideal, as it can displace artifacts and disturb and damage site components sensitive to water or moisture (like mud mortar), inundation can protect resources through sedimentation, if it is consistent over time. Inundation can also prevent weathering and provide a low oxygen environment that can protect artifacts. Resources that have previously been inundated and are exposed through fluctuating water levels are particularly vulnerable to wave action, etc., as well as to impacts from visitation. Like fluctuating lake levels, changes in river flows may impact archaeological sites through erosion, wet-dry cycling, exposure to the elements, and increased visitation of exposed resources. Discussion of lake elevations is based on minimum water-year (WY) and end-of-water-year (EOWY) elevations for Lake Powell, and minimum calendar-year (CY) and end-of-calendar-year (EOCY) elevations for Lake Mead (see **TA 3**, Hydrologic Resources). The analysis references applicable tables presented in **TA 3** for corresponding elevations (in feet) at Lake Powell (minimum WY and EOWY) and Lake Mead (minimum CY and EOCY) for each of the different hydrological conditions under different modeled scenarios. These include the maximum, 90th percentile, 75th percentile, median (50th percentile), 25th percentile, 10th percentile, and minimum elevations. The analysis also references applicable figures in **TA 3** that visualize the elevation data for Lake Powell and Lake Mead using side-by-side conditional box plots where the bold lines through each box represents the median

elevation (50th percentile), the top and bottom of each box captures the 25th and 75th percentile of the modeled results (the interquartile range), the lines extend to the 10th and 90th percentiles, and the outliers are represented as dots beyond these lines (maximum and minimum elevation ranges for the modeled results). Specific tables and figures from **TA 3**, Hydrologic Resources, are called out as appropriate in each section below.

Preservation Risk Modeling

The USGS, in cooperation with NPS, developed a model to assess "preservation risk" for archaeological resources at or below full pool elevation at Lake Powell and Lake Mead (Caster et al. 2026). This Preservation Risk model is a spatial model that considers several landscape characteristics, locations of previously recorded cultural resources, and potential for water-related impacts, such as wave action and erosion. The lake landscape was gridded off into 10-meter resolution cells, and each 10-meter resolution grid cell within the model was categorically ranked 1 to 5 based on low (1) to high (5) potential for site preservation to be negatively affected by water at a given reservoir elevation. The Preservation Risk model incorporates two other models: the Site Distribution model, which identifies where archaeological resources are more likely or less likely to be found, and the Preservation Hazard model, which identifies where site impacts related to lake fluctuations will likely occur.

Specific for archaeological sites, the Site Distribution model is based on landscape characteristics (geologic and geomorphic context-geologic maps and digital elevation models [DEMs]), topographic position-DEMs/bathymetry, proximity to major runoff flow concentrations seen in National Hydrology Dataset flowlines and DEMs, and known locations of archaeological sites (precontact and postcontact). As mentioned above, not all of Lake Powell was surveyed prior to the completion of Glen Canyon Dam construction, and very little of Lake Mead prior to when filling began in 1934, so this model allows for the prediction of site distribution based on the correlation of landscape characteristics to known site location. However, the known site distribution was used within Lake Powell (a larger percent surveyed) to help define the distribution ranks (Rank 1 – no known archaeological sites, Rank 2 – known site density less than 1.5 per square mile (2.6 square kilometer), Rank 3 – known site density greater than and equal to 1.5 per square mile and less than 3 per square mile, Rank 4 – known site density greater than and equal to 3 per square mile and less than 4.5 per square mile, and Rank 5 – known site density greater than and equal to 4.5 per square mile).

The Preservation Hazard model is based on the simplified physical factors influencing lake shore geomorphic change. Like with coastal environments, wave action is a major player in erosion, but reservoirs have the added risk of large, rapid, and sustained changes in water level that affect runoff base level conditions, soil deformation, and chemical weathering with submersion and exposure. These aspects were incorporated into the model using available USGS topography and bathymetric data and the known relationships between slope-wave interactions/baselevel adjustments, lake fetch lengths (distance wind travels over water surfaces to help build waves), and lake shoreline area change, as well as a given change in elevation. In this model, the highest rank (5) correlates to a higher potential for impacts, and the lowest rank (1) correlates to a lower risk from these factors.

When combining the Site Distribution and Preservation Hazard models, a simple rule set was used based on the assumptions that: 1) regardless of hazard rank, areas likely to contain resources have

potential to be affected by dam management operations; 2) even where archaeological resource likelihood is low, hazards from water levels can impact a potentially significant site; 3) areas with very high likelihood of containing archaeological sites and very high potential for impacts are at the highest risk of resource condition changes; and 4) areas with very low likelihood of containing archaeological sites and very low potential for impacts are at the lowest risk of resource condition changes.

The above concepts allow for each grid cell in the reservoir footprint to be ranked. For the analysis, the Preservation Risk model was summarized for greater than 60 units of 10-foot elevation bins at and below full pool. The summaries represent statistics of the Preservation Risk rank at the lake shoreline between the upper and lower reservoir elevations, defining each 10-foot bin (i.e., each bin represents a different summary area). Monthly modeled reservoir values are used in this model. In this way, each monthly modeled reservoir level will fall into one of the 10-foot summary bins and can be assigned a preservation risk rank summary statistic, such as the mean risk rank, that represents generalized potential impacts along the lake shoreline for that reservoir level. Monthly risk values, based on reservoir elevations, can then be used to evaluate differences between scenarios and traces within the modeling period.

Wind-deposited Sediment

Research conducted by the USGS and NPS has demonstrated that wind-deposited (aeolian) sediment can help stabilize and preserve archaeological sites along the Colorado River over long periods of time (East et al. 2016; Sankey et al. 2023). Fine sand or sediment can be blown from flow-deposited source areas and deposited on cultural sites (East et al. 2016). The effects of deposition or erosion may be negative or positive depending on the nature of the site. One important recent finding is that sandbars created by high-flow events at Glen Canyon Dam can provide sources of windblown sand that can cover archaeological sites (East et al. 2016) as well as anneal, or reverse, the formation of gullies (Sankey and Draut 2014). In this context, changes in dam operations can affect erosion rates on archaeological sites (East et al. 2016; Collins et al. 2016). Sediment is generally deposited via wind on nearby terraces with archaeological sites at an average rate of a few millimeters a year; however, operations of the Glen Canyon Dam can inhibit the formation of sand bars from which the sediment is blown. Management of the Colorado River influences the supply of windblown river sand in two ways: (1) the reduction of river flows below current average baseflow levels causes sand in the river channel to be exposed subaerially and, given sufficient time, can dry out and become available for wind transport (Sankey et al. 2022); and (2) when high-flow experiments (HFEs) are successfully implemented to rebuild river sandbars, the sand in the subaerial portion of the sandbars becomes available for wind transport in the Grand Canyon (Caster et al. 2022; Sankey et al. 2018). However, riparian vegetation can block the windblown transport of sand; when vegetation cover decreases, the potential for wind transport increases (Sankey et al. 2023).

The analysis integrated three independent models: the aeolian sand availability model (hereafter referred to as the "Sand Area model"; Kasprak et al. 2024; Kelley et al. 2026), the Vegetation Habitat Suitability model (Butterfield et al. 2018; Butterfield and Palmquist 2026), and the Sandbar Volume model (initially modified from Mueller and Grams 2021; Salter and Grams 2026). The Sand Area model was specifically developed to predict the supply of river-sourced, windblown sand as a function of river discharge and subaerial exposure time; however, the Sand Area model used here

does not incorporate changes in vegetation cover that occur as a function of river hydrology or geomorphic changes (deposition and erosion of sand) that would also affect sand area. Therefore, the Sand Area model was then coupled with the outputs with those from the Marble Canyon Vegetation Habitat Suitability model. Scenarios were assessed in which modeled sand availability exceeded a defined threshold while vegetation suitability remained below a specified benchmark—conditions presumed to favor increased aeolian transport.

To further capture the dynamic influence of high-flow events, which can increase sandbar volume and enhance future sand supply, the Sandbar Volume model output was then included in the evaluation framework. In this analysis, a future is defined as a "preferred minimum performance" if one of the following logical criteria was met: (1) the Sand Area model exceeded and the Vegetation Habitat Suitability model simultaneously fell below their respective thresholds (suggesting favorable conditions for aeolian transport), or (2) the Sandbar Volume model exceeded the threshold, indicating enhanced sand supply via fluvial-related deposition. Previous work suggests that dam releases that allow for these conditions to be met at least once every 1–3 years may slow the rate of degradation to enable time for proactive mitigation and planning (Sankey et al. 2018). Considering temporal variability of future preferred minimum performance, it is a preferred minimum performance if these conditions are met at least once every 3 years.

Model thresholds were derived from recent historical baselines: the sand area and vegetation (Marble Canyon only) thresholds reflect the 50th percentile of model outputs from 2000 to 2023, while the sandbar volume threshold is set at 1.5 times the modeled initial condition beginning in 2027. For sandbars to grow in volume and provide a continuous supply of river sand for aeolian transport to protect cultural resources, HFEs must be conducted on a frequent basis (e.g., every 1–3 years). However, the frequency of HFE occurrence, and thus sandbar volume growth, is likely overpredicted in the modeling, as the decision for an HFE to occur or not in a given year is a policy decision based on environmental conditions and other factors.

Built Environment Resources

No modeling was conducted specifically for built environment resources. Recalling that built environment resources are those human-made and/or intentionally modified components of our environment, these types of resources are much less vulnerable to impacts compared to archaeological resources. The most prominent of the built environment resources identified in the study area also constitute critical infrastructure, constructed as part of major Reclamation projects like Glen Canyon Dam, Hoover Dam, as well as Davis and Parker dams. This also includes the smaller dams like the Palo Verde Diversion Dam, Imperial Dam, Laguna Dam, and Morelos Dam, along with the various canals and levee systems in the lowest reaches. Collectively, these facilities are key to Colorado River operations, and none of the alternatives would result in the decommissioning or substantial alteration of such critical infrastructure, so the historic importance of these resources would not be jeopardized. Therefore, it is assumed there would be no direct or indirect impacts on this critical infrastructure, and they are not carried forward for analysis.

In terms of built environment resources around the reservoirs and immediately along the river corridor that are not considered critical infrastructure for river operations, these properties were developed in response to either the creation of both Lake Powell and Lake Mead or to provide

access to and/or across the river itself. Historic-era transportation roadway and railway networks spanned the river via bridges, while trails were established to provide river access. Recreation areas like those identified in Lake Mead NRA were intentionally placed in locations that took advantage of proximity to water. Other tourist facilities, like those in GCNP, were designed to accommodate visitors near the river and provide safe crossing between the North and South Rims. As such, for most built environment resources in the study area, these types of properties were designed or located in consideration of fluctuating water levels both around the reservoirs and the river corridor. They are not considered vulnerable to inundation or varying water levels, increased wave impacts, wet-dry cycling, or erosion like archaeological sites because they were designed to withstand or avoid those impacts historically. Therefore, impacts on NRHP-listed and NRHP-eligible built environment resources would occur where uncharacteristic water levels and river flows exceed historical ranges.

Specially Designated Cultural Resources

No modeling was undertaken for NHLs, NHAs, or NHTs. The one NHA identified in the study area (Yuma Crossing) coincides with the Arizona portion of the Yuma Crossing and Associated Sites NHL; therefore, it is analyzed as an NHL. There are no confirmed segments of the original trail in the study area for the three NHTs. Impacts on NHLs, as the only specially designated cultural resources identified in the study area, could occur only if river flows are outside the historical ranges.

Impact Analysis Area

The impacts analysis area consists of the Colorado River corridor from the upper limits of Lake Powell in Utah, through the Grand Canyon in Arizona, and Lake Mead in Arizona, and from Hoover Dam to the SIB.

Assumptions

- Once a resource has been inundated by a reservoir, being continuously inundated thereafter is more conducive to preservation than repeated cycles of inundation and exposure (i.e., wet-dry cycling and wave action).
- Repeating cycles of inundation and exposure of resources by the reservoirs and/or the river are damaging to archaeological resources.
- The covering of resources by wind-deposited, river-sourced sediment is conducive to preservation.
- While HFEs were considered in the aeolian transport model as part of the individual vegetation and sandbar models, actual HFE frequency may differ from that assumed or predicted in the modeling.
- Impacts on cultural resources can be characterized based on projected minimum and end-of-year lake elevations for very wet through very dry conditions and river flow volumes.
- Cultural resources that have not been previously inundated would not be inundated under the Continued Current Strategies (CCS) Comparative Baseline, the No Action Alternative, or any action alternatives (i.e., no cultural resources located above reservoir spillway elevations or above the level of current river flows would be inundated).

- The limit of physical impacts on cultural resources by the river is constrained to resources within the river corridor (bank to bank) or within 20 meters (66 feet) of the river.
- Where previous survey coverage is absent within the study area, there may be sites that have not yet been identified (i.e., undiscovered) that could be affected under the CCS Comparative Baseline, the No Action Alternative, or any action alternatives.
- The Class I records search conducted for the study area in Arizona, California, Nevada, and Utah serves as a representative dataset for the purposes of analysis.
- Lake Mohave and Lake Havasu would continue to follow their target end-of-the-month elevation schedules ("rule curve") (see **TA 3**, Hydrologic Resources), therefore, no cultural resource impacts are expected at these reservoirs.

Impact Indicators

- Projected monthly and end-of-year lake elevations that may expose cultural resources to damage from wave action, wet-dry cycling, or increased ease of access
- Projected WY and CY dam releases resulting in potential river-flow changes that leave cultural resources susceptible to damage from erosion, wet-dry cycling, or increased ease of access
- Projected availability of sediments along the river, which may be transported by wind and deposited on archaeological sites

TA 11.2.2 Issue 1: How will any changes in dam operations affect (1) lake elevations at Lake Powell and Lake Mead and (2) river flows downstream, which may affect cultural resources?

Lakes

As water levels in Lake Powell and Lake Mead fluctuate, archaeological sites that were previously inundated become vulnerable to several hazards. Direct impacts from wave action, wet-dry cycling, and erosion are more likely to occur as water levels drop to expose previously inundated resources; indirect impacts may occur from increased visitor traffic as access to exposed resources becomes easier. This section discusses the potential for archaeological resources to be exposed, and therefore potential impacts from exposure, using the distribution by elevation of cultural resources and the hydrologic modeling results for Lake Powell and Lake Mead elevations. However, please note that more data was available for Lake Powell than for Lake Mead because of variable archaeological survey coverage. The following discussion incorporates the discussion of hydrological modeling as presented in **TA 3**, Hydrologic Resources.

Because survey coverage varies across the study area and much of the locational data for recorded sites predates modern technology, precise site counts are not feasible for analysis. Instead, site counts should be considered a representative sample used to understand the overall level of sensitivity within the study area. Representative site counts by elevation were compiled from Class I data using associated elevations based on critical conditions for each lake, which are discussed in **TA 3**, Hydrologic Resources. For Lake Powell, the associated elevations for critical conditions pertinent to this analysis are 3,700 feet (top of the Glen Canyon Dam spillway) down to 3,490 feet (minimum power pool; see **Table TA 3-2** in **Section TA 3.2.1** of **TA 3**, Hydrologic Resources). For

Lake Mead, these associated elevations for critical conditions pertinent to this analysis are 1,221 feet (top of the Hoover Dam Spillway) down to 950 feet (minimum power pool; see **Table TA 3-5** in **Section TA 3.2.1** of **TA 3**, Hydrologic Resources).

Archaeological sites identified in the Lake Powell dataset are presented by elevation range in **Table TA 11-19**, while those identified in the Lake Mead dataset are presented (also by elevation range) in **Table TA 11-20**. Overall survey coverage for both lakes is very low (around 3 percent), which means the numbers in **Table TA 11-19** and **Table TA 11-20** greatly underrepresent the total number of sites present.

Table TA 11-19
Recorded Archaeological Sites in the Lake Powell Dataset by Elevation Range (Arizona and Utah)

Elevation Range (feet)	Elevation Range (meters)	No. of Sites (NPS)	No. of Sites (non-NPS)	Total
3,700–3,680	1,128–1,122	66	N/A	66
3,680–3,660	1,122–1,116	40	N/A	40
3,660–3,640	1,116–1,109	32	N/A	32
3,640–3,620	1,109–1,103	59	N/A	59
3,620–3,600	1,103–1,097	52	N/A	52
3,600–3,580	1,097–1,091	31	N/A	31
3,580–3,560	1,091–1,085	36	N/A	36
3,560–3,540	1,085–1,079	34	N/A	34
3,540–3,520	1,079–1,073	31	N/A	31
3,520–3,500	1,073–1,067	34	N/A	34
<3,500	<1,067	442	N/A	442
			Total Sites in the Lake Powell Dataset	**857**

Source: Glen Canyon NRA staff
Notes:

- N/A = not applicable; all lands within Glen Canyon NRA are NPS lands.
- Glen Canyon NRA staff provided updated NPS site counts by elevation in March 2026, stating that lands within the study area under 3,580 feet are NPS lands and should be accounted for in the updated data; therefore, the non-NPS data acquired during the Class I records search (which relies on agency data acquired in August 2023) have been omitted. Therefore, this table does not correlate with the NPS site counts (or the total number of sites) identified by the Class I records search.
- Survey coverage at Lake Powell is calculated to be 3.3 percent of the area below full pool meaning the number of sites in the Lake Powell data set represents a fraction of the total number of sites present.

Table TA 11-20
Recorded Archaeological Sites in the Lake Mead Dataset by Elevation Range (Arizona and Nevada)

Elevation Range (feet)	Elevation Range (meters)	No. of Sites (NPS)	No. of Sites (non-NPS)	Total
1,221–1,201	372–366	75	10	85
1,201–1,181	366–360	49	8	57
1,181–1,161	360–354	52	2	54
1,161–1,141	354–348	27	4	31
1,141–1,121	348–342	13	5	18
1,121–1,101	342–336	17	3	20
1,101–1,081	336–329	8	2	10
1,081–1,061	329–323	5	ND	5
1,061–1,041	323–317	6	ND	6
1,041–1,021	317–311	5	ND	5
1,021–1,001	311–305	5	ND	5
1,001–981	305–299	5	ND	5
981–961	299–293	5	ND	5
<961	<293	4	ND	4
		Total Sites in the Lake Mead Dataset		**310**

Sources: Lake Mead NRA staff; Tremblay et al. 2024b; Winslow, et al. 2024
Notes:

- ND = no data available; site counts for elevations below 1,081 feet were lacking for the non-NPS dataset.
- Lake Mead NRA staff provided updated NPS site counts by elevation in March 2026, acknowledging that the park's database may contain errors. For this reason, non-NPS data acquired in August 2023 for the Class I records search have been retained for analysis. Therefore, this table does not correlate with the NPS and non-NPS site counts (or the total number of sites) identified by the Class I records search.
- Survey coverage at Lake Mead is calculated to be 2.8 percent of the area below full pool meaning the number of sites in the Lake Mead data set represents a fraction of the total number of sites present.

There are no NRHP-listed or NRHP-eligible built environment resources within the elevation range for Lake Powell (3,700–3,490 feet), but there is one NRHP-eligible district within the elevation range for Lake Mead (1,221–950 feet): the Echo Bay Developed Area in Lake Mead NRA. The historic-era boat ramp within the district boundary falls between 1,221 and 1,100 feet.

Lake Powell

This section references **Figure TA 3-6** in **Section TA 3.2.1**, Issue 1, and **Table TA 3-3** and **Table TA 3-4** at the end of **TA 3**, Hydrologic Resources.

The following discussion uses the known number of sites within the Lake Powell dataset provided by NPS staff. Survey coverage at Lake Powell is calculated to be 3.3 percent of the area below full pool, meaning the number of sites in the Lake Powell dataset represents a fraction of the total number of sites present.

In general, where water-level elevations are at the top of the Glen Canyon Dam spillway (3,700 feet), all 857 archaeological sites in the Lake Powell dataset would be inundated, while water levels dropping to minimum power pool could expose up to all 857 archaeological sites (depending on how many of those in the Lake Powell dataset remain above 3,490 feet), leaving them vulnerable to impacts. A total of 442 sites (equating to around 52 percent of the sites in the Lake Powell dataset) are below 3,500 feet; thus, where any of the modeled scenarios result in reservoir levels below this elevation, a greater proportion of archaeological sites would be left vulnerable to impacts. Additionally, it is important to note that because some areas at Lake Powell have not been surveyed, any of the modeled scenarios have the potential to impact undiscovered archaeological resources. Based on these parameters, this section will focus on median and interquartile elevations for analysis as presented in **TA 3**, Hydrologic Resources, where appropriate.

As presented in **Table TA 3-3** and **Table TA 3-4** at the end of **TA 3**, Hydrologic Resources, the CCS Comparative Baseline and the No Action, Basic Coordination, Enhanced Coordination, and Maximum Operational Flexibility Alternatives all perform similarly under the Wet Flow Category with minimum WY median elevations around or just below 3,670 feet and EOWY median elevations around 3,680 feet. Therefore, based on these median elevations, any of these modeled scenarios could expose at least 66 archaeological sites, as well as any undiscovered sites that may be present above the EOWY median within the 3,680-3,660-foot zone. The Supply Driven Alternative (both Lower Basin [LB] Priority and LB Pro Rata approaches) has a minimum WY median elevation around 3,640 feet, which could potentially expose up to 138 sites above this elevation while up to 106 sites could be exposed (impacting 32 fewer sites) relative to an EOWY median elevation of around 3,660 feet. The Representative Preferred Alternative has a minimum WY median elevation of around 3,650 feet, which could potentially expose at least 106 archaeological sites and any additional sites above this elevation within the 3,660–3,640-foot zone along with any undiscovered sites that may be present. The EOWY median elevation for the Representative Preferred Alternative at just above 3,660 feet, similar to the same elevation for the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), also exposing up to 106 sites above this elevation. Sites exposed at higher elevations may be less vulnerable to impacts from wet-dry cycling and wave action, but may have increased ease of access depending on their location.

As conditions move toward average, the sites affected by wet-dry cycling are found at lower elevations in the lake, while sites exposed at higher elevations would see less of those impacts but may have increased ease of access. In the Average Flow Category, the modeled scenarios begin to perform differently compared to wetter hydrological conditions. Minimum WY median elevations for the CCS Comparative Baseline, and the No Action Alternative fall around and just below 3,550 feet, which could expose at least 316 archaeological sites as well as those above this elevation within the 3,540–3,560-foot zone along with any undiscovered sites that may be present. EOWY median elevations for the CCS Comparative Baseline and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) are around 3,570 feet and just above 3,580 feet for the No Action Alternative under average hydrological conditions. This would leave at least 280 known sites (and any undiscovered sites) present as well as those above 3,570 feet in the 3,580-3,560-foot zone vulnerable to impacts if elevations drop that low. Additional sites would continue to be exposed as water levels drop, depending on elevation (see **Table TA 11-19** above).

For the Average Flow Category, the Basic Coordination Alternative and the Representative Preferred Alternative both perform slightly better with a minimum WY median elevation of around 3,560 feet and around 3,570 feet, respectively, potentially exposing up to 316 sites (and any undiscovered sites present), leaving them vulnerable to impacts. The EOWY median elevation for these two alternatives is higher, around 3,590 feet for the Basic Coordination Alternative and just below 3,600 feet for the Representative Preferred Alternative, potentially leaving at least 249 known sites exposed as well as those above 3,590 feet in the 3,600-3,580-foot zone. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform the best with minimum WY median elevations around 3,610 feet to around, 3,600 feet, respectively, which would expose at between 197 and 249 known sites (and any undiscovered sites). The EOWY median elevations are around 3,630 feet for the Enhanced Coordination Alternative and around 3,620 feet for the Maximum Operational Flexibility Alternative, with the Enhanced Coordination Alternative exposing at least 138 sites (plus any additional sites present above 3,630 feet within the 3,640-3,620-foot zone) and the Maximum Operational Flexibility Alternative exposing up to 197 known sites. Both the Enhanced Coordination and the Maximum Operational Flexibility Alternatives also have the narrowest interquartile ranges for these median elevations (see **Figure TA 3-6** in **TA 3**, Hydrologic Resources).

As hydrological conditions become critically dry, the CCS Comparative Baseline, No Action Alternative, and all action alternatives struggle to reach key elevations for Lake Powell (see **Table TA 3-3** and **Table TA 3-4** at the end of **TA 3**, Hydrologic Resources). For the Critically Dry Flow Category, the CCS Comparative Baseline, and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives have flows for minimum WY and EOWY median elevations as well as interquartile ranges that are below 3,490 feet (minimum power pool), dropping down even lower to just below 3,440 feet for the No Action Alternative. Therefore, there is the potential for at least 415 archaeological sites (around 48 percent of the sites in the Lake Powell dataset), along with any undiscovered sites that may be present, to be left exposed and vulnerable under critically dry flow conditions. Additional sites could be left vulnerable as water levels drop below 3,490 feet (minimum power pool), depending on the elevations of the 442 sites recorded below 3,500 feet. As discussed in **Section TA 3.2.1**, Issue 1, in **TA 3**, Hydrologic Resources, the 3,500-foot elevation is important because it provides a 10-foot buffer for water supply and hydropower to stay above minimum power pool. These are also the elevations where sites are vulnerable to wet-dry cycling and wave action would be the lowest for all scenarios because more of the sites would be above the inundation line as water levels drop, but would also have the potential for increased ease of access.

For the Critically Dry Flow Category, the Representative Preferred Alternative fares slightly better with a minimum WY median elevation just above 3,490 feet, which would leave at least 415 sites exposed above 3,500 feet but would protect more sites if they are present above the minimum power pool elevation. The Representative Preferred Alternative performs even better relative to its EOWY median elevation just below 3,510 feet, which would inundate more sites below this elevation in the 3,520-3,500-foot zone. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform better with the minimum WY elevations at around 3,520 feet and 3,510 feet, respectively. EOWY median elevations are higher at around 3,560 feet and around 3,550 feet, respectively. This means that, relative to EOWY median elevations, both alternatives have the

potential to expose at least 316 known sites (and any undiscovered sites present) down to 3,560 feet with the Maximum Operational Flexibility Alternative exposing more sites if any are present above 3,550 feet within the 3,560-3,540-foot zone. The interquartile ranges for the Enhanced Coordination Alternative indicates that this is the only alternative that has the potential to expose the fewest sites of all modeled scenarios relative to critically dry conditions with an that have the potential to expose the fewest sites (up to 249 sites) as the uppermost limit of the EOWY median elevation (75th percentile) for this action alternative reaches around 3,600 feet.

Lake Mead

This section references **Figure TA 3-11** in **Section TA 3.2.1**, Issue 1, and **Tables TA 3-6** and **TA 3-7** at the end of **TA 3**, Hydrologic Resources. Like Lake Powell, this section focuses on median and interquartile elevations for analysis.

The following discussion uses the known number of sites within the Lake Mead dataset provided by NPS staff. Survey coverage at Lake Mead is calculated to be 2.8 percent of the area below full pool meaning the number of sites in the Lake Mead data set represents a fraction of the total number of sites present. For Lake Mead generally, when water-level elevations are at or above 1,221 feet, all 310 archaeological sites in the datasets (and any undiscovered sites present) would be inundated. Conversely, if water levels drop to 950 feet, up to 310 sites in the Lake Mead datasets (and any undiscovered sites above this elevation) would be exposed, depending on the elevations of sites below 961 feet (see **Table TA 11-20**). The archaeological sites recorded at Lake Mead are distributed relatively evenly across the uppermost elevation ranges of the reservoir, with 275 sites (around 89 percent of sites in the Lake Mead datasets) recorded above 1,081 feet. Therefore, if any of the modeled scenarios result in reservoir levels below 1,081 feet, a greater proportion of archaeological sites would be exposed. However, sites exposed at higher elevations may be less vulnerable to impacts from wet-dry cycling and wave action, but they may have increased ease of access depending on their location.

To reiterate, very little of Lake Mead was surveyed prior to the construction of the Hoover Dam in the early 1930s; as a result, undiscovered archaeological resources are likely to be present in unsurveyed areas that could be affected under any of the modeled scenarios.

Although Wet Flow Category conditions as modeled for Lake Mead are less likely to occur based on conditions in recent years, the CCS Comparative Baseline and No Action Alternative perform similarly for minimum CY and EOCY median elevations and interquartile ranges. As presented in **Table TA 3-6** and **Table TA 3-7** at the end of **TA 3**, Hydrologic Resources, even under the wettest hydrological conditions for the modeled scenarios, elevations for the CCS Comparative Baseline and No Action Alternative for both the minimum CY and EOCY median scenarios are between around 1,150 feet and 1,100 feet, exposing between 196 and 265 known archaeological sites and any undiscovered sites at or above these median elevations.

For the Basic Coordination Alternative in the Wet Flow Category, the minimum CY and EOCY median elevations are around 1,170 feet and 1,180 feet, respectively, exposing a minimum of 142 known sites and any undiscovered sites present above these elevations. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform better, with median elevations around

1,200 to 1,210 feet for both minimum CY and EOCY elevations. This would expose up to 85 known sites (and any undiscovered sites) present down to 1,200 feet; fewer sites would be exposed as water levels rise (see **Table TA 11-20** above). The Representative Preferred Alternative performs similarly, with a minimum CY median elevation of just below 1,200 and an EOCY median elevation of around 1,210 feet under the wettest conditions, potentially exposing the same number of known sites (and any undiscovered sites present) as the Enhanced Coordination and Maximum Operational Flexibility Alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs only slightly better compared to all the modeled scenarios in this flow category, with minimum CY and EOCY median elevations above 1,210 feet, which would expose fewer than 85 sites depending on their elevations within the 1,221-1,201-foot zone. As mentioned above for Lake Powell, sites exposed at higher elevations at Lake Mead may be less vulnerable to impacts from wet-dry cycling and wave action, but at the same time they may have increased ease of access depending on their location.

In the Average Flow Category, the modeled scenarios result in a variable range of performance respective to minimum CY and EOCY median elevations (refer to **Table TA 3-6** and **Table TA 3-7** at the end of **TA 3**, Hydrologic Resources). The No Action Alternative performs the poorest with median values for both minimum CY and EOCY elevations just below 970 feet and just below 980 feet, respectively, which would expose at least 301 known archaeological sites in the Lake Mead dataset as well as those below this elevation in the 981–961-foot zone (including any undiscovered sites that may be present). The CCS Comparative Baseline has higher median elevations than the No Action Alternative, with a minimum CY median elevation of 1,030 feet and an EOCY median elevation of around 1,040 feet, but it would still leave a minimum of 286 archaeological sites and any additional undiscovered archaeological sites present vulnerable from exposure.

Under average flow conditions, the Basic Coordination Alternative has minimum CY median elevation just above 1,050 feet and EOCY median elevation of just above 1,060 feet, leaving at least 280 archaeological sites (along with any undiscovered sites present) exposed, while the corresponding interquartile ranges from 1,130 feet at the upper limit down to around 1,000 feet could leave, at a minimum, between 227 to 296 known sites (and any undiscovered sites) left vulnerable to impacts from exposure, depending on elevation. The Representative Preferred Alternative performs slightly better with a minimum CY median elevation of just above 1,090 feet and a EOCY median elevation just above 1,100 feet, exposing at least 265 known archaeological sites as well as any undiscovered sites present. Additional sites would be exposed as water levels drop (refer to **Table TA 11-20** above). Additionally for the Average Flow Category, the Enhanced Coordination Alternative has a minimum CY median elevation around 1,100 feet and an EOCY median elevation of around 1,110 feet, which has the potential to at least 245 sites and up to 265 sites (and any undiscovered sites present) depending on elevation. The interquartile range for this alternative is similar for both minimum CY and EOCY elevations, from around 1,130 feet to around 1,060 feet, and around 1,140 feet to around 1,070 feet, respectively, which may expose at least 227 known sites above 1,140 feet and up to 280 known sites (and any undiscovered sites present in the study area at Lake Mead), depending on elevation. The Maximum Operational Flexibility Alternative has a minimum CY median elevation of just below 1,120 feet and an EOCY median elevation of just below 1,130 feet, potentially exposing at least 227 known sites and up to 245 known sites, along with

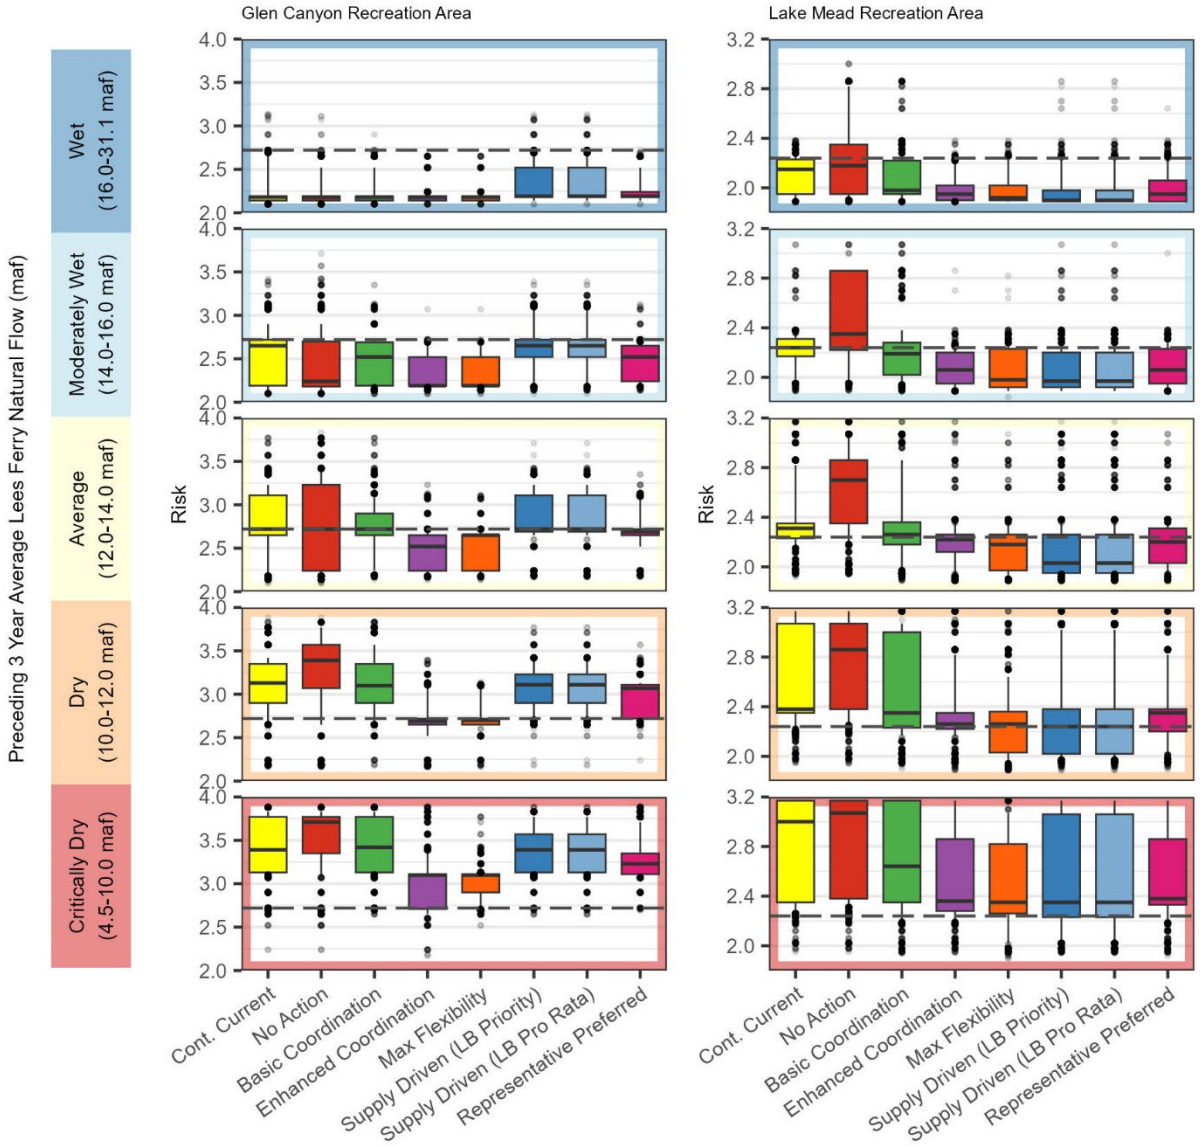
any undiscovered sites present. The interquartile range for the Maximum Operational Flexibility Alternative is the largest of all modeled scenarios for both minimum CY and EOCY elevations, from around 1,180 feet, leaving up to 142 known sites exposed, down to just above 1,040 feet, which would leave up to 286 archaeological sites (and any undiscovered sites present) vulnerable to impacts.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs the best in the Average Flow Category. The Supply Driven Alternative (LB Priority approach) minimum CY and EOCY median elevations of around 1,140 feet and 1,150 feet, respectively, would expose between 196 known sites up to 227 sites as well as any undiscovered sites present in those elevation ranges. The Supply Driven Alternative (LB Pro Rata approach) has a minimum CY median elevation of just above 1,150 feet and an EOCY median elevation of 1,160 feet, which has the potential to expose at least 196 known sites (and any undiscovered sites) down to 1,160 feet as well as those present above 1,150 feet within the 1,161-1,141-foot zone, leaving them vulnerable to impacts. The interquartile ranges for the Supply Driven Alternative vary, with the range for the LB Pro Rata approach performing the best from just below 1,190 feet (75th percentile) down to just below 1,070 feet (25th percentile) and around 1,180 feet (75th percentile) down to just below 1,060 feet (25th percentile for the LB Priority approach. This has the potential to leave (at minimum) between 85 and 275 known sites vulnerable to exposure under the LB Pro Rata approach and (at minimum) between 142 and 280 known sites exposed under the LB Pro Rata approach (and any undiscovered sites present) during average hydrological conditions.

As conditions grow drier, the modeled scenarios remain the same in relation to one another relative to minimum CY and EOCY median elevations, but they shift downward collectively in elevation about 100 feet in the Critically Dry Flow Category. As discussed in **Section TA 3.2.1**, Issue 1, in **TA 3**, Hydrologic Resources, the 975-foot elevation is important for Lake Mead because it provides a 25-foot buffer for water supply and hydropower to stay above minimum power pool. Like Lake Powell, as conditions for Lake Mead become drier, the sites affected by wet-dry cycling are found at lower elevations in the lake, while sites exposed at higher elevations would see less of those impacts but may have increased ease of access.

Under critically dry hydrological conditions, the elevation where sites are vulnerable to wet-dry cycling and wave action would be the lowest for all scenarios. The CCS Comparative Baseline has a minimum CY median elevation of around 930 feet, while the No Action Alternative drops to around 900, both of which are well below minimum power pool (950 feet). The EOCY median elevation for the CCS Comparative Baseline is around 960 feet; with the No Action Alternative EOCY median elevation dropping below that to around 930 feet. Both would potentially leave all 310 archaeological sites in the Lake Mead datasets (and any undiscovered sites present) vulnerable from exposure, depending on the elevations of the four sites below 961 feet. For the Critically Dry Category, the Basic Coordination Alternative fares slightly better with a minimum CY median elevation of just above 970 feet and an EOCY median elevation of around 980 feet. The Representative Preferred Alternative performs slightly better with a minimum CY median elevation of around 980 feet and an EOCY median elevation of just above 990 feet. Despite having slightly higher median elevations, these two action alternatives still have the potential to leave a minimum of 296 known archaeological sites (over 95 percent of sites in the Lake Mead dataset) and any

undiscovered sites present) exposed during critically dry conditions. The Enhanced Coordination Alternative, which has minimum CY and EOCY median elevations of around or just above 1,000 feet and interquartile ranges from 1,050 feet down to around 950 feet, would have the potential to leave up to all 310 known sites (and any undiscovered sites) exposed, depending on the elevations of the four known sites (and any undiscovered sites present) below 961 feet. The Maximum Operational Flexibility Alternative has similar median elevations of just above 1,010 feet down to around 1,000 feet, which would still leave between 291 and 296 known sites vulnerable to impacts. The interquartile ranges for this alternative are from around 1,060 feet down to around 970 feet, potentially exposing (at minimum) between 280 and 301 known sites at or above 981 feet as well as those down to 970 feet if any of the four known archaeological sites (and any undiscovered sites) in the 981–961-foot zone are present above that elevation.



The LB Priority approach under the Supply Driven Alternative has similar minimum CY and EOCY median elevations of around 1,010 feet, while the Supply Driven Alternative (LB Pro Rata approach) has median elevations at or just below around 1,030 feet, the latter of which is the highest median elevation for any of the modeled scenarios in the Critically Dry Flow Category. Regardless of this, a minimum of 286 to 291 known sites (and any undiscovered sites) have the potential to be exposed based on median elevations under the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches). The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) does have the potential to protect some sites through inundation when examining the upper limits of their interquartile ranges for both minimum CY and EOYC median elevations, which are at or just above 1,070 feet for the LB Priority approach (exposing at least 275 known sites) and around 1,090 feet for the LB Pro Rata approach (exposing at least 265 sites); however, both scenarios would still leave at least 85 percent of the sites in the Lake Mead dataset, in addition to any undiscovered sites present, exposed above the water level and thus vulnerable to impacts.

For the Echo Bay Developed Area, modeled scenarios with minimum CY and EOCY median elevations below 1,100 feet expose additional portions of the boat ramp; however, this would occur outside the NRHP-eligible district boundary toward the receding lakeshore. Conversely, modeled scenarios with elevations above 1,100 feet could partially inundate the ramp, with full submersion occurring at higher elevations along the ramp, which extends up to approximately 1,221 feet. These conditions would be more likely under the Supply Driven Alternative, as the interquartile ranges for minimum CY and EOCY elevation for the LB Priority approach extends to around 1,090 feet. Reservoir elevations exceeding 1,221 feet, would begin to impact recreation area infrastructure within the district boundary.

Preservation Risk Modeling

Preservation risk modeling results were compared to the 90th percentile values of modeled values for WY 2008 to 2025 (i.e., the Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead [2007 Interim Guidelines] period); the 90th percentile risk value for Lake Powell is 2.72 and for Lake Mead is 2.24 (Caster et al. 2026). If preservation risk exceeds these threshold values, impacts on archaeological sites may occur at levels beyond those expected under historical conditions for the specific reservoir. For the purposes of this analysis, "historical conditions" coincide with the 2007 Interim Guidelines period (WY 2008–2025). **Figure TA 11-1** shows the WY maximum archaeological preservation risk for Lake Powell and Lake Mead.

Figure TA 11-1
Water Year Maximum Archaeological Preservation Risk at Glen Canyon NRA and Lake Mead NRA

For both Lake Powell and Lake Mead, the WY maximum preservation risk median is lowest in the Wet Flow Category for the CCS Comparative Baseline, No Action Alternative, and all action alternatives. The median for Lake Powell is 2.18 for all except for the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and the Representative Preferred Alternative, which are slightly higher at 2.19. All the median risk values remain below 2.72 during wet flow periods for Lake Powell, meaning that impacts on archaeological sites, if they occur, would like those anticipated under similar historical conditions. At Lake Mead, the median risk value in the Wet Flow Category is at or below 2.0 for all alternatives (including the Representative Preferred Alternative at 1.95), except for the No Action Alternative at 2.18 and the CCS Comparative Baseline at 2.15. None of the

median risk values are above 2.24 for Lake Mead, which means impacts to archaeological sites, if they occur, would not be at levels greater than expected under similar historical conditions. However, the interquartile range for the No Action Alternative does reach up to 2.35 (75th percentile), the highest of any of the modeled scenarios.

In the Average Flow Category, the CCS Comparative Baseline, and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives all have preservation risk median values at the 2.72 threshold for Lake Powell. The Representative Preferred Alternative has a median value of 2.69, followed by the Maximum Operational Flexibility Alternative at 2.65 and the Enhanced Coordination Alternative at 2.52. The preservation risk median for the Enhanced Coordination Alternative is 2.52 and for the Maximum Operational Flexibility Alternative at 2.65; both have the same interquartile ranges from 2.65 to 2.24 under average hydrological conditions. The Representative Preferred Alternative has the narrowest interquartile range from 2.72 (75th percentile) to 2.65 (25th percentile) while the No Action Alternative has the greatest variation in risk in the interquartile range from 3.23 (75th percentile) down to 2.24 (25th percentile). Therefore, under average flow periods as modeled, if impacts on archaeological sites occur, they would not be at levels beyond those otherwise expected under similar average conditions historically.

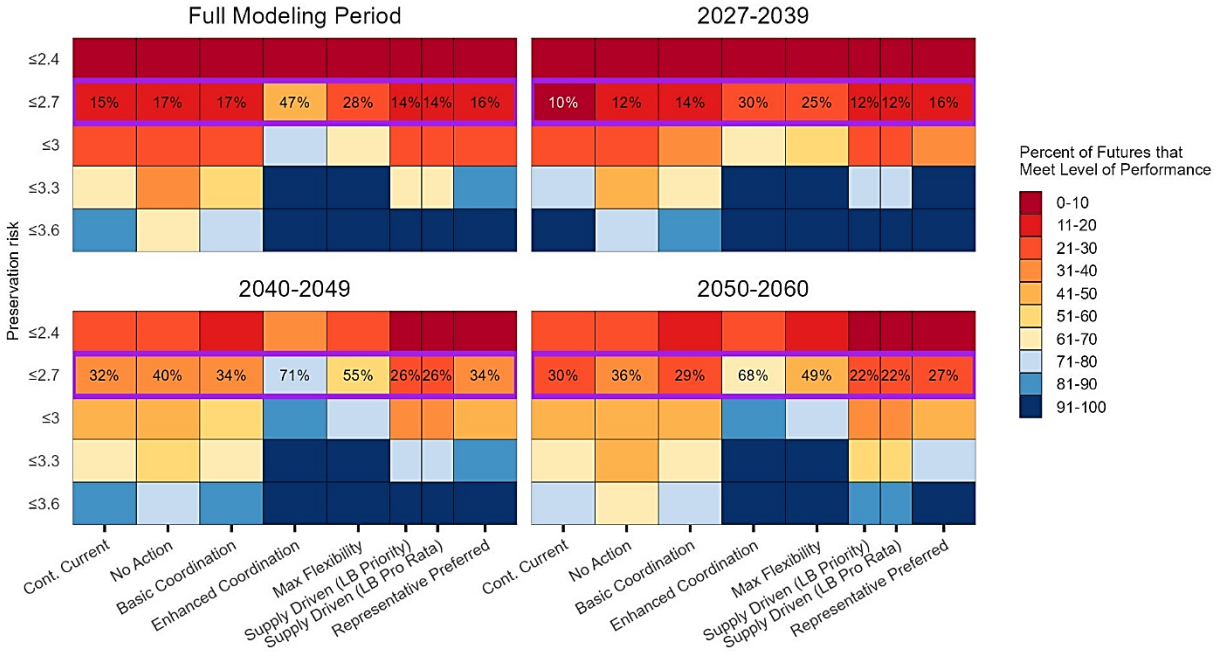
For Lake Mead in the Average Flow Category, the preservation risk median value is highest for the No Action Alternative at 2.70. The CCS Comparative Baseline is the second highest at 2.31 while the Basic Coordination Alternative is at 2.26, which remains above the preservation risk value threshold of 2.24. This means that, during average flows, the risk to archaeological sites is greater than would otherwise be expected under similar historical conditions. The Enhanced Coordination Alternative has a preservation risk median of just below 2.24 at 2.22 followed by the Representative Preferred Alternative at 2.20 and the Maximum Operational Flexibility Alternative at 2.18. The interquartile ranges for the CCS Comparative Baseline, the No Action Alternative as well as all the action alternatives have upper preservation risk values above 2.24, including the Representative Preferred Alternative at 2.31. The lower extent of these interquartile ranges drops below 2.24 except for the No Action Alternative, which remains above it at 2.35 in the Average Flow Category. The median risk value for the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the lowest at 2.03.

In the Critically Dry Flow Category for Lake Powell, the preservation risk median values for CCS Comparative Baseline and all the alternatives are over the 2.72 threshold. The No Action Alternative has the median highest preservation risk for Lake Powell, which is well over 2.72 at 3.71, followed by the Basic Coordination Alternative at 3.42, and the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative at 3.39. The Representative Preferred Alternative has a preservation risk median value of 3.23 while both the Maximum Operational Flexibility and Enhanced Coordination Alternatives have at 3.10; however, the interquartile range of the Enhanced Coordination drops to 2.71. Again, the lower the preservation risk value, the better the performance and where these median values fall below 2.72 at Lake Powell, impacts to archaeological sites, if they occur, would not be beyond those anticipated under similar historical conditions.

The preservation risk median values for Lake Mead in the Critically Dry Flow Category for all scenarios are well above the 2.24 preservation risk value threshold. The No Action Alternative performs the worst at 3.07 followed by the No Action Alternative at 3.0. All of the action alternatives thus fall below 3.0, with the Basic Coordination Alternative at 2.64, the Representative Preferred Alternative at 2.38, the Enhanced Coordination Alternative at 2.36, and the Maximum Operational Flexibility and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives at 2.35. Because neither the CCS Comparative Baseline, the No Action Alternative, nor the action alternatives have preservation risk median values below 2.24, impacts to archaeological sites would be at levels beyond those anticipated under critically dry conditions historically.

Figure TA 11-2 and **Figure TA 11-3** compare alternatives by showing the percentage of futures in which the preservation risk is below 2.72 for Lake Powell and 2.24 for Lake Mead in at least 90 percent of months. The 2.72 and 2.24 preservation risk values represent the 90th percentile of modeled historical values for WY 2008–2025 (the 2007 Interim Guidelines period), which includes the period of significant reservoir storage loss. To reiterate, if preservation risk exceeds these value thresholds for the reservoirs, impacts on archaeological sites may occur at levels greater than those expected under historical conditions. The highlighted row shows the percentage of futures at that preferred minimum performance.

Figure TA 11-2
Cultural Resources in Glen Canyon NRA: Robustness
Percentage of futures in which monthly preservation risk stays below the value specified in each row in at least 90 percent of months



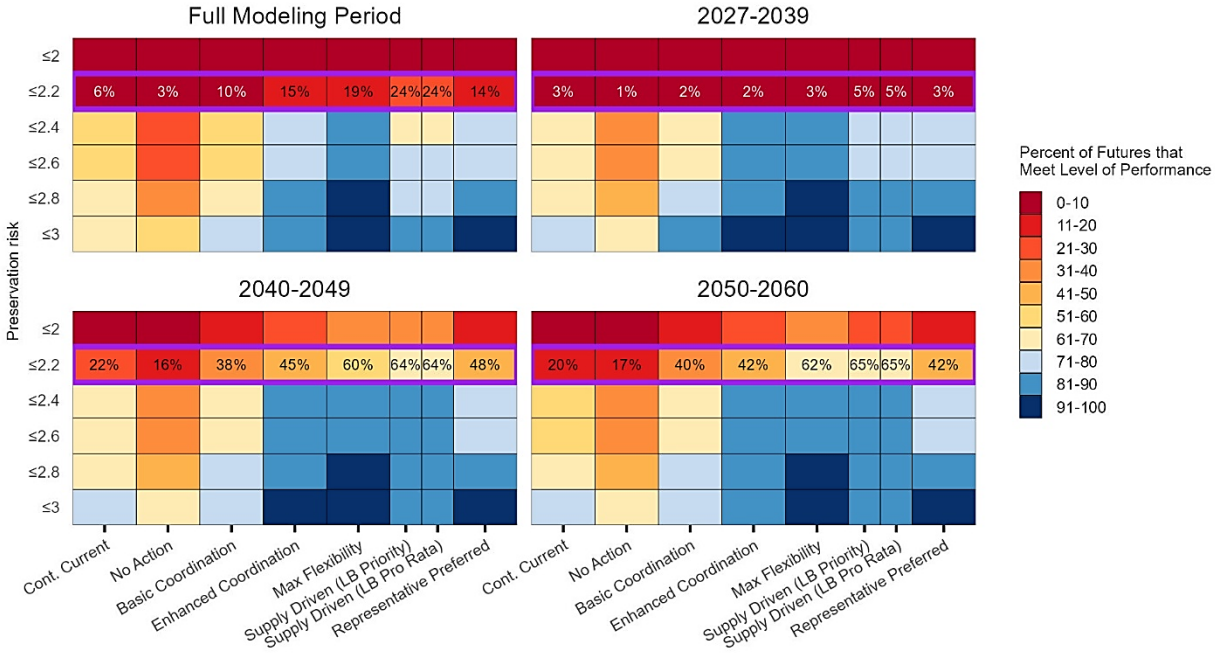


Figure TA 11-3
Cultural Resources in Lake Mead NRA: Robustness
Percentage of futures in which monthly preservation risk stays below the value specified in each row in at least 90 percent of months

For Lake Powell, over the full modeling period, the Enhanced Coordination Alternative is the most robust, meeting the 2.72 risk threshold in 47 percent of futures. The Maximum Operational Flexibility Alternative is less robust, meeting the 2.72 threshold in 28 percent of futures, followed by the No Action and Basic Coordination Alternatives at 17 percent, the Representative Preferred Alternative at 16 percent, and the CCS Comparative Baseline at 15 percent. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) meets the preferred level of performance in 14 percent of futures. This relational pattern is consistent if the full modeling period is broken out into shorter periods, including the first decadal period from 2027–2039 where the Enhanced Coordination Alternative also performs the best at 30 percent whereas the CCS Comparative Baseline performs the worst at 10 percent. It is important to note that 2027, as the beginning of the first 10-year interval, is anticipated to have low reservoir elevations and, therefore, the modeling for this breakout (2027–2039) shows very low percentages of futures met for the preferred minimum of performance across the CCS Comparative Baseline, the No Action Alternative, and all other action alternatives. See **Figure TA 11-2** above for robustness modeled for 2040–2049 and 2050–2060 at Lake Powell.

For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust by meeting the 2.24 risk threshold in 24 percent of futures over the full modeling period. The CCS Comparative Baseline and No Action Alternative meet the preferred minimum of performance in only 6 and 3 percent of futures, respectively. The Maximum Operational Flexibility Alternative meets the threshold in 19 percent of futures, followed by the Enhanced Coordination

Alternative at 15 percent, the Representative Preferred Alternative at 14 percent, and the Basic Coordination Alternative at 10 percent. If the modeling period is broken out, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) can be seen to meet the threshold for only 5 percent of futures in the first decadal period (2027–2039), followed by the CCS Comparative Baseline, the Maximum Operational Flexibility Alternative, and the Representative Preferred Alternative, all three of which meet the preferred level of performance in only 3 percent of futures. The Basic Coordination and Enhanced Coordination Alternatives meet the threshold 2 percent of the time while the No Action Alternative is at 1 percent for the 2027–2039 modeling period. It is important to note that, when examining the first decadal period (2027–2039) at Lake Mead, the percentage of futures meeting the preferred minimum of performance drops drastically because the anticipated water levels for Lake Mead in 2027 are expected to be low. Therefore, the robustness modeling shows a substantial drop in performance compared to the full modeling period. See **Figure TA 11-3** above for robustness modeled for 2014–2049 and 2050–2060 at Lake Mead.

Overall, the Enhanced Coordination Alternative is the most robust for Lake Powell for the full modeling period and the first decadal modeling period (2027–2039), followed by the Maximum Operational Flexibility Alternative. For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust for, followed by the Maximum Operational Flexibility Alternative for the full modeling period. Looking at only the 2027–2039 modeling period, while the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) still remains the most robust at 5 percent, the CCS Comparative Baseline, Representative Preferred Alternative, and Maximum Operational Flexibility Alternative are all equally, but lesser, robust for the first 10-year period at 3 percent.

River Flows

This section references the discussion presented in **Section TA 3.2.4**, Issue 4, as presented in **TA 3**, Hydrologic Conditions, with additional references to other sections as appropriate.

For the purposes of analyzing potential impacts related to changes in river flow, archaeological sites that may be physically affected are those located along or immediately adjacent to the river, where erosion caused by moving water may occur. As with the lake site data discussed above, variable survey coverage and older locational data must be taken into account. To identify a representative number of sites that may be affected by changes in flow, sites with all or portions of their boundaries in the river corridor or within 20 meters (66 feet) of the river corridor (bank to bank) were identified from the overall datasets using a geographic information system. **Table TA 11-21** lists the number of sites along the river.

Like archaeological sites, built environment resources, and specially designated cultural resources that may be most affected by river flow changes are those immediately along the river corridor. As previously mentioned, built environment resources along the river tend to be more resilient to changes in river flow because they were designed to avoid impacts from shifts in conditions. Using elevations from DEM and other data sources, NRHP-listed and NRHP-eligible built environment resources and specially designated cultural resources that are all or in part within 20 meters (66 feet) of the riverbank and/or above the river itself (such as in the case of bridges) were identified.

Unevaluated built environment resources are treated as eligible for the purposes of analysis. **Table TA 11-22** summarizes these properties.

Table TA 11-21
Representative Number of Sites within 20 Meters (66 Feet) of the River by Reach

Reach	No. of NPS Sites	No. of Sites (non-NPS)	Total
Glen Canyon Dam to Lake Mead	128	43	171
Hoover Dam to Davis Dam	180	78	258
Davis Dam to Parker Dam	N/A	64	64
Parker Dam to Imperial Dam	N/A	16	16
Imperial Dam to the SIB	N/A	2	2

Note: The information presented in this table incorporates NPS and non-NPS data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.

Table TA 11-22
Built Environment and Specially Designated Cultural Resources within 20 Meters (66 Feet) of the River by Reach

Reach	Resource Name	Status	Property Type
Glen Canyon Dam to Lake Mead	Lee's Ferry and Lonely Dell Historic District	NRHP (Listed)	District
Hoover Dam to Davis Dam	Willow Beach Gauging Station	NRHP (Listed)	Structure
Davis Dam to Parker Dam	Historic U.S. Route 66	NRHP (Listed)	Structure
	National Old Trails Arch Bridge (Topock Bridge)	NRHP (Listed)	Structure
Parker Dam to Imperial Dam	Fisher's Landing	Unevaluated	District
Imperial Dam to the SIB	Southern Pacific Railroad Bridge	Unevaluated	Structure
	Ocean-to-Ocean Highway Bridge	NRHP (Listed)	Structure
	Yuma Crossing and Associated Sites	NHL, NRHP (Listed)	District

Source: Eddy et al. 2024; Eskenazi 2024; Tremblay et al. 2024b; Winslow et al. 2024
Notes: The Hoover Dam to Davis Dam and Davis Dam to Parker Dam reaches exclude Lake Mohave and Lake Havasu, respectively, because these two reservoirs would continue to be operated under their same rule curves for target end-of-month elevations, regardless of modeled scenario. The information presented in this table incorporates data acquired in August 2023 for the Class I records search; therefore, the number of sites and/or their corresponding NRHP status do not reflect current agency databases.

Glen Canyon Dam to Lake Mead

This section references the median and interquartile WY release volumes (in maf) from Glen Canyon Dam illustrated in **Figure TA 3-21** in **Section TA 3.2.3**, Issue 3, with the full statistical

summary presented in **Table TA 3-14** at the end of **TA 3**, Hydrologic Resources. In all categories except the Critically Dry Flow Category, the high end of the results range has been cut off to improve comparisons in the average and drier flow conditions.

Since 2008, WY release volumes from Glen Canyon Dam have been from around 7.0 maf to around 12.5 maf, averaging around 8.7 maf. The annual average release of around 8.7 maf is just over 1.0 maf lower than the average annual releases from 1996 to 2007 of 9.8 maf, which is the result of both hydrologic conditions in the Colorado River Basin and operations under the 2007 Interim Guidelines (see **Section TA 3.1.3**, Lake Powell and Glen Canyon Dam, in **TA 3**, Hydrologic Resources). In general, WY releases from Glen Canyon Dam deviate that fall outside the historical range of around 7.0–12.5 maf have greater potential to impact known cultural resources within 20 meters (66 feet) of the river as well as to undiscovered resources that may be present along the river corridor. In addition, higher WY release volumes can increase erosion along the river corridor, even when releases remain in this historical range. As stated above, impacts from changes in river flow would include water erosion from river currents during higher releases, but may also include exposure from lower water levels where dam release volumes are reduced; however, these impacts are only be considered in terms of this analysis when these volumes are outside past releases or flows.

River flows from Lake Powell to Lake Mead primarily consist of controlled releases from Glen Canyon Dam. WY releases from Glen Canyon Dam under the Wet Flow and Average Flow Categories would generally fall within the range of past annual release volumes for all modeled scenarios. Under wet flow conditions, the median volumes of WY releases range from around 8.4 maf for the CCS Comparative Baseline up to 12.0 maf for the Representative Preferred Alternative. Neither the CCS Comparative Baseline, No Action Alternative, nor the action alternatives (including the Representative Preferred Alternative) have median volumes that fall below 7.9 maf in the Average Flow Category. In terms of interquartile ranges under wetter hydrological conditions, none of the modeled scenarios exceed past release volumes (7.0–12.5 maf). For sites within 20 meters (66 feet) of the river in this reach, it is anticipated that, under wetter conditions, there would be no additional impacts because none of the modeled scenarios deviate outside the established range. This is also true for the one NRHP-listed built environment resource found along this reach because the boundary of the Lees Ferry and Lonely Dell Historic District extends into the river channel.

For the Average Flow Category, the interquartile range for the Enhanced Coordination Alternative is the only modeled scenario that has the potential to deviate the most from the range of past release volumes (7.0 maf up to 12.5 maf), as it is modeled as potentially dropping to around 6.9 maf (25th percentile). Reductions in the volume of WY releases would affect river flows, thereby potentially exposing the Steamboat Charles Spencer. The same drops in river flows, resulting from reduced WY releases from Glen Canyon Dam, would not be detrimental to the only known historic property within 20 meters (66 feet) of the river, as lower water levels would protect the Lee's Ferry and Lonely Dell Historic District from river currents.

For the Critically Dry Flow Category, median WY release volumes for the CCS Comparative Baseline, No Action Alternative, and all action alternatives (including the Representative Preferred Alternative) fall below 7.0 maf, down as low as around 5.1 maf for the Enhanced Coordination

Alternative. Under the critically dry hydrological conditions, the No Action Alternative performs better than the others relative to the upper limits of the interquartile range (75th percentile), which is 8.2 maf, followed by the CCS Comparative Baseline at around 7.7 maf. The Representative Preferred Alternative has one of the narrowest interquartile ranges under critically dry hydrological conditions, with an upper limit around 6.0 maf, which is still below the bottom of the range of past flow volumes at 7.0 maf. All the modeled scenarios could expose the Steamboat Charles Spenser if the reduced volumes of these WY releases cause the river to drop below previous water levels. On the other hand, these same potential drops in river water level would protect the only NRHP-listed property within 20 meters (66 feet) of the river (the Lee's Ferry and Lonely Dell Historic District), as previously discussed.

Hoover Dam to Davis Dam

This section references the median and interquartile CY release volumes from Hoover Dam illustrated in **Figure TA 3-25** in **Section TA 3.2.3**, Issue 3*,* with the full range of statistical data presented in **Table TA 3-19** at the end of **TA 3**, Hydrologic Resources. In all categories, the high end of the results range has been cut off to improve comparisons in the average and drier flow conditions.

Since 2008, CY releases from Hoover Dam have been from around 8.5 maf to around 9.6 maf, averaging around 9.2 maf (see **TA 3.1.7**, Hoover Dam to Lake Mohave*,* in **TA 3**). Since the implementation of the 2007 Interim Guidelines, releases from Hoover Dam have decreased to meet monthly elevation targets, resulting in lower river flows through this reach. The 2007 Interim Guidelines have reduced average CY releases from Hoover Dam by approximately 1.0 maf (averaging 9.2 maf). In general, CY releases from Hoover Dam occurring outside the historical range of around 8.5–9.6 maf have greater potential for impacts on known cultural resources within 20 meters (66 feet) of the river as well to undiscovered resources that may be present along the river corridor. The impacts from changes in river flow would include water erosion from river currents during higher releases, but may also include exposure from lower water levels where dam release volumes are reduced; however, these impacts are only considered in terms of this analysis when these volumes are outside past releases that in turn change river flows. Based on these parameters, this section will focus on median and interquartile release volumes (in maf) for analysis and frequently refers to **TA 3**, Hydrologic Resources, where appropriate.

River flows below Lake Mead primarily consist of controlled releases from Hoover Dam. Median CY releases under the Wet Flow Category would remain within the range of past volumes except for the Supply Driven Alternative, with the LB Priority approach around 10.2 maf and the LB Pro Rata approach around 10.4 maf. Under this alternative, the median CY release volumes would exceed 9.6 maf by up to 0.8 maf, potentially causing erosion to sites along the river. Interquartile ranges for the CCS Comparative Baseline and the No Action Alternative are narrow, with the upper range (75th percentile) for both exceeding past CY release ranges at around 10.1 maf while the lower range (25th percentile) stays within past conditions. Similarly for the action alternatives, while the interquartile ranges vary, the upper limits (75th percentile) of all (including the Representative Preferred Alternative) exceed CY releases of 9.6 maf with the LB Pro Rata approach under the Supply Driven Alternative being the highest at around 11.4 maf. Exceeding the range of past CY release volumes (i.e., above 9.6 maf) risks impacting archaeological sites within 20 meters (66 feet) of the river that

have not been previously affected by river flows if releases from Hoover Dam that are above 9.6 maf cause river water levels to also rise within this reach. Depending on these river levels, the substructure of the one NRHP-listed built environment resource (Willow Beach Gaging Station) identified within this reach could be affected, but this structure was designed to withstand changes in historical river flows and was built directly above the river's surface; therefore, impacts are unlikely even under the wet hydrological conditions presented under the different modeled scenarios.

For the Average Flow Category, median CY release volumes for the No Action Alternative is the only modeled scenario that remains within the 8.5–9.6 maf range for previous release volumes below Hoover Dam in this reach at around 8.6 maf. The CCS Comparative Baseline falls just under previous release volumes at around 8.3 maf. The action alternatives do not perform as well, with the median CY release volume for the Basic Coordination Alternative in the Average Flow Category around 8.0 maf, followed by the Representative Preferred Alternative at around 7.9 maf, the Maximum Operational Flexibility Alternative at around 7.8 maf, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) at around and just below 7.7 maf, and the Enhanced Coordination Alternative at just below 7.6 maf. Where impacts on archaeological sites result from erosion caused by moving water, these may be less likely to occur if the reduced CY release volumes cause the river to drop below previous water levels. The same drops in river water levels below Hoover Dam would not be detrimental to NRHP-listed Willow Beach Gaging Station.

For the Critically Dry Flow Category, median CY release volumes would be well below previous volume ranges (i.e., below 8.5 maf) for the CCS Comparative Baseline, No Action Alternative, and all action alternatives, which fall below 8.0 maf, down as low as 6.4 maf for the Maximum Operational Flexibility Alternative, with the Enhanced Coordination Alternative slightly higher at around 6.5 maf. Under the driest hydrological conditions, the No Action Alternative, followed by the CCS Comparative Baseline, performs better than the others relative to the upper limits of their interquartile ranges (75th percentile), which are around 8.6 maf for the No Action Alternative and around 8.3 maf for the CCS Comparative Baseline. The Representative Preferred Alternative has an upper interquartile range limit of around 7.9 maf, which again is below the range past flow volumes (8.5–9.6 maf). Again, relative to impacts to archaeological sites that may be subject to erosion caused by moving water, the modeled scenarios may be less likely to physically affect archaeological sites if the reduced CY release volumes cause the river to drop below previous water levels. Likewise, these same potential drops in river water level would not affect the NRHP-listed Willow Beach Gaging Station previously discussed.

Within this reach is Lake Mohave, which is operated under a rule curve that maintains end-of-month target elevations between 630 feet up to around 646 feet, has been kept relatively constant at around 641 feet since 2008 (see **Section TA 3.1.7**, Hoover Dam to Lake Mohave*,* in **TA 3**, Hydrologic Resources). Because Lake Mohave would continue to be operated under this rule curve, regardless of scenario, there are no anticipated impacts on any known cultural resources around the reservoir in this portion of the reach.

Davis Dam to Parker Dam

The 84-mile-long reach from Davis Dam to Parker Dam forms Lake Havasu. Davis and Parker Dams are operated under the same rule curve that determines end-of-month target elevations, which are between 445 and 450 feet for Lake Havasu (see **Section TA 3.1.8**, Davis Dam to Lake Havasu, in **TA 3**, Hydrologic Resources). Therefore, no impacts from the CCS Comparative Baseline, the No Action Alternative, nor any of the action alternatives (including the Representative Preferred Alternative) to 64 known archaeological sites within 20 meters (66 feet) of the river between Davis Dam and Parker Dam are anticipated. This is also true for the portions of NRHP-listed Historic U.S. Route 66 or the NRHP-listed National Old Trails Bridge (Topock Bridge) as the only two built environment resources within 20 meters (66 feet) of the river.

Parker Dam to Imperial Dam

Parker Dam releases are scheduled on both a daily and hourly basis, and while the 2007 Interim Guidelines did not specifically target operations of this dam, implementation of these guidelines has resulted in reduced annual release rates (see **Section TA 3.1.9**, Parker Dam to Cibola Gage, in **TA 3**, Hydrologic Resources). Parker Dam annual releases since 2008 have ranged from 6.2 maf to 6.7 maf, averaging 6.4 maf, which represents an average annual decrease of 1.0 maf in volume from the previous pre-2008 average of 7.4 maf. At the end of this reach is Imperial Dam and the Imperial Reservoir, which is operated to maintain a nearly constant elevation to meet water delivery requirements for major diversions to California (All-American Canal) and Arizona (Gila Main Canal) (see **Section TA 3.1.10**, Cibola Gage to Imperial Dam, in **TA 3**, Hydrologic Resources). Additionally, this reach is characterized by several stretches of mechanically channelized river corridor (particularly through wildlife refuges) and no impacts on the 16 known archaeological sites or the one built environment resource (Fisher's Landing) within 20 meters (66 feet) of the river are expected regardless of flow volume through these areas.

Imperial Dam to SIB

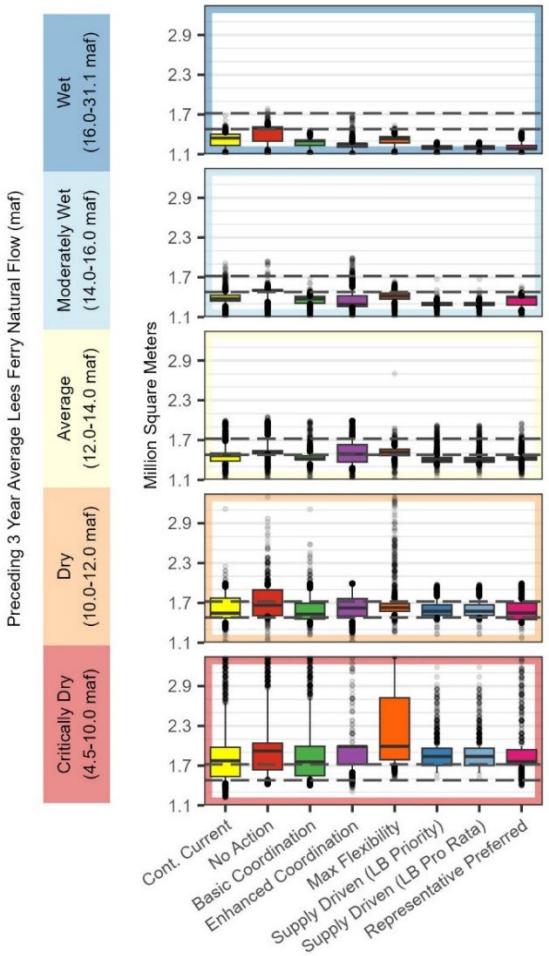
The Colorado River channel is reinforced by a system of leaves from Imperial Dam south to the Northerly International Boundary (NIB) and flows through this first portion of this reach are influenced primarily by Imperial Dam releases made for water deliveries. Other factors, like the Laguna Dam and the confluence with the Gila River, also influence river flows in this reach. Implementation of the 2007 Interim Guidelines did not affect the operations or flows in the upper portion of the reach between Imperial Dam and the NIB (see **Section TA 3.1.11**, Imperial Dam to Northerly International Boundary, in **TA 3**, Hydrologic Resources). Because of the levee system from Imperial Dam south to the NIB, there are no anticipated impacts on the two archaeological sites, two built environment resources (Southern Pacific Railroad Bridge and the NRHP-listed Ocean-to-Ocean Highway Bridge) or the Yuma Crossing NHL (also NRHP listed) located within 20 meters (66 feet) of the river.

Just downstream of the NIB is Morelos Dam, which impounds most of the water supply to be diverted to the United Mexican States (Mexico), and is owned, operated, and maintained by Mexico per the 1944 United States-Mexico Treaty on Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande. Most of the remaining Colorado River water supply that makes it to the Morelos Dam is diverted to Mexico via the Reforma Canal. Thus, the remaining river flows below Morelos Dam to the SIB consist of excess water volumes above Mexico's scheduled delivery

due to Flood Control operations at Hoover Dam, seepage from Morelos Dam and other return/inflows. Morelos Dam operations did not change with the implementation of the 2007 Interim Guidelines because of the required 1.5 maf annual water delivery (see **Section TA 3.1.12**, NIB to SIB*,* in **TA 3**, Hydrologic Resources). There are no other known cultural resources (aside from Morelos Dam, which is excluded from analysis) between the lower portion of this reach from the NIB to the SIB.

TA 11.2.3 Issue 2: How will changes in dam operations affect sediment availability for aeolian transport to protect archaeological sites in the Grand Canyon?

As discussed above in **Section TA 11.2.1**, the aeolian transport model looks at favorable conditions for wind-born sand to be present to protect archaeological sites over long periods of time using projected vegetation cover and exposed sand area or sandbar volume (Butterfield and Palmquist 2026; Kelley et al. 2026; Salter and Grams 2026). The vegetation and sandbar volume modeling used is from the Marble Canyon sub-reach from Lees Ferry Gaging Station to the Little Colorado River. The exposed sand modeling was conducted for the portion of the river from Lees Ferry to Bright Angel Creek. While these analyses are limited to those reaches, the results provide general insight into sediment and vegetation responses that may also be relevant to other portions of the river corridor with similar geomorphic and hydrologic conditions.



The results of the annual vegetation cover modeling are presented in **TA 9**, Vegetation, Including Special Status Species. Overall, less vegetation is better for aeolian sand transport because it leaves available sand exposed to be picked up by the wind. As discussed in **Section TA 9.2.2**, Issue 1, and seen in **Figure TA 9-14** (see **TA 9**, Vegetation, Including Special Status Species), for all modeled scenarios under the wet and moderately wet conditions, there would be less annual total vegetation cover (below modeled historical conditions, indicated by the dashed line in **Figure TA 9-14**) from higher water levels and longer HFEs. As conditions grow drier, water flows diminish, and HFEs are shorter, annual total vegetation cover thereby increases (see **Figure TA 9-14** in **TA 9.2.2** of **TA 9**, Vegetation, Including Special Status Species). For the Average Flow Category, the median for the CCS Comparative Baseline, the No Action Alternative and all action alternatives (including the Representative Preferred Alternative) is at or just below the modeled historical conditions (i.e., the 2007 Interim Guidelines period [WY 2008–2025]) and the interquartile ranges are relatively small. This indicates that the annual total vegetation may be similar to historical conditions under average flows. Conversely, under the dry and critically dry conditions, annual total vegetation cover increases, and differentiation between alternatives can be seen. For the Critically Dry Flow Category, the medians and interquartile ranges are above the modeled historical conditions (dashed line) for all sub-reaches and all alternatives except the interquartile range for the CCS Comparative Baseline, which drops just below the dashed line (see **Figure TA 9-14** in **TA 9**). This indicates that there may be more annual total vegetation cover, especially under critically dry flows.

The results of the sandbar volume modeling are presented in **TA 5,** Geomorphology and Sediment. As discussed in **TA 5**, for an HFE to be triggered, enough sand needs to be available in Marble Canyon and enough water needs to be available in Lake Powell (as measured by water level), with both the required amounts of sand and water being dependent on the selected HFE duration. Additionally, HFE releases can only be implemented when Lake Powell water levels are at or above

3,500 feet, with sandbar deposition occurring most rapidly during the first 4 days of an HFE event. Lastly, sandbar volume modeling uses the assumption that HFEs are implemented as often as possible (see **TA 5.2.1**, Modeling Criteria and Assumptions). For the aeolian transport model, increased exposed sandbar volume (or the amount of "useable" sand) means more sand is available to protect archaeological sites. In general, as conditions get drier and the amount of water flowing through the river decrease, exposed sandbar volume increases (see **Section TA 5.2.5**, Issue 4, in **TA 5**, Geomorphology and Sediment). Differences in performance among the alternatives also increase as hydrological conditions become drier, with the Enhanced Coordination and Maximum Operational Flexibility Alternatives performing the best for the Critically Dry Flow Category (see **Figure TA 5-12** in **Section TA 5.2.5**).

Figure TA 11-4 shows the results of the WY average of exposed sand area modeling, with the 90th percentile and median (50th percentile) of modeled sand areas depicted as the two dashed lines. As with exposed sandbar volume, increased exposed sand area is beneficial for the aeolian transport of sand to protect archaeological sites. In the Average Flow Category, median exposed sand area is

Figure TA 11-4
Water Year Average of Exposed Sand Area

around the 90th percentile (upper dashed line) and the median (50th percentile, lower dashed line) of modeled sand area (in million square meters). As conditions become drier, all modeled scenarios perform similarly with modeled median exposed sand area above the observed median, with the No Action, Enhanced Coordination, and Maximum Operational Flexibility Alternatives having slightly higher median values than the CCS Comparative Baseline and the other action alternatives, particularly in the Critically Dry Flow Category. Under critically dry conditions, the Maximum Operational Flexibility Alternative has the most variability with the greatest interquartile range.

Figure TA 11-5 shows the results of the aeolian sand modeling in which the percentage of futures meet one of two criteria: either the annual sand area is greater than the median observed sand area over the last 20 years and the vegetation cover area is less than the median observed area over the last 20 years, or the sandbar volume is greater than 1.5 times the initial condition. The highlighted row shows when those conditions are met at least 1 out of every 3 years, which is the optimal time frame for enough sand to be available for aeolian transport based on previous studies.

Figure TA 11-5
Multi-model Aeolian Transport Condition: Robustness
Percent of futures in which annual sand area is >50th and vegetation cover is <50th percentile or sandbar volume is >1.5 times initial condition in the frequency specified in each row

Over the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust; they meet the preferred minimum of performance in 19 and 18 percent of futures, respectively, followed by the No Action Alternative only in 14 percent of futures. The Basic Coordination Alternative meets the preferred minimum of performance in only 9 percent of futures, with the Representative Preferred Alternative meeting it in only 6 percent of futures. The

Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the least robust, meeting the preferred minimum of performance in only 3 percent of futures with the CCS Comparative Baseline only slightly higher at 4 percent of futures. If the year interval is lengthened (i.e., to 1 out of 4, 5, or 6 years), the models perform in a similar overall pattern with the Enhanced Coordination Alternative performing the best until reaching the 1-out-of-6-year interval when the No Action Alternative performs the best over the full modeling period.

If the modeling period is broken out for the first 10 years, the No Action Alternative performs the best, meeting the preferred minimum performance in 38 percent of futures for the highlighted interval, followed by the Enhanced Coordination Alternative at 35 percent of futures in the first decadal period (2027–2039), followed by the Maximum Operational Flexibility Alternative at 30 percent of futures. The Basic Coordination Alternative and the CCS Comparative Baseline meet the preferred minimum of performance in 18 percent and 19 percent of futures, respectively, followed by the Representative Preferred Alternative at 17 percent. The Supply Driven Alternative (both the LB Priority and LB Pro Rata approaches) performs with only 9 percent of futures meeting the minimum preferred performance. Due to aeolian transport favoring drier conditions because more useable sand is available and the beginning of the first decadal period (2027-2039) is anticipated to have low reservoir elevations, the modeling for this breakout (2027–2039) depicts more modeled futures meeting the preferred minimum of performance across the CCS Comparative Baseline, the No Action Alternative, and all action alternatives than over the full modeling period. See **Figure TA 11-5** above for robustness modeled for 2040–2049 and 2050–2060 relative to multi-model aeolian transport condition.

The overall results seem to indicate an increase in the percentage of futures over time, which may correlate to increased available sand over time; however, the perceived increase is driven by an increase in sandbar volume over time in the modeling with the understanding that HFEs would continue as planned. In reality, the decision to conduct HFEs depends on annual review and the actual HFE frequency may differ from that assumed or predicted in the modeling.

TA 11.2.4 Summary Comparison of Alternatives

Issue 1: How will any changes in dam operations affect (1) lake elevations at Lake Powell and Lake Mead and (2) river flows downstream, which may affect cultural resources?

Lake Powell and Lake Mead

Because the continual inundation of archaeological sites is more conducive to preservation than repeating cycles of inundation and exposure due to the risks of wave action, changes in lake elevations that may expose previously inundated resources is the biggest concern. As water elevations drop, the elevation at which sites become vulnerable to wet-dry cycling and wave action becomes lower; however, while sites exposed at higher elevations may be less vulnerable to impacts from wet-dry cycling and wave action, they may also have increased ease of access depending on their location. Based on the hydrological models, during the wet hydrological conditions, median elevations at Lake Powell are projected to stay around or above 3,640 feet for all modeled scenarios. As conditions become drier, the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform the best in the Average Flow Category, with median water elevations from around 3,600 feet to around 3,630 feet relative to average hydrological conditions. They also

perform best in the Critically Dry Flow Category; however, the projected medians are between 3,510 feet and 3,560 feet for these two action alternatives, potentially leaving (at minimum) between 316 and 381 archaeological sites and any undiscovered sites above these elevations exposed. Under critically dry conditions, the Representative Preferred Alternative has median water levels from just above 3,490 feet (minimum WY), up to just below 3,510 feet (EOWY), which has the potential to leave up to 415 sites exposed above 3,500 feet, but would inundate more sites if they are present above the minimum power pool elevation of 3,490 feet.

For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs best over in both the Average Flow and Critically Dry Flow Categories, followed by the Enhanced Coordination and Maximum Operational Flexibility Alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) have projected median elevations between 1,140 feet and 1,160 feet under average hydrological conditions, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives have median elevations between 1,100 feet and 1,130 feet, respectively. Higher reservoir levels means that more sites are inundated as opposed to exposed at lower reservoir levels. The Representative Preferred Alternative has median water levels of around 1,080 to 1,090 feet, exposing between 265 and 275 known archaeological sites as well as any undiscovered sites present above these elevations relative to average hydrological conditions. For the Critically Dry Flow Category, all scenarios would result in the exposure of at least 306 archaeological sites (all but four in the Lake Mead dataset) and any undiscovered sites that may be present based on median water levels; however, the LB Pro Rata approach under the Supply Driven Alternative has the potential to expose the fewest number of known sites (286) with median elevations up to around 1,030 feet. The Representative Preferred Alternative has median water levels from around 980 feet to around 990 feet, potentially leaving up to 301 archaeological sites (and any undiscovered sites present) exposed during critically dry conditions.

For preservation risk, the Enhanced Coordination Alternative is the most robust for Lake Powell, with 47 percent of the modeled futures over the full modeling period meeting the 2.72 threshold, followed by the Maximum Operational Flexibility Alternative with 28 percent of futures. This relational pattern is consistent if the full modeling period is broken out into shorter ranges, including the first decadal period (2027–2039) where the Enhanced Coordination Alternative also performs the best at 30 percent of futures, followed again by the Maximum Operational Flexibility Alternative at 25 percent of futures. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust for Lake Mead, meeting the 2.24 risk threshold in 24 percent of the modeled futures over the full modeling period, followed by the Maximum Operational Flexibility Alternative with 19 percent of futures. When examining the first decadal period (2027–2039) at Lake Mead, the percentage of futures meeting the preferred minimum of performance drops drastically. This is because the anticipated water levels for Lake Mead in 2027 are expected to be low and for this reason, robustness modeling shows a substantial drop in performance. For this first 10-year period, the Supply Driven Alternative (both LB Priority and LB Pro Rata) continues to perform the best, but only at 5 percent of futures, followed by the CCS Comparative Baseline, the Maximum Operational Flexibility Alternative, and the Representative Preferred Alternative, all three of which meet the preferred level of performance in only 3 percent of futures.

Overall, for Lake Powell, the Enhanced Coordination and the Maximum Operational Flexibility Alternatives perform better in drier conditions and have the greatest potential to expose fewer archaeological sites and protect more through inundation. For the preservation risk model results, this is true for the full modeling period or for the first decadal period (2027–2039); however, the percentage at which the threshold of 2.72 for Lake Powell is met declines drastically approaching critically dry conditions for the first 10-year period.

For Lake Mead overall, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) followed by the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform better in drier conditions. This can be seen in the results from the preservation risk model for the full modeling period; however, for the first 10-year period (2027–2039) the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is followed closely by the CCS Comparative Baseline, the Maximum Operational Flexibility Alternative, and the Representative Preferred Alternative under critically dry conditions. Overall, preservation risk for the Representative Preferred Alternative falls in the middle for both lakes compared to the other modeled scenarios as conditions become drier. The No Action and Basic Coordination Alternatives have the greatest potential to expose the most archaeological sites (thereby protecting the fewest sites) at both lakes.

River Flows

For the reaches between Glen Canyon Dam and Lake Mead and Hoover Dam to Lake Mohave, in the Wet and Average Flow Categories, all modeled scenarios generally fall within the ranges of past release volumes. However, in the Critically Dry Flow Category, the median WY release volumes all fall below 7.0 maf for the reach below Glen Canyon Dam, with the Enhanced Coordination Alternative falling to 5.1 maf. The Representative Preferred Alternative has the narrowest interquartile range under critically dry hydrological conditions, with the upper limit at around 6.6 maf, which is still below the bottom of the range of past flow volumes at 7.0 maf. Below Hoover Dam, median CY release volumes all fall at or below 8.0 maf, with the Representative Preferred Alternative at around 7.2 maf. The Enhanced Coordination and Maximum Operational Flexibility Alternatives have the poorest performance, falling as low as 6.4 maf for CY releases. Therefore, under the Critically Dry Flow Category, there is greater potential for sites to be impacted by fluctuating water levels; however, any impacts, if they occur, would be to those sites closest to the riverbanks.

Below Davis Dam, little to no impacts, regardless of flow category, are expected. This is because the dams below Lake Mohave are operated under guidelines that maintain lake elevations or target water deliveries. Also, they have several stretches of channelized banks.

Issue 2: How will changes in dam operations affect sediment availability for aeolian transport in the Grand Canyon?

Based on the aeolian transport model for the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would have the best outcome for increasing the availability of sand for wind transport to protect archaeological sites. Both alternatives have a similar percentage of futures meeting the minimum preferred performance in at least 1 out of every 3 years at 19 and 18 percent, respectively. Although this is a small percentage, the two alternatives perform

better than the No Action, Basic Coordination, the Representative Preferred, and the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives as well as the CCS Comparative Baseline, which all have values at 9 percent or lower. This changes, however, when examining the first decadal period (2027–2039) where the No Action Alternative performs the best, meeting the preferred minimum performance in 38 percent of futures, followed by the Enhanced Coordination Alternative at 35 percent and the Maximum Operational Flexibility Alternative at 30 percent in 1 out of every 3 years. The Basic Coordination Alternative, CCS Comparative Baseline, and Representative Preferred Alternative perform similarly at 19 percent, 18 percent, and 17 percent, respectively, but all still notably perform more poorly than the No Action and Enhanced Coordination Alternatives. The Supply Driven Alternative (both the LB Priority and LB Pro Rata approaches) performs the worst, meeting the preferred minimum performance in only 9 percent of futures.

TA 12. Paleontological Resources

TA 12.1 Affected Environment

Paleontological resources include any fossilized remains, traces, or imprints of organisms preserved in rock. The Paleontological Resources Preservation Act of 2009 (PRPA; 16 United States [U.S.] Code 470aaa–470aaa-11) and its implementation rule (43 Code of Federal Regulations 49) require that U.S. Department of the Interior (Department) agencies preserve, manage, and protect paleontological resources on lands administered by the Bureau of Reclamation (Reclamation), the National Park Service (NPS), the Bureau of Land Management (BLM), and the U.S. Fish and Wildlife Service. The PRPA ensures these federally owned resources are available for current and future generations to enjoy and study as part of America's national heritage.

The Colorado River Basin, a region renowned for its rich biodiversity and invaluable paleontological resources, faces a range of significant challenges stemming from fluctuating water levels, climate trends, and increasing human demands. As one of the most heavily managed rivers in the U.S., its waters are primarily allocated for agricultural, urban, and hydropower needs. However, this management, while crucial for sustaining these sectors, inadvertently impacts the delicate ecosystems that rely on the river's flow. Beyond the biological consequences, the fluctuating water levels also affect the paleontological sites embedded within the riverbanks and surrounding landscapes. Fossils, trackways, and other paleontological remains, often hidden beneath layers of sediment, are increasingly exposed as water levels fluctuate, leaving them vulnerable to erosion, weathering, and human disturbances. Fossils are nonrenewable resources and once degraded or destroyed can result in the permanent loss of important scientific information about life and environments in the earth's past. Proper management actions can identify how to reduce impacts on paleontological resources, leading to their preservation and enhancing our knowledge of earth and life through time.

The NPS is primarily responsible for conservation of natural and cultural resources and the visitor experience, including recreation, at both Lake Mead and Lake Powell. Reclamation manages water operations. Both agencies comply with the PRPA.

The Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead Final Environmental Impact Statement (2007 Final EIS; Reclamation 2007) and the 2024 Glen Canyon Dam Long-Term Experimental Management Plan (LTEMP) Final Supplemental Environmental Impact Statement (Reclamation 2024a) do not address paleontological resources as a separate resource concern; the Near-term Colorado River Operations Final Supplemental Environmental Impact Statement does (Reclamation 2024b). In the 2007 and 2024 analyses, many potential impact issues related to reservoir levels and changes in river flows are analogous to those for cultural resources, such as paleontological resources.

TA 12.1.1 Study Area

The study area for paleontological resources stretches from the northern extent of Lake Powell to the Southerly International Boundary (SIB) in California. It covers approximately 1 million acres across Utah, Arizona, Nevada, and California. The study area encompasses the Colorado River channel from bank to bank, extending from the canyon rim to canyon rim in areas from Glen Canyon Dam to Lake Mead through the Grand Canyon. A 0.5-mile buffer is applied to the full-pool volume of Lake Powell and Lake Mead. The same buffer is applied to the lower Colorado River corridor from Hoover Dam to the SIB. This includes the known and unknown resources in Lake Powell and Lake Mead. It is important to note that the resources within fluctuating water levels are vulnerable to wave action; those above are at risk from visitation impacts.

This region of the southwestern U.S. contains a rich paleontological record, with fossils and traces of marine and terrestrial life preserved in the sedimentary strata, dating back over 1.2 billion years (Santucci and Tweet 2021). However, much of these resources have been submerged by the creation of the reservoirs at Lake Powell and Lake Mead, with minimal data available on the deepwater zones, which are less vulnerable to disturbance. In contrast, the operational zones and areas above fluctuating water levels, which have been partially inventoried, are at greater risk from erosion, wave action, and human activity. Erosion, accelerated by land and water management along the Colorado River, exposes fossils more quickly, providing opportunities for discovery but also increasing the risk of loss. As water levels fluctuate, previously submerged fossils are exposed to environmental threats like wind, sun, and temperature fluctuations, causing weathering and degradation.

The PRPA requires federal protection, but the ongoing exposure of these resources highlights the need for more effective preservation efforts. The PRPA also requires Department agencies to develop plans to inventory and monitor using scientific principles and expertise. These plans should emphasize interagency coordination and collaborative efforts, when possible.

Paleontological Resources Assessment Criteria

In recognizing that paleontological resources are considered to include not only fossil remains and traces but also the fossil-collecting localities and the geologic units containing those fossils and localities, the BLM developed a procedure for evaluating the paleontological resource potential of individual geologic units. This procedure uses the Potential Fossil Yield Classification (PFYC) system to assign ranks to geologic units based on the relative abundance of vertebrate fossils or scientifically significant invertebrate or plant fossils and the sensitivity of these fossils to adverse impacts (BLM 2007, 2016). Under the PFYC system, geologic units with a higher potential are assigned a higher classification number. The PFYC system, as defined by the BLM, is used by other Department agencies (BLM-IM-2016-124) and is outlined as follows:

PFYC Class 5—Very High
This class includes highly fossiliferous geologic units that consistently and predictably produce significant paleontological resources. Units assigned to Class 5 have some or all of the following characteristics:

- Significant paleontological resources have been documented and occur consistently.
- Paleontological resources are highly susceptible to adverse impacts from surface-disturbing activities.
- The unit is frequently the focus of illegal collecting activities.

PFYC Class 4—High
This class includes geologic units that are known to contain a high occurrence of paleontological resources. Units assigned to Class 4 typically have the following characteristics:

- Significant paleontological resources have been documented but may vary in occurrence and predictability.
- Surface-disturbing activities may adversely affect paleontological resources.
- Rare or uncommon fossils, including nonvertebrate (such as soft body preservation) or unusual plant fossils, may be present.
- Illegal collecting activities may impact some areas.

PFYC Class 3—Moderate
This class includes sedimentary geologic units where fossil content varies in significance, abundance, and predictable occurrence. Units assigned to Class 3 have some of the following characteristics:

- They are marine in origin with sporadic known occurrences of paleontological resources.
- Paleontological resources may occur intermittently, but abundance is known to be low.
- Units may contain significant paleontological resources, but these occurrences are widely scattered.
- The potential for an authorized land use to impact a significant paleontological resource is known to be low to moderate.

PFYC Class 2—Low
This class includes geologic units that are not likely to contain paleontological resources. Units assigned to Class 2 typically have one or more of the following characteristics:

- Field surveys have verified that significant paleontological resources are not present or are very rare.
- Units are generally younger than 10,000 years before present.
- There are recent aeolian deposits.
- Sediments exhibit significant physical and chemical changes (that is, diagenetic alteration) that make fossil preservation unlikely.

PFYC Class 1—Very Low
This class includes geologic units that are not likely to contain recognizable paleontological resources. Units assigned to Class 1 typically have one or more of the following characteristics.

- The geologic units are igneous or metamorphic, excluding air-fall and reworked volcanic ash units.
- The geologic units are Precambrian (for example, Proterozoic) in age.

PFYC Class U—Unknown
This class includes geologic units that cannot receive an informed PFYC assignment. Characteristics of Class U may include the following:

- The geologic units may exhibit features or preservation conditions that suggest significant paleontological resources could be present, but little information about the actual paleontological resources of the unit or area is known.
- The geologic units represented on a map are based on lithologic character or basis of origin, but they have not been studied in detail.
- Scientific literature does not exist or does not reveal the nature of paleontological resources.
- Reports of paleontological resources are anecdotal or have not been verified.
- The area or geologic unit is poorly studied or understudied.
- BLM staff has not yet been able to assess the nature of the geologic unit.

PFYC Class W—Water
This class includes any surface area that is mapped as water. Most bodies of water do not normally contain paleontological resources. However, shorelines should be carefully considered for uncovered or transported paleontological resources. Reservoirs are a special concern because important paleontological resources are often exposed during low water intervals. In karst areas, sinkholes and cenotes may trap animals and contain paleontological resources. Dredging river systems may result in the disturbance of sediments that contain paleontological resources.

Deep Time and the Geologic Time Scale

Earth's history extends back more than 4.6 billion years and reflects a long and complex sequence of physical and biological events. To organize this vast span of time, geologists developed the geologic time scale, which serves as an international framework for describing the earth's past. The time scale divides geologic history into formally named intervals—such as eras, periods, and epochs—based on rock sequences that preserve evidence of past environments, geologic events, and life forms.

Similar to how a calendar divides a year into months, weeks, and days, the geologic time scale uses a hierarchy of time units that allows scientists to describe events at different levels of detail. The names of these intervals were often derived from geographic regions where representative rock formations were first studied.

When the time scale was first developed in the 18th and 19th centuries, it was based on relative dating, recognizing that in an undisturbed sequence of rock layers, the lower layers are older than

those above. With the discovery of radioactivity in the late 19th century, scientists gained the ability to determine absolute ages of rocks by measuring the decay of radioactive isotopes. This advancement made it possible to assign numerical ages to geologic time intervals and better understand the timing of major geologic and biological events.

Figure TA 12-1, below, depicts the geologic time scale put together by the NPS, and includes the geologic time divisions discussed in the text and included in the PFYC geodatabase. **Figure TA 12-2** is a more in-depth depiction of the time scale.

Table TA 12-1 summarizes the number of acres by PFYC value in the study area. **Map TA 12-1** through **Map TA 12-8** depict PFYC values in the study area. These PFYC maps were created by first compiling a composite geologic map of the study area and then assigning PFYC rankings to each geologic rock unit.

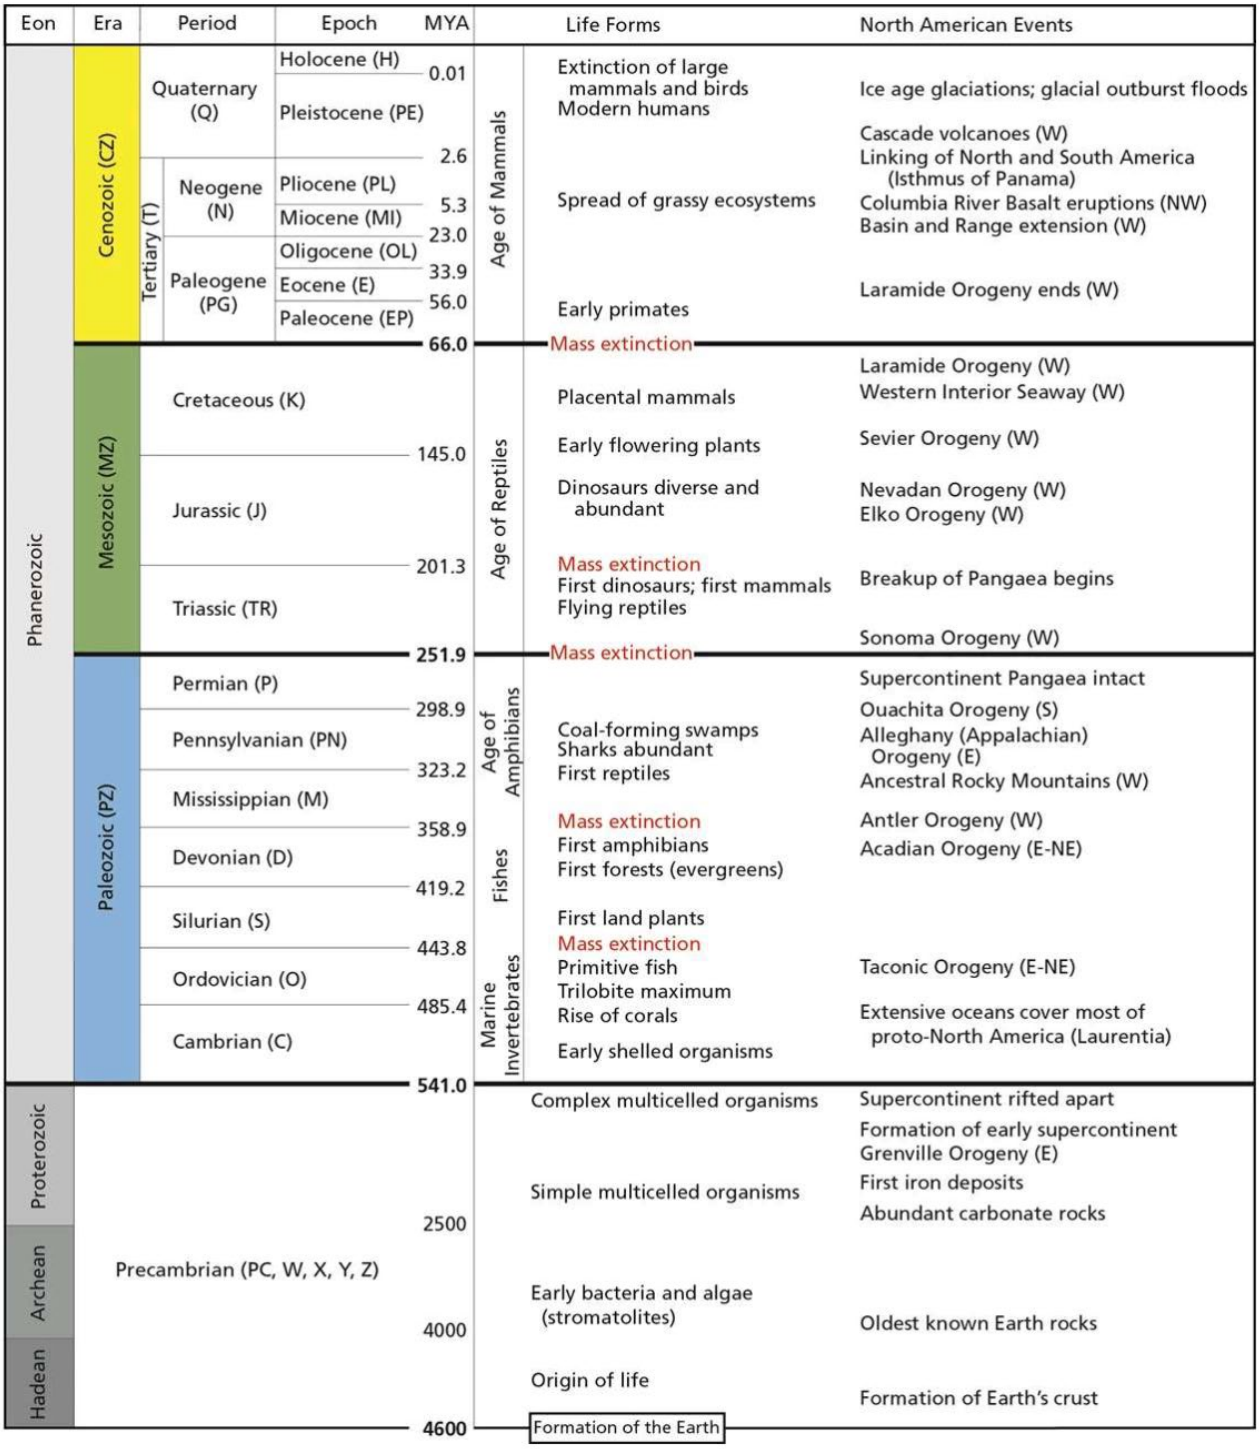

Table TA 12-1
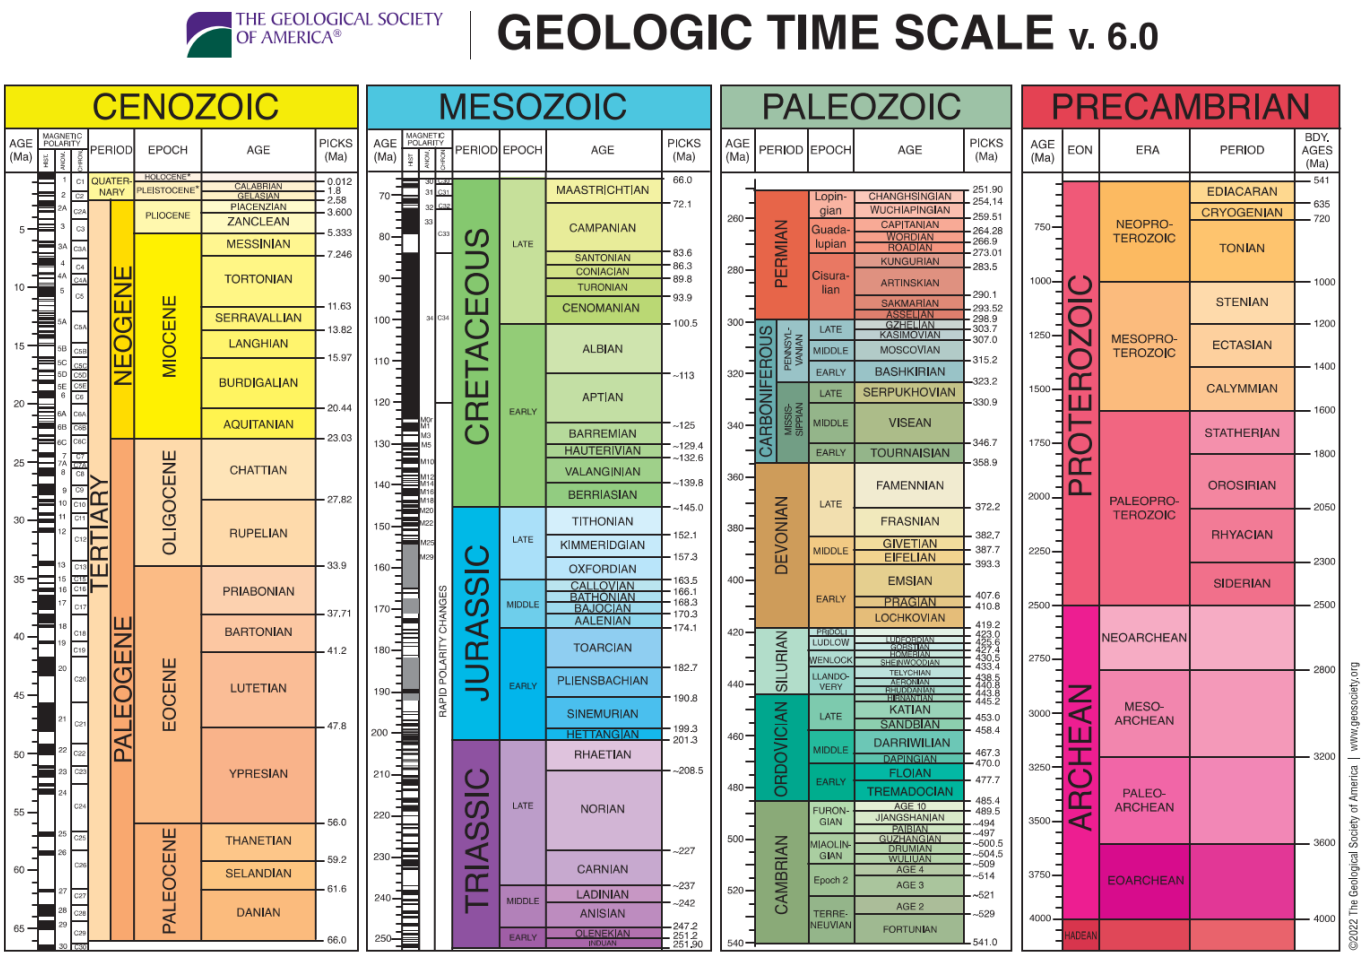
Acres of PFYC within the Study Area

PFYC	Total Acres
1	70,500
2	154,600
3	103,600
4	179,300
5	24,200
U	113,700
W	373,100
Total acres	**1,019,000**

Source: BLM GIS 2025
Note: PFYC data do not cover the entire study area, especially in the waterbodies and portions of the Colorado River.



Formation-by-formation summaries of resource type, distribution, and PFYC system classes for all geologic units in the study area are in **Table TA 12-2**.

Figure TA 12-1
Simplified Geologic Time Scale

Source: NPS 2018

Figure TA 12-2
Geologic Time Scale

*The Pleistocene is divided into four ages, but only two are shown here. What is shown as Calabrian is actually three ages: Calabrian from 1.8 to 0.774 Ma, Chibanian from 0.774 to 0.129 Ma, and Late from 0.129 to 0.0117 Ma. The Holocene is divided into three ages: Greenlandian from 0.0117 to 0.0082 Ma, Northgrippian from 0.0082 to 0.0042 Ma, and Meghalayan from 0.0042 to present. The geologic community broadly recognizes the Anthropocene as a proposed new time interval of Earth history, partly coincident with the Holocene. Currently, the Anthropocene has an informal designation, with a proposed age span extending from the present to a beginning point between ca. 15,000 yr B.P. and as recent as 1960 CE.

The Cenozoic, Mesozoic, and Paleozoic are the Eras of the Phanerozoic Eon. Names of units and age boundaries usually follow the Gradstein et al. (2012), Cohen et al. (2012), and Cohen et al. (2013, updated) compilations. Numerical age estimates and picks of boundaries usually follow the Cohen et al. (2013, updated) compilation. The numbered epochs and ages of the Cambrian are provisional. A "~" before a numerical age estimate typically indicates an associated error of ± 0.4 to more than 1.6 Ma.

Lake Powell and Glen Canyon Dam

The Glen Canyon NRA, encompassing portions of southern Utah and northern Arizona, contains one of the most extensive and complete sedimentary records on the Colorado Plateau. The stratigraphic sequence within Glen Canyon NRA exceeds 10,000 feet in cumulative thickness and represents approximately 300 million years of the earth's geologic history (Anderson et al. 2010). These strata chronicle a dynamic history that includes the assembly and breakup of the supercontinent Pangea, repeated transgressions and regressions of shallow inland seas, the development of vast eolian dune systems, and the incision of the modern Colorado River (Graham 2020). The resulting depositional environments—marine, fluvial, lacustrine, and eolian—record the complex interplay of tectonics, sedimentation, and biological evolution that shaped the region through Paleozoic, Mesozoic, and Cenozoic time.

Lake Powell, a reservoir formed by the impoundment of the Colorado River behind Glen Canyon Dam, occupies the central portion of Glen Canyon NRA. The reservoir extends approximately 186 miles and includes nearly 1,960 miles of shoreline with 96 major side canyons. Fluctuations in the lake level due to dam operations and hydrologic variation periodically expose new rock surfaces, revealing fossil-bearing strata that had been previously submerged (Milner et al. 2024). These exposures, along with naturally eroding canyon walls, make the area an important locality for the discovery and documentation of paleontological resources.

Glen Canyon NRA preserves fossil assemblages spanning the Paleozoic, Mesozoic, and Cenozoic Eras, offering insights into changing environments and biotic communities through time. Paleozoic formations, including the Kaibab Limestone and Toroweap Formation, contain abundant marine fossils, such as brachiopods, crinoids, and corals, which reflect deposition in warm, shallow marine environments during the Permian Period. Overlying Triassic units, such as the Moenkopi and Chinle Formations, record a transition to continental fluvial environments. These strata preserve vertebrate trackways, petrified wood, and early dinosaur remains, documenting faunal diversification following the Permian-Triassic extinction event. The Chinle Formation, in particular, is world-renowned for its

early dinosaur tracksites and vertebrate assemblages, which record one of the earliest radiations of dinosaurs in North America (Graham 2016). Although there are limited areas mapped for the Coconino Sandstone, Toroweap Formation, Hermit Shale, Kaibab Formation, and Dinosaur Canyon Member of the Moenave Formation in the southern areas of Glen Canyon NRA—all known to be fossiliferous at localities outside Glen Canyon NRA—no fossils have been reported yet from any of these units in the recreation area (Milner et al. 2024).

The overlying Jurassic formations of the Glen Canyon Group—including the Wingate, Kayenta, and Navajo Sandstone—capture the transition from fluvial to eolian depositional systems. The Wingate and Kayenta Formations preserve small vertebrate fossils and trackways, while the Navajo Sandstone records a vast ancient dune field representing one of the largest preserved erg systems in the geologic record. These formations are particularly rich in vertebrate trace fossils, including extensive trackways of dinosaurs, reptiles, and amphibians (Milner et al. 2024). Many of these tracksites occur along the modern shoreline of Lake Powell, where fluctuating water levels periodically uncover new fossil surfaces.

In 2023, receding lake levels revealed a previously submerged fossil locality within the Navajo Sandstone, where paleontologists discovered a tritylodontid mammaliaform bonebed dating to approximately 180 million years ago. This discovery represents one of the most complete early mammal-relative assemblages yet documented in the Navajo Sandstone and provides valuable insight into vertebrate evolution during the Early Jurassic (NPS 2023).

Cretaceous formations, including the Naturita Formation and Tropic Shale, preserve a record of the Western Interior Seaway and contain marine invertebrates, plant fossils, and marine reptiles, illustrating the return of widespread marine conditions during the mid-Cretaceous (Titus et al. 2016). Alcoves, including the best-known Quaternary site (Bechan Cave), are important fossil sites associated with fossil dung in Glen Canyon NRA. Fossil pollen and plant macrofossils preserved in packrat middens and dung deposits further document ecological and climatic changes during the Late Quaternary (Graham 2016; Mead et al. 2020).

Glen Canyon NRA staff is completing a paleontological resources inventory survey; because of the size of the recreation area, the survey is being done in phases, with the latest phase completed in 2024. The three inventory reports provide the baseline data for the breadth of paleontological resources found from Glen Canyon NRA. Despite these efforts, natural processes, such as erosion, mass wasting, and fluctuating water levels, continue to expose and degrade fossil-bearing strata. Additionally, anthropogenic influences, including reservoir sedimentation, vandalism, and unauthorized fossil collection, pose ongoing threats to resource preservation (Graham 2016; Santucci et al. 2009). In some areas, sediment accumulation resulting from dam operations may enhance fossil preservation by burial, while in others, it obscures or prevents discovery. Consequently, Glen Canyon NRA represents a dynamic and scientifically valuable setting where both natural and human processes continually shape the exposure, preservation, and accessibility of paleontological resources.

Grand Canyon National Park

The Colorado River corridor of Grand Canyon National Park contains paleontological resources of exceptional scientific significance, spanning nearly 1.2 billion years of the earth's history. The river corridor is renowned for its dramatic display of geomorphic effects created by fluvial incision and its unique dry preservation of fossils from the Ice Age (Mead et al. 2020). The river channel serves as the physical axis along which the park's oldest and youngest fossil-bearing strata are exposed. The river channel is organized into two principal paleontological occurrences documented in the Grand Canyon National Park Centennial Paleontological Resource Inventory (Santucci and Tweet 2021): ancient body and trace fossils preserved within the canyon's deep bedrock formations, and Pleistocene and Holocene fossils recovered from dry caves and sediment deposits along the corridor walls.

The oldest fossil-bearing rocks in the park are exposed along the river's edge in the eastern and central canyon. Precambrian sedimentary units of the Grand Canyon Supergroup (Bass Formation, Hakatai Shale, Dox Formation, Galeros Formation, and Kwagunt Formation) preserve stromatolites, acritarchs, and vase-shaped microfossils representing some of the earliest evidence of life documented in the National Park System, beginning approximately 1.25 billion years ago (Santucci and Tweet 2021). Above these, Cambrian units of the Tonto Group (Tapeats Sandstone, Bright Angel Shale, and Muav Limestone) are among the most fossil-rich formations accessible from the river corridor, preserving abundant invertebrate trace fossils, including burrows, trails, and feeding traces, as well as body fossils such as trilobites and brachiopods (Santucci and Tweet 2021). The Temple Butte Formation, exposed in isolated channel-cut pockets near the river in portions of the canyon, yields Devonian fish remains representing the earliest vertebrate fossils in the park (Santucci and Tweet 2021).

The river corridor is equally significant for its Pleistocene and Holocene fossil record. Dry caves and alcoves embedded in the corridor walls create the arid, sheltered conditions necessary to preserve organic material in exceptional detail (Mead et al. 2020). Among the most significant localities is Sandblast Cave, where excavations produced important data on the California condor, including a preserved nest, in addition to specimens of extinct mountain goat, bison, camel, and horse, along with the only reported mammoth remains from the Grand Canyon (Mead et al. 2020). Other fossil-bearing localities along the corridor include Stanton's Cave, Little Nankoweap, Skylight Cave, Hummingbird Cave, and Rampart and Vulture Caves in the western canyon, where thick deposits of Shasta ground sloth dung, hair, and skin were recovered (Mead et al. 2020). Packrat middens from these sites yield plant macrofossils, pollen, insects, and small vertebrate remains that document ecological and climatic shifts across the late Pleistocene and into the Holocene (Mead et al. 2020).

The objective of the Grand Canyon National Park Centennial Paleontological Resource Inventory was to identify the scope, significance, distribution, and management issues associated with fossils in the park (Santucci and Tweet 2021). The river corridor presents particular management challenges due to its difficult terrain and limited accessibility, and the inventory acknowledges that systematic survey of inner canyon fossil localities remains incomplete. Despite this, the Colorado River corridor constitutes one of the most scientifically valuable zones within Grand Canyon National Park.

Lake Mead and Hoover Dam

The Lake Mead NRA encompasses a geologically diverse landscape extending across portions of southeastern Nevada and northwestern Arizona. The stratigraphic record within Lake Mead NRA spans from the Paleozoic through Cenozoic Eras, representing more than 500 million years of the earth's history (BLM GIS 2025; Beard et al. 2007). These rocks preserve an array of marine, fluvial, and terrestrial depositional environments that document the evolution of the southwestern margin of the North American continent and provide an exceptional record of paleontological change through geologic time.

Fossils in Lake Mead NRA span the Paleozoic, Mesozoic, and Cenozoic Eras. Marine fossils such as trilobites and Cenozoic bivalves can be found along the Cottonwood Wash in Lake Mead, representing a crucial moment in the emergence of multicellular life on earth. As terrestrial landscapes dried up into the Jurassic Period 180 million years ago, present-day Lake Mead underwent a period of extensive erosion that resulted in a geological gap between the rock record of fossils until the later portion of the Cenozoic Era. Lake Mead has an impressive list of fossils documented from the Oligocene Epoch of the Cenozoic Era, particularly in the forms of mammals, amphibians, birds, and reptiles (NPS 2022).

The NPS completed a comprehensive paleontological resource inventory for Lake Mead NRA in 2018. While this inventory is confidential to the NPS, it established baseline data for fossil-bearing formations, recorded known localities, and assessed the relative potential for new discoveries. The report concluded that several formations have high fossil potential and merit continued monitoring and research. This inventory is the most recently completed report for the NRA.

Fluctuating lake levels have a direct influence on fossil exposure and preservation within Lake Mead NRA. Periods of low water levels at Lake Mead have exposed previously submerged geologic formations, resulting in increased accessibility to fossil-bearing strata along the shoreline. These exposures, while scientifically valuable, are also vulnerable to erosion and visitor impacts. As water levels fluctuate, cycles of inundation and exposure accelerate mechanical weathering and can lead to disarticulation or loss of fossil specimens. Conversely, sediment deposition in shallow nearshore zones may help preserve fossils by rapid reburial under fine-grained sediments.

Continued reductions in lake elevation are expected to expose additional outcrops of fossil-bearing formations, particularly along the upper reaches of the reservoir and tributary canyons. The NPS has identified these newly emergent areas as priorities for future surveying and monitoring. Overall, Lake Mead NRA contains a high diversity of paleontological resources, including the Miocene Horse Spring Formation, Muddy Creek Formation, and Pliocene and Pleistocene river gravels, that span marine, fluvial, and terrestrial systems, making it one of the most scientifically significant and geologically varied regions in the southwestern U.S.

Lower Colorado River Corridor

The lower Colorado River corridor follows the Colorado River from southern Nevada to the international border with the United Mexican States. Reclamation completed a paleontological resources inventory of the entire corridor in 2020 (Bonde and Slaughter 2020). The inventory report is confidential to Reclamation because it includes paleontological localities; however, the

information gained from this inventory expanded the knowledge of the paleontological record for the entire river corridor.

The sedimentary geologic record for the lower Colorado River corridor extends from the Middle Cambrian to the Pleistocene. While the geologic record is not fully continuous, units representative of most periods of geologic time are present in this area (Bonde and Slaughter 2020).

Current Conditions

Fluctuating water levels in both Lake Mead and Lake Powell pose significant threats to paleontological resources, including fossils and trackways preserved in sedimentary rocks. In reservoirs, cycles of inundation and exposure cause softer rocks like sandstone, which often contain delicate trackways, to become friable and more prone to erosion. As water levels drop, previously submerged fossils are exposed to environmental forces such as wind, sun, and temperature fluctuations, which accelerate the fossils' degradation. While sediment deposition can temporarily protect some sites, the exposure of fossil-rich layers as water levels recede increases the likelihood of weathering, fragmentation, and disturbance from human activity.

In addition to direct threats to fossils, fluctuating water levels disrupt the stability of sediment layers crucial for preserving these paleontological resources. The disturbance of these sediments destabilizes both the fossils themselves and the broader habitats they rely on. Sensitive plant species, animal burrows, and other ecological components can be damaged or destroyed as human activity increases in exposed areas. The exposure of fossil-rich sites also encourages further human impacts, such as increased recreational activities (hiking, off-highway vehicle use, and unauthorized fossil collection), which lead to soil compaction, vegetation trampling, and pollution from waste and chemicals, all of which undermine preservation efforts and hasten degradation.

Lands in the study area are subject to fluctuating water levels under current conditions. Water is a catalyst for erosion and a popular outlet for recreation. Possible water-related impacts that result in the threat or loss of paleontological resources in the study area include the following:

- Flooding events or controlled capture of reservoir levels lead to the elevation of water levels and consequent submersion of fossil-bearing rock layers.
- The controlled release of reservoir waters results in an increase in river velocity and downstream erosion rates, consequently removing fossil resources preserved in the geologic units that line the river corridors.
- Water systems are often associated with areas of high topographic relief formed from downcutting by a water source (that is, the steep canyon walls of the Grand Canyon carved by the Colorado River); these areas of high topographic relief are subject to higher rates of erosion and potential resources lost versus areas of lower topographic relief.
- Rivers and reservoirs are highly associated with recreation. The high density of people and popular use of public lands along the lower Colorado River may unintentionally invite theft, vandalism, or disturbance to fossil resources exposed along the margins of the waterways (Reclamation 2020).

Erosion is the primary agent that exposes paleontological resources on the surface to then await discovery and documentation. Lake Powell and Lake Mead are interconnected; adjustments of water releases at Lake Powell have a downstream effect on Lake Mead. The impacts on paleontological resources due to natural processes are the same at both reservoirs, but the intensity at which they occur and to what resources they occur vary. Paleontological resources in Glen Canyon NRA are largely more understood and considered to be highly scientifically important. As depicted in **Figure TA 12-8**, most of the area is ranked PFYC 4 (high) or PFYC 5 (very high). This is true at the mapped shorelines. In Lake Mead, the paleontological resources are less understood, and much of the shoreline is mapped PFYC U (unknown; **Figure TA 12-12**). Erosion concerns at Lake Powell are extremely high because erosion and other natural processes are impacting the geologic units with known high and very high paleontological value.

TA 12.2 Environmental Consequences

TA 12.2.1 Methodology

Changes in lake levels or river flows from the annual releases could directly and indirectly impact paleontological resources. Of greatest concern are effects on paleontological resources that degrade or that damage those resources before the resources can be preserved. Direct impacts may occur from processes such as wave action and wet-dry cycling. Direct impacts include any impact that is immediate in place and time; indirect impacts, such as those from increased visitation, are those that occur later in time.

Impacts on paleontological resources analyzed in this section only include those from Reclamation's management of the water in Lake Powell and Lake Mead. Two types of analyses are used to evaluate potential impacts on paleontological resources: preservation risk modeling developed by the U.S. Geological Survey (USGS) and NPS and aeolian transport-vegetation cover–high-flow experiment (HFE) joint modeling also developed by the USGS. Additionally, PFYC data were used to analyze areas of high fossiliferous potential within the study area.

Refer to **Section 3.2**, Analysis Methods, for additional information on Decision Making under Deep Uncertainty (DMDU) and **Appendix E**, DMDU Overview and Approach, for an overview of how to interpret the DMDU conditional box plots, robustness heat maps, and vulnerability bar plots.

PFYC System

Paleontological localities were not used in this analysis because they are confidential and information is limited for an analysis at this scale. Instead, the BLM's PFYC system was used. As described above, the PFYC system is a tool used to predict impacts on fossil resources from planned actions. The system is straightforward: some rock units are more likely to contain scientifically interesting fossils than others. The assessment can be made by rock type and generalized from previously recorded fossil discoveries. The system is simple, ranked from 1 (very low potential) to 5 (very high potential), with a "U" category for unknown or understudied areas. The PFYC system is continuously updated by the BLM and other agencies, and it was used to map the entire study area.

Preservation Risk Modeling

The USGS, in cooperation with the NPS, developed a preservation risk model for paleontological resources at or below full-pool elevations at Lake Powell and Lake Mead (Caster et al. 2026). The preservation risk model is a spatial model that considers several landscape characteristics, locations of previously recorded paleontological resources, and the potential for water-related impacts such as wave action and erosion. The USGS mapped the shoreline areas and ranked the preservation risk from 1 (low) to 5 (high) based on low to high potential for resource preservation to be affected by water at a given reservoir elevation. The ranking incorporates two other models: (1) the PFYC system, which identifies where paleontological resources are more likely or less likely to be found, and (2) the Preservation Hazard Model, which identifies where site impacts related to lake fluctuations will likely occur.

The Preservation Hazard Model is based on the simplified physical factors influencing lake shore geomorphic change. Similar to coastal environments, wave action drives erosion, but reservoirs have the added risk of large, rapid, and sustained changes in water level that affect runoff base levels, soil deformation, and chemical weathering through submersion and exposure. These aspects were incorporated into the model using available USGS topography and bathymetric data and the known relationships between slope-wave interactions, base level adjustments, lake fetch lengths, and lake shoreline area change, as well as a given volume of reservoir storage loss. In this model, the highest rank (5) corelates to a higher potential for impacts, and the lowest rank (1) correlates to a lower risk from these factors. Human impacts, such as vandalism or unauthorized collection, are not included in this model.

When combining the PFYC and Preservation Hazard Models, a simple rule was used based on the assumptions that (1) regardless of hazard rank, areas likely to contain resources have the potential to be affected by lake management actions; (2) even where resource likelihood is low, hazards from water levels can impact a potentially significant resource; (3) areas with a very high likelihood of containing resources and a very high potential for impacts are at the highest risk of resource condition changes; and (4) areas with a very low likelihood of containing resources and a very low potential for impacts are at the lowest risk of resource condition changes.

The Preservation Hazard Model uses the same ranking system as the PFYC system. However, preservation risk ranks 1–5 are not equivalent to PFYC ranks 1–5.

Wind-Deposited Sediment

Research conducted by the USGS and NPS has demonstrated that wind-deposited (aeolian) sediment can help stabilize and preserve paleontological sites along the Colorado River over long periods of time (Santucci et al. 2009). Sediment is generally deposited via wind on nearby terraces at an average of a few millimeters a year; however, Glen Canyon Dam operations can inhibit the formation of sandbars from which the sediment is blown. Management of the Colorado River influences the supply of windblown river sand in two ways: (1) the reduction of river flows below current average baseflow levels causes sand in the river channel to be exposed subaerially, and given sufficient time, can dry out and become available for wind transport; and (2) when HFEs are successfully implemented to rebuild river sandbars, the sand in the subaerial portion of the sandbars

becomes available for wind transport. However, riparian vegetation can block the windblown transport of sand; when cover decreases, the potential for wind transport increases.

The analysis integrated three independent models: the aeolian sand availability model (hereafter referred to as the "Sand Area Model" by Kasprak et al. 2024), the Vegetation Habitat Suitability Model (Butterfield et al. 2018), and the Sandbar Volume Model (modified from Mueller and Grams 2021). The Sand Area Model was specifically developed to predict the supply of river-sourced, windblown sand as a function of river discharge and subaerial exposure time; however, the Sand Area Model used here does not incorporate changes in vegetation cover that occur as a function of river hydrology or geomorphic changes (deposition and erosion of sand) that would also affect sand area. Therefore, the Sand Area Model was coupled with outputs from the Marble Canyon Vegetation Habitat Suitability Model (Kelley et al. 2026). Scenarios were assessed in which modeled sand availability exceeded a defined threshold while vegetation suitability remained below a specific benchmark, indicating conditions favorable for aeolian transport.

To account for the dynamic influence of high-flow events, which can increase sandbar volume and enhance future sand supply, the Sandbar Volume Model output was then incorporated. In this analysis, a future is defined as a "preferred minimum performance" if one of the following logical criteria was met: (1) the Sand Area and Vegetation Habitat Suitability Models simultaneously exceeded and fell below their respective thresholds (suggesting favorable conditions for aeolian transport), or (2) the Sandbar Volume Model exceeded the threshold, indicating enhanced sand supply via fluvial-related deposition. Previous studies suggest that dam releases that allow these conditions to be met 1–3 years may slow the rate of degradation to enable time for mitigation and planning. Considering temporal variability of future acceptability, it is ideal if these conditions are met at least once every 3 years. Model thresholds were derived from recent historical baselines; the sand area and vegetation (Marble Canyon only) thresholds reflect the 50th percentile of model outputs from 2000 to 2023, while the sandbar volume threshold is set at 1.5 times the modeled initial condition beginning in 2027.

Impact Analysis Area

The impact analysis area for paleontological resources consists of the Colorado River corridor from the upper limits of Lake Powell, through the Grand Canyon and Lake Mead, and from Hoover Dam to the SIB.

Assumptions

- The analysis of physical impacts on paleontological resources resulting from changes in lake levels, river flows, and sediment changes is informed by the cultural resources analysis.
- Impacts on paleontological resources can be characterized based on projected lake elevations and river flows.
- The impact analysis area includes known, unrecorded, and predicted paleontological resources that may be submerged or exposed and those geologic units that are sensitive for the presence of scientifically important paleontological resources.
- Specific paleontological locations are not discussed in this analysis, but the level of information available is assumed to be sufficient for this broadscale analysis.

- The exposure of paleontological resources may lead to the discovery of scientifically important fossils; however, the process and practical means of recovering paleontological resources within the reservoirs or along the Colorado River channel are limited.
- Landforms with steeper slopes are more susceptible to wave action erosion compared with low-slope areas.

Impact Indicators

- End-of-year lake elevations that may expose paleontological resources to damage from wave action, wet-dry cycling, increased visitation, and unauthorized collection or vandalism
- Changes in river flows that may contribute to erosion and exposure of resources that may expose fossils and trackways to damage from erosion, wet-dry cycling, or increased visitation
- Increase or decrease in sandbar building and availability of windblown sediments to protect paleontological localities or exposed fossils

Summary of Impact Mechanisms

This section provides a high-level summary of the primary physical, environmental, and human-related mechanisms through which changes in reservoir elevations and river flows may affect paleontological resources within the impact analysis area. Paleontological resources in Lake Powell, in Lake Mead, and along the Colorado River corridor may be affected by processes associated with reservoir inundation and exposure, shoreline and channel erosion, sediment transport, weathering, and changes in human access. **Table TA 12-3** summarizes these mechanisms and describes the general ways in which each can affect the preservation, stability, and scientific integrity of fossils and trackways. The table is intended to orient the reader to the types of impacts evaluated in this chapter and does not distinguish differences in impact magnitude or severity among the alternatives, which are addressed in subsequent sections.

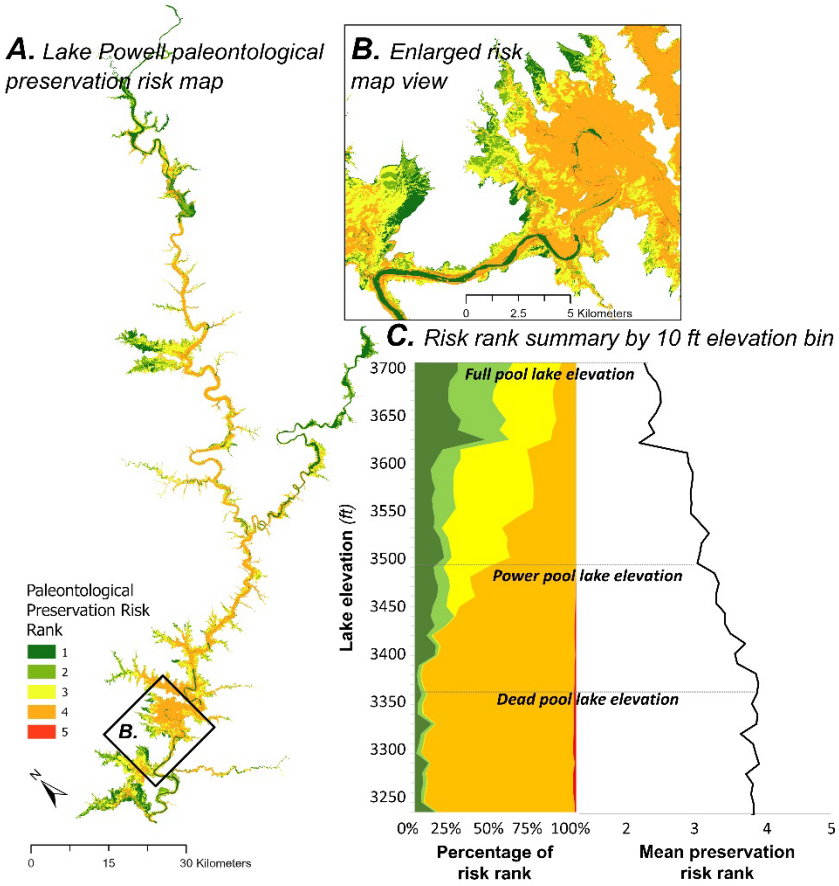
Table TA 12-3
Paleontological Resource Impact Mechanisms

Impact Mechanism	Description of Mechanism	Summary of Impacts on Paleontological Resources
Reservoir inundation and exposure	Fluctuations in Lake Powell and Lake Mead reservoir elevations alternately submerge and expose paleontological resources along shorelines and reservoir margins.	Repeated exposure increases vulnerability to physical and chemical degradation of fossils and trackways. Continuous inundation generally preserves paleontological resources more effectively than repeated cycles of exposure and inundation.
Wave action	Wind-driven wave energy acts on shoreline slopes and exposed reservoir margins, particularly where fetch length and slope increase wave power.	Mechanical erosion from wave action can undercut fossil-bearing strata, abrade exposed surfaces, and displace or destroy fossils and trackways, resulting in the loss of scientific context.

Impact Mechanism	Description of Mechanism	Summary of Impacts on Paleontological Resources
Wet-dry cycling	Reservoir drawdown and refill cause alternating periods of submersion and exposure.	These cycles accelerate the breakdown of fossil-bearing rock, particularly softer lithologies such as sandstone; this breakdown leads to cracking, spalling, loss of surface detail, and reduced integrity of fossils and track surfaces.
Chemical weathering	Prolonged contact with water followed by exposure to oxygen and atmospheric conditions breaks down or molecularly alters paleontological resources.	The weathering alters the mineral composition of enclosing rock, increasing friability after exposure and contributing to long-term degradation of fossils, even where physical erosion is limited.
Sunlight and ultraviolet exposure	Following reservoir drawdown, there is direct solar radiation on newly exposed fossil surfaces.	This exposure promotes surface weathering and thermal stress that can weaken fossil-bearing rock and accelerate degradation of exposed fossils and trackways.
Freeze–thaw processes	Seasonal temperature fluctuations allow water within fractures to freeze and expand, then thaw and contract.	These processes expand fractures and weaken rock matrices, increasing the likelihood of breakage, detachment, or loss of fossil material from outcrops.
Wind erosion	Wind acts directly on exposed sediments and fossil surfaces along reservoir margins and river terraces.	Wind erosion removes fine sediments that may otherwise protect fossils, abrades exposed surfaces, and increases rates of fossil degradation.
Fluvial erosion and deposition	Changes in river flows alter erosion and sediment deposition patterns along the Colorado River corridor.	Increased erosion can expose or damage fossils and trackways, while deposition and burial by fluvial sediments can temporarily protect paleontological resources from weathering and disturbance.
Aeolian sediment deposition	Windblown sand from exposed sandbars and river sediments accumulates on adjacent terraces and slopes.	Burial by aeolian sediments can stabilize and preserve paleontological resources over long periods by reducing exposure to erosion, weathering, and human disturbance.
Vegetation cover changes	Changes in river flows and sediment supply influence riparian vegetation extent, affecting windblown sediment transport.	Increased vegetation can limit aeolian sediment transport and reduce the natural burial of fossils, while reduced vegetation can enhance sediment deposition and protective burial.
Human access and visitation	Lower reservoir elevations expand exposed shorelines and increase accessibility by recreationists.	Trampling, inadvertent disturbance, vandalism, and unauthorized fossil collection may increase, resulting in loss of scientific context and irreversible damage to paleontological resources.

Impact Mechanism	Description of Mechanism	Summary of Impacts on Paleontological Resources
Unauthorized collection and vandalism	There can be intentional or opportunistic removal or defacement of exposed fossils.	Unauthorized collection permanently remove fossils from their geologic context, resulting in irreversible loss of scientific and educational value.

Note: This table provides a qualitative summary of impact mechanisms and does not distinguish differences in severity among the alternatives.



TA 12.2.2 Issue 1: How will fluctuations in water levels due to changes in dam operations (primarily in Lake Powell and Lake Mead) impact the exposure, erosion, and degradation of paleontological resources, including fossils and trackways?

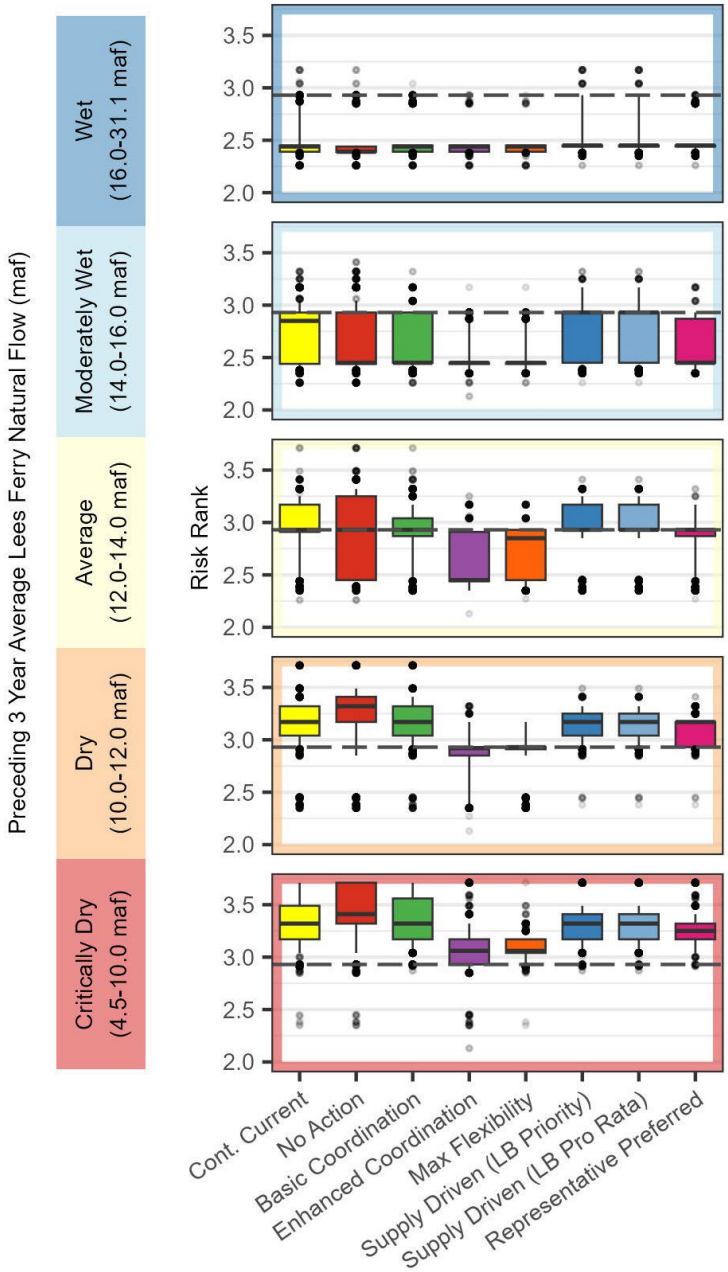
The USGS, in cooperation with the NPS, created the Paleontological Preservation Hazard Model, which was used in the decision-making under the DMDU modeling process. This spatial model summarizes 10-foot-elevation bins in Lake Powell and 5-foot-elevation bins in Lake Mead, so that each elevation from full pool to empty has a preservation risk rank. Next, projected monthly lake elevations are related to those elevation bins to estimate the preservation risk rank. **Figure TA 12-3**, below, below depicts the relationship between lake elevation and preservation risk rank at Lake Powell (Caster et al. 2026). This relationship is consistent with general reservoir conditions; the same trend is true for Lake Mead (the risk rises as elevations fall).

As lake elevations decrease, paleontological preservation risk increases. The threshold for preservation risk at each reservoir was derived from the 90th percentile values of the 2008–2024 LTEMP. At Lake Powell, for example, the threshold is 2.93, which occurs at approximately 3,600-foot elevation. The more time that a risk rank is exceeded (in this case, the more time that lake elevations remain below 3,600 feet), the more paleontological resources that have likely never been exposed may become exposed. Those resources are subjected to higher preservation hazards than any time since the reservoir was filled.

Fluctuations in water levels due to changes in dam operations at Lake Powell and Lake Mead could significantly impact paleontological resources, particularly fossils and trackways found in sedimentary formations like sandstone. These resources are vulnerable to erosion, weathering, and degradation when exposed repeatedly as water levels rise and fall. Specific studies of paleontological sites and effects of inundation have not been conducted at Lake Powell or Lake Mead. Anecdotal evidence from field staff indicates that sandstone becomes friable and crumbly after periods of inundation and exposure. It is assumed that certain types of paleontological resources, especially trackways in softer bedrock such as sandstone, could be destroyed or severely affected by the inundation and exposure, resulting in loss of rock outcrop integrity. However, it is unclear whether greater damage is caused only by a single inundation event or by repeated cycles of inundation and exposure. It is assumed that paleontological resources, including fossils and trackways, will experience similar impacts as those paleontological resources subjected to similar processes.

Figure TA 12-3
Risk Rank Summary at Lake Powell

Source: Caster et al. 2026



Lake Powell

This section presents a comparison of the No Action Alternative, Continued Current Strategies (CCS) Comparative Baseline, and action alternatives with respect to the paleontological preservation risk at Lake Powell. **Figure TA 12-4**, below, looks at the response of paleontological preservation risk in Lake Powell to different hydrologic conditions under different alternatives by looking at the preceding 3-year average of Lees Ferry natural flow. The figure presents the preservation risk rank values in a conditional box plot panel. The bold center line of each box represents the median value, the top and bottom of each box captures the 25th to 75th percentile of the modeled results, the lines extend to the 10th and 90th percentiles, and the outliers are represented as dots beyond these lines. In each flow category shown in the box plot, the historically derived threshold is identified with a dashed line.

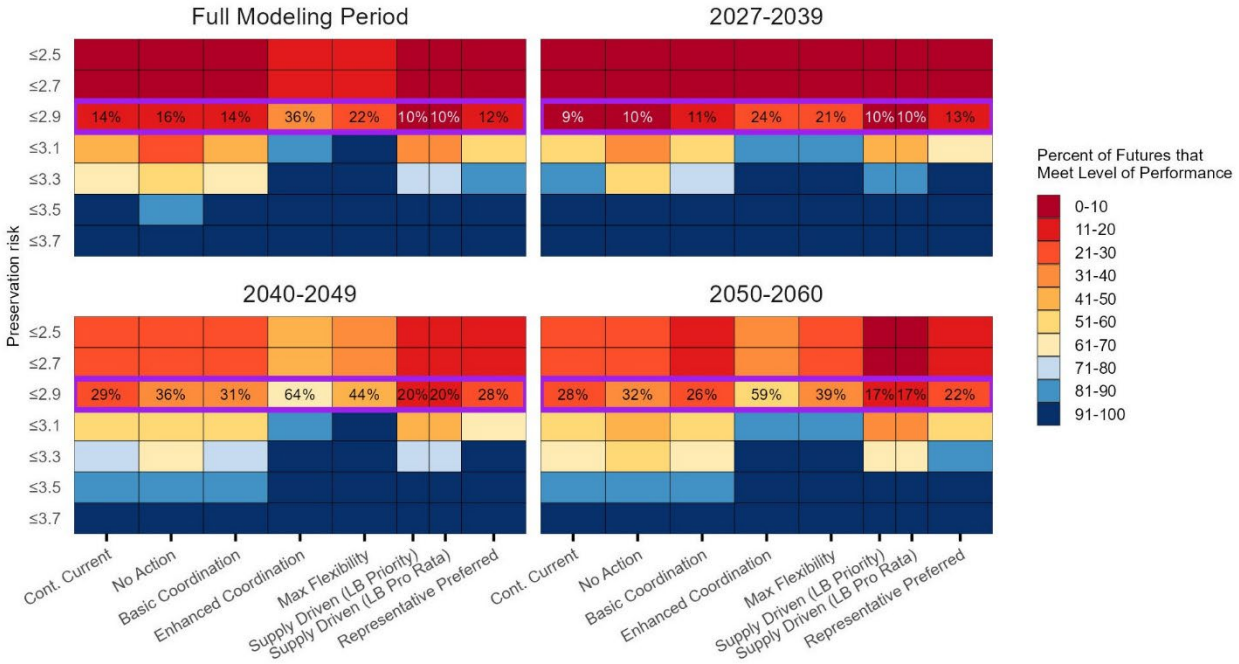
Note that the performance of the Supply Driven Alternative (both Lower Basin Priority [LB Priority] and Lower Basin Pro Rata [LB Pro Rata] approaches) will not differ for the Lake Powell preservation risk because they use the same operation of Lake Powell. See **Table TA 12-4** at the end of this technical appendix for the statistical breakdown of preservation risk rank at Lake Powell for each hydrologic condition and alternative, including the maximum, 90th percentile, 75th percentile, median, 25th percentile, 10th percentile, and minimum preservation risk rank.

In the Average Flow Category, the Maximum Operational Flexibility Alternative and Enhanced Coordination Alternative have similar ranges that are around or below the threshold. However, the Enhanced Coordination Alternative has a median risk value that is approximately 14 percent lower than what is modeled for the Maximum Operational Flexibility Alternative (2.45 and 2.85, respectively). In the Dry Flow Category, the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative perform similarly well, although all alternatives exceed the historically derived threshold under the Critically Dry Flow Category.

Figure TA 12-4
Water Year Maximum Paleontological Preservation Risk at Lake Powell

In all flow categories, the Basic Coordination Alternative has similar medians to the CCS Comparative Baseline and No Action Alternative. Under the Average Flow Category, the No Action Alternative has greater variability, while the Basic Coordination Alternative and CCS Comparative Baseline perform almost identically. All medians are at the historically derived threshold (see **Table TA 12-4**).

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) exceeds the historically derived threshold at the Average Flow Category and wetter conditions, with medians at or above 2.93. In the Wet Flow Category, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), Basic Coordination Alternative, No Action Alternative, and CCS Comparative Baseline still have outliers that exceed the historically derived threshold. At Lake Powell, the Enhanced Coordination Alternative results in the least variability and most values below the threshold.



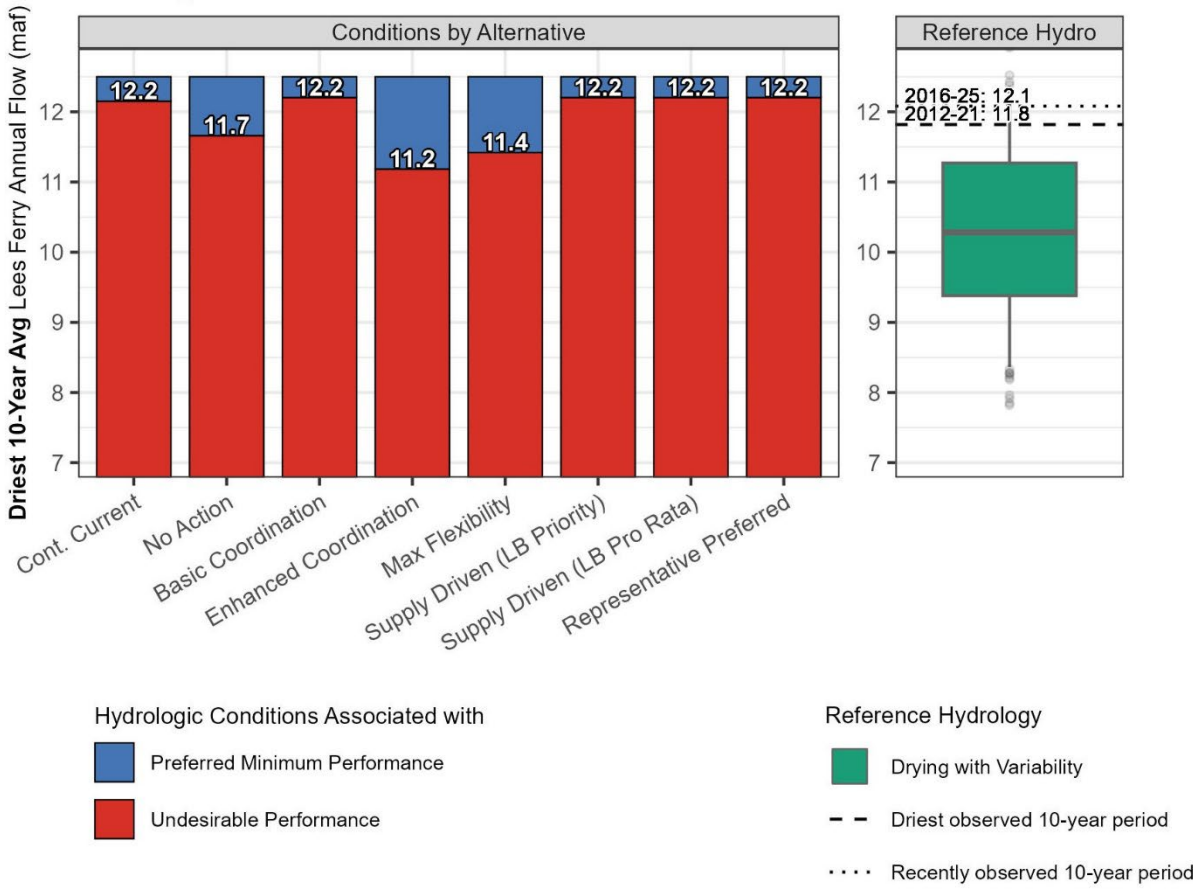
The Representative Preferred Alternative generally performs in the middle of the range of alternatives; it performs slightly better than the Supply Driven Alternatives and slightly worse than the Maximum Operational Flexibility Alternative. At Lake Powell, the Representative Preferred Alternative does not perform notably for preserving paleontological resources.

Figure TA 12-5, below, depicts the performance of each alternative with respect to keeping paleontological preservation risk ranks at Lake Powell below the historically derived threshold in at least 90 percent of months. This is the same threshold that what was used in **Figure TA 12-4**. The figure is broken into four heat maps, each showing a different time period during the analysis: the top left heat map shows the full modeling period from 2027 through 2060, and the remaining three panels show subperiods. Rows of the heat map show different preservation risk ranks, with higher rows corresponding to lower (more challenging) ranks. The highlighted row captures the percentage of futures that an alternative achieves a rank of 2.9 in 90 percent of the months (futures equal modeled hydrologic scenarios).

The Enhanced Coordination Alternative is the most robust at achieving a risk rank of 2.9 in 90 percent of months over the full modeling period, doing so in 36 percent of the futures. The Basic Coordination, No Action, and Representative Preferred Alternatives perform similarly to the CCS Comparative Baseline, succeeding in 14 percent, 16 percent, 12 percent, and 14 percent of futures, respectively. The Maximum Operational Flexibility Alternative succeeds 22 percent of the time over the full modeling period, which is just similar enough to the CCS Comparative Baseline and the No Action Alternative. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has the least robust success rate over the full modeling period at 10 percent.

In lower rows of the heat maps, the Maximum Operational Flexibility Alternative begins to perform better as the preservation risk increases than the Enhanced Coordination Alternative; the Maximum Operational Flexibility Alternative consistently achieves 91–100 percent robustness by 3.1 and 3.3, respectively, over the full modeling period. The other alternatives reach 91–100 percent robustness at 3.5 while the CCS Comparative Baseline reaches 91–100 percent robustness at 3.7.

Figure TA 12-5
Paleontological Resources in Glen Canyon NRA: Robustness.
Percentage of Futures in Which Monthly Preservation Risk Stays Below the Value Specified in Each Row in at Least 90 Percent of Months



In the first decadal subperiod, the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the historically derived threshold in 24 percent and 21 percent of futures, respectively. Given the planned length of this decision, it is notable that the Representative Preferred Alternative meets the historically derived threshold in only 13 percent of futures between 2027-2039. This suggests that existing challenges related to reservoir fluctuations at Lake Powell, including exposure, erosion, and degradation of paleontological resources, will continue under all alternatives.

Figure TA 12-6, below, looks at flow conditions that could cause the preservation risk rank to exceed the historically derived threshold in more than 10 percent of months of the 34-year modeling horizon. The driest 10-year average Lees Ferry natural flow was identified as a good predictor of undesirable performance; this is shown in the reference hydrology panel along with the recently observed 10-year average flow.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results in undesirable performance (that is, it becomes vulnerable to paleontological preservation risk rank exceeding the historically derived threshold), when the future includes a 10-year average flow of 12.2 maf or lower. Nearly all reference hydrologic traces include average flows of 12.1 or lower; the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results in futures where paleontological resources are most vulnerable to increased risk.

Figure TA 12-6
Paleontological Resources in Glen Canyon NRA: Vulnerability. Conditions that Could Cause Risk to Paleontological Sites in Lake Powell Exceeding Historical Benchmark More than 10 Percent of Months

The Enhanced Coordination Alternative results in undesirable performance when the 10-year average flow is below 11.2 maf. Approximately 75 percent of the reference hydrologic traces include averages this low or lower. The No Action Alternative and Maximum Operational Flexibility Alternative perform similarly to the driest 10-year average flow from 2012 to 2021 (11.7 maf and 11.4 maf, respectively). Under these alternatives, paleontological resources are vulnerable to conditions that are close to what has already occurred.

The CCS Comparative Baseline and the Basic Coordination, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives perform the same, with paleontological resources becoming vulnerable at approximately 12.2 maf. Nearly 100 percent of the reference hydrologic traces include average flows this low or lower, so the vulnerability is very high.

Lake Mead

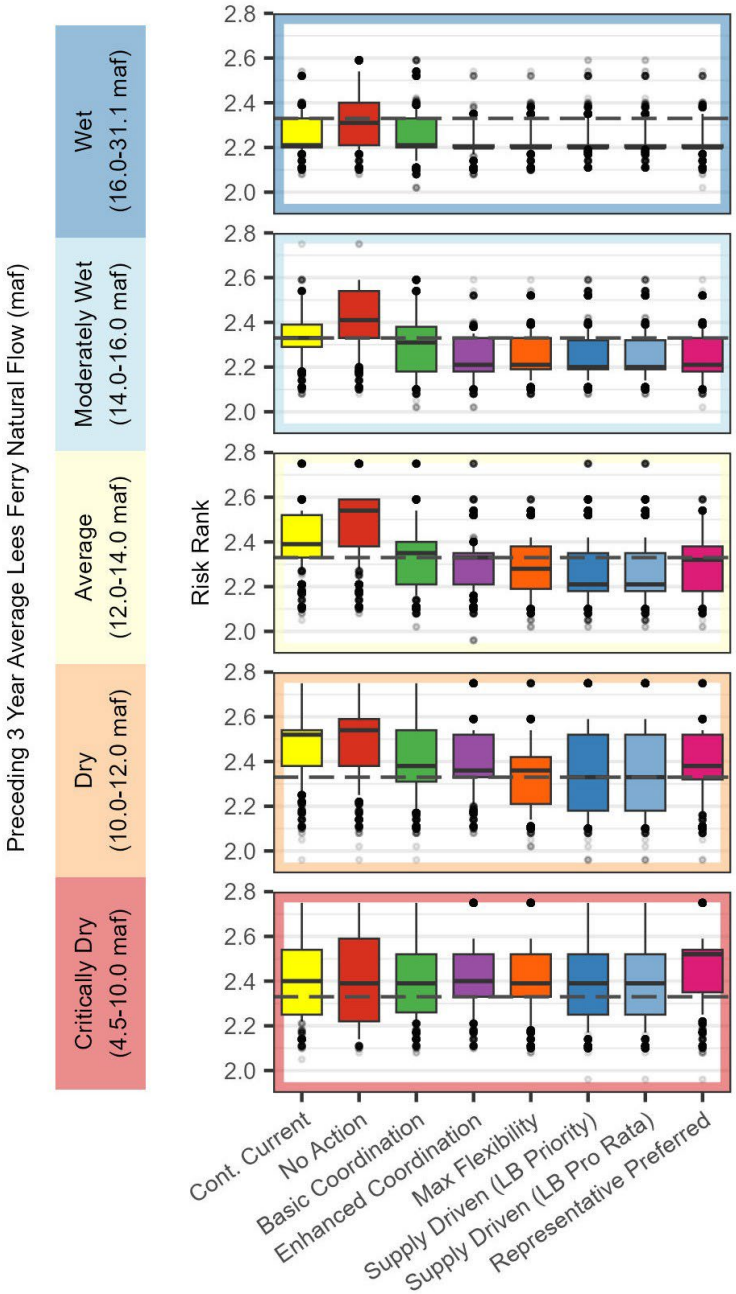
This section presents a comparison of the No Action Alternative, CCS Comparative Baseline, and action alternatives with respect to paleontological preservation risk at Lake Mead. **Figure TA 12-7**, below, looks at the response of paleontological preservation risk in Lake Mead to different hydrologic conditions under different alternatives by looking at the preceding 3-year average of Lees Ferry natural flow. The figure presents the preservation risk rank values in a conditional box plot panel. The historically derived threshold at Lake Mead is a risk rank of 2.33. Note that the performance of the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) will not differ in Lake Mead preservation risk because the modeling assumes no banking activity. See **Table TA 12-5** at the end of this technical appendix for the statistical breakdown of preservation risk rank at Lake Mead for each hydrologic condition and alternative.

In each flow category shown in the box plot, the historically derived threshold (2.33) is identified with a dashed line. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs best in the Average Flow Category, with median preservation risk ranks and an interquartile range below the 2008-2024 defined threshold. The Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives perform similarly to one another, with median preservation risk ranks at or below the threshold and interquartile ranges that are mostly below the threshold. As the modeling enters the Critically Dry Flow Category, performance shifts to the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven Alternatives maintaining interquartile ranges below the threshold. Preservation risk ranks across all alternatives are above the threshold, with the Representative Preferred Alternative exhibiting the highest median. Large boxes on the plot represent more uncertainty as to how conditions might change, and the larger the section of the box that is above the threshold line, the more resources that are being exposed to risks they have not faced since Lake Mead was filled.

For all hydrology except the Critically Dry Flow Category, the Maximum Operational Flexibility Alternative and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) perform similarly with a median preservation risk around, or just above, the historical threshold. The Maximum Operational Flexibility Alternative appears to have slightly less variability with a smaller interquartile range, though a larger percentage of the range is above the historical threshold. The Enhanced Coordination Alternative has a slightly larger median preservation risk rank but a smaller interquartile range, suggesting less variability in results but more certainty of the preservation risk exceeding historical conditions. Under the driest conditions, all alternatives have a moderately strong chance of exceeding the historical preservation risk conditions.

At Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results in the least variability and most values below the threshold. The Representative Preferred Alternative performs generally in the middle of the alternatives, suggesting that preservation risk ranks will exceed historical conditions over the planned length of the decision.

Figure TA 12-7
Water Year Maximum Paleontological Preservation Risk at Lake Mead



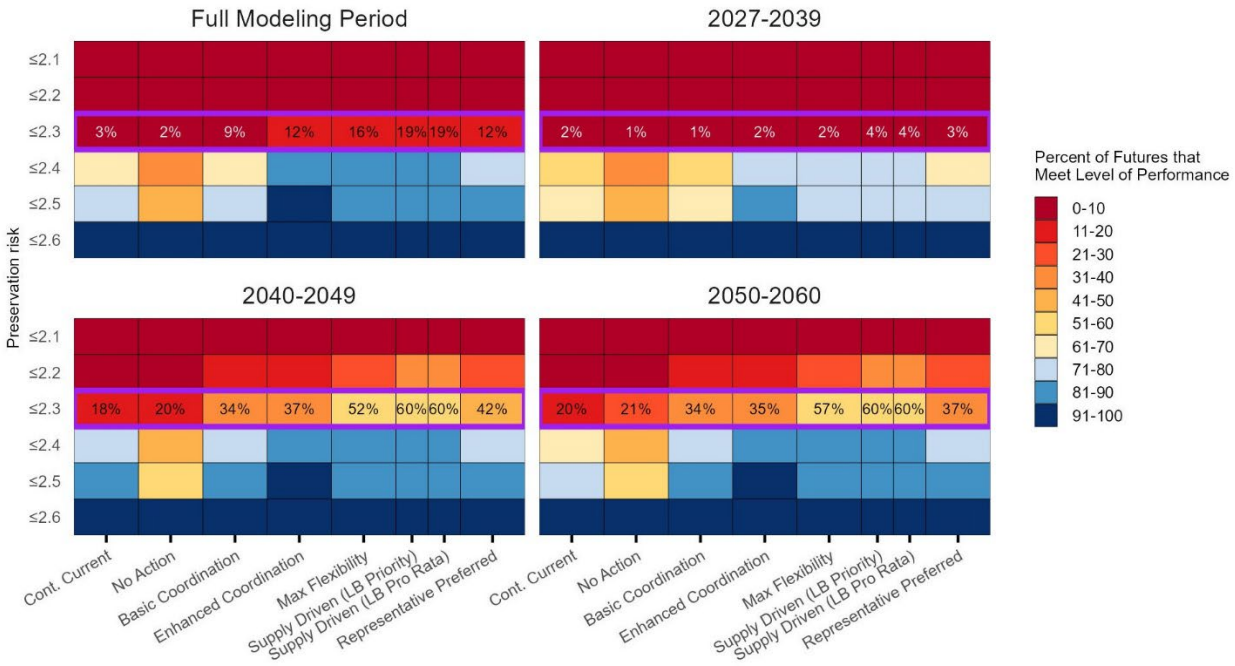


Figure TA 12-8, below, depicts the performance of each alternative with respect to keeping paleontological preservation risk ranks at Lake Mead below the historically derived threshold in at least 90 percent of months. This is the same threshold as what was used in **Figure TA 12-7**. The figure is broken into four heat maps, each showing a different time period during the analysis. The top left heat map shows the full modeling period from 2027 through 2060, and the remaining three panels show subperiods. Rows of the heat map show different preservation risk ranks, with higher

rows corresponding to lower (more challenging) ranks. The highlighted row captures the percentage of futures that an alternative achieves a rank of 2.3 in 90 percent of the months.

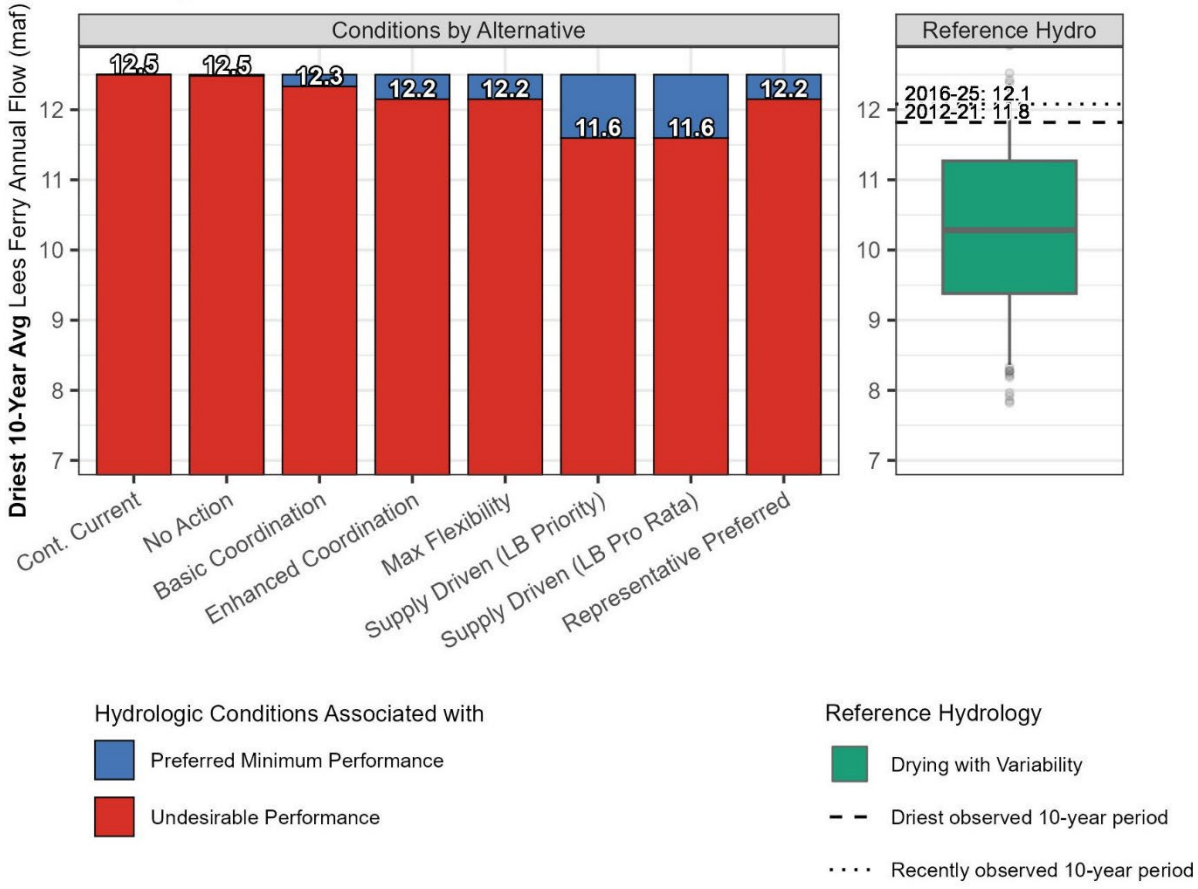
The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust at achieving a risk rank of 2.3 in 90 percent of months over the full modeling period, doing so in 19 percent of the futures. The Maximum Operational Flexibility Alternative performs similarly to the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), achieving a risk rank of 2.3 in 16 percent of futures. The No Action Alternative and CCS Comparative Baseline are the least robust and perform identically, succeeding in 2 percent and 3 percent of futures, respectively; the Representative Preferred Alternative and Enhanced Coordination Alternative perform the same (12 percent successful futures). In lower rows of the heat map, the Enhanced Coordination Alternative achieves 91–100 percent robustness by 2.5. The CCS Comparative Baseline and all other alternatives achieve 91–100 percent robustness at 2.6.

Figure TA 12-8
Paleontological Resources in Lake Mead NRA: Robustness. Percentage of Futures in Which Monthly Preservation Risk Stays Below the Value Specified in Each Row in at Least 90 Percent of Months

Robustness of the alternatives does not immediately improve when analyzing shorter modeling periods. In the 2027–2039 period, robustness of the CCS Comparative Baseline and all action alternatives drop; the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) drops more than 10 percent, from 19 percent in the full modeling period to 4 percent in the 2027–2039 decadal subperiod. Given the planned length of the decision, it is notable that the Representative Preferred Alternative is robust in only 3 percent of futures between 2027 and 2039,

suggesting that reservoir fluctuations in Lake Mead will result in exposure, erosion, and degradation of paleontological resources at rates greater than historically observed.

Robustness quickly improves in the 2040–2049 and 2050–2060 subperiods. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust in 2040–2049, with 60 percent of futures achieving a risk rank of 2.3 in 90 percent of months. However, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is slower to improve performance in the lower rows; the Enhanced Coordination Alternative reaches 91–100 percent robustness at 2.5. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) reaches 91–100 percent robustness at 2.6.



In the 2050–2060 subperiod, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) continues to perform best with respect to the historically derived threshold. However, the Enhanced Coordination Alternative reaches 91–100 percent robustness at 2.5. At the historically derived threshold, the Maximum Operational Flexibility Alternative is more robust than the Enhanced Coordination Alternative (57 percent and 35 percent, respectively). However, the Enhanced Coordination Alternative is faster to achieve 91–100 percent robustness. Overall, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust alternative at Lake Mead in the 2050–2060 subperiod, achieving 90 percent of months where the historically derived threshold is met in 60 percent of futures. The Representative Preferred Alternative continues to perform generally in the middle of the alternatives at Lake Mead.

Figure TA 12-9, below, looks at flow conditions that could cause the preservation risk rank at Lake Mead to exceed the historically derived threshold in more than 10 percent of months of the 34-year modeling horizon. The driest 10-year average Lees Ferry natural flow was identified as a good predictor of undesirable performance; this is shown in the reference hydrology panel along with the driest and recently observed 10-year period.

Paleontological resources are the most vulnerable to risk under the CCS Comparative Baseline and No Action Alternative. Undesirable performance occurs at 12.5 maf; nearly 100 percent of the reference hydrology traces include average flows of 12.5 maf or lower. These two scenarios are vulnerable to conditions that have already occurred; average flows of 11.8 maf occurred during the driest observed 10-year period. The Basic Coordination Alternative and Enhanced Coordination Alternative are vulnerable to increased risk to paleontology sites at flows of 12.3 maf and 12.2 maf, respectively. Under all alternatives where the undesirable performance is greater than 12.1 maf, vulnerability is nearly certain.

The Maximum Operational Flexibility and Representative Preferred Alternatives result in undesirable performance if the future includes a driest 10-year flow of 12.2 maf, which is the greater than the 2012–2021 driest observed flow. Under the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), paleontological resources become vulnerable to risk at flows of 11.6 maf. Approximately 75 percent of reference hydrology traces are drier than 11.6 maf, so the vulnerability is considered high. It is notable that under the Representative Preferred Alternative, paleontological resources in Lake Mead would be vulnerable to exposure, erosion, and degradation when flows are 12.2 maf or less.

Figure TA 12-9
Paleontological Resources in Lake Mead NRA: Vulnerability.
Conditions that Could Cause Risk to Paleontological Sites in Lake Mead Exceeding Historical Benchmark More than 10 Percent of Months

Summary Comparison of Alternatives

Lake Powell and Lake Mead

Continuous inundation preserves paleontological resources better than repeated exposure to waves and wet-dry cycles. Changes in lake elevations that may expose previously inundated paleontological resources are the biggest concern; the Paleontological Preservation Risk Model uses lake elevations to establish risk. For Lake Powell, the Enhanced Coordination Alternative performs best with regard to meeting the paleontological preservation risk rank threshold in all hydrologic conditions except the Critically Dry Flow Category; this alternative is followed by the Maximum Operational Flexibility Alternative. Both alternatives exhibit median risk ranks that are at or below the threshold. The Basic Coordination Alternative is the least effective action alternative with regard to meeting the paleontological preservation risk threshold. This alternative becomes successful at the Moderately Wet Flow Category but consistently exceeds the threshold at the Average Flow Category and drier. The No Action Alternative and CCS Comparative Baseline perform similarly to the Basic Coordination Alternative.

For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and Maximum Operational Flexibility Alternative perform similarly and produce median preservation risk rank around, or just above, the historically derived threshold in all hydrologic conditions except the Critically Dry Flow Category. All alternatives exceed historical preservation risk conditions under the Critically Dry Flow Category.

For both Lake Powell and Lake Mead, the Representative Preferred Alternative generally performs somewhere in the middle of the action alternatives, never outperforming all alternatives in terms of paleontological resource risk reduction. Given the length of the planned decision, it is notable that paleontological preservation risk will likely be heightened under the Representative Preferred Alternative, as more resources will become exposed and eroded due to fluctuating reservoir levels and flows.

Under the Maximum Operational Flexibility Alternative, the paleontological preservation risk rank would be maintained at or below the threshold of significance for the most amount of time across both reservoirs. Paleontological resources that are inundated by lake elevations would not be exposed to erosion, degradation, and the repeated cycles of inundation and exposure and wave action. The Maximum Operational Flexibility Alternative would be a balanced approach minimizing preservation risk. The Enhanced Coordination Alternative would also maintain paleontological preservation risk rank in the reservoirs, but not as consistently as under the Maximum Operational Flexibility Alternative.

TA 12.2.3 Issue 2: How will altered sediment transport, including both fluvial and aeolian deposition patterns, affect the preservation and stability of paleontological resources?

The preservation and stability of paleontological resources along the Colorado River corridor are closely tied to sediment dynamics, particularly the deposition and redistribution of fine sediments through fluvial and aeolian processes. Sediment burial helps protect surface-exposed resources from erosion, weathering, and human disturbance, while changes in the magnitude or timing of sediment delivery may either enhance or degrade preservation conditions. However, increased exposure of sandbars and sediment surfaces typically heightens the risk of erosion, weathering, and loss of fossil integrity, while sediment deposition and rapid burial may provide temporary protection from degradation. Frequent fluctuations in the water level that alternately expose and inundate sediments are generally detrimental to long-term preservation.

Fluvial Sediment Transport

Figure TA 12-10 depicts the performance of each alternative with respect to the fraction of total sand mass transported by sandbar-forming flows, defined as releases greater than 37,000 cubic feet per second (cfs), over the 34-year modeling horizon. As detailed in **TA 5**, Geomorphology and Sediment, HFE releases represent Reclamation's primary tool for managing the limited sediment resources and maintaining or increasing sandbar size. These controlled floods, which range from approximately 31,500 cfs to over 37,000 cfs, are the only mechanism capable of producing widespread sandbar building (Hazel et al. 2022; Salter et al. 2025). Sandbars erode between HFE releases (Hazel et al. 2022), with the highest rates immediately after a flood (when bars have the most sediment available for erosion) and decreasing with time (Grams et al. 2010). Steadier flows erode bars at a lower rate than fluctuating flows (Wright et al. 2008).

Figure TA 12-10
Sand-Load Index: Robustness.
Percentage of Futures in Which the Fraction of Sand Mass Transported Above 37,000 cfs is the Value Specified in Each Row

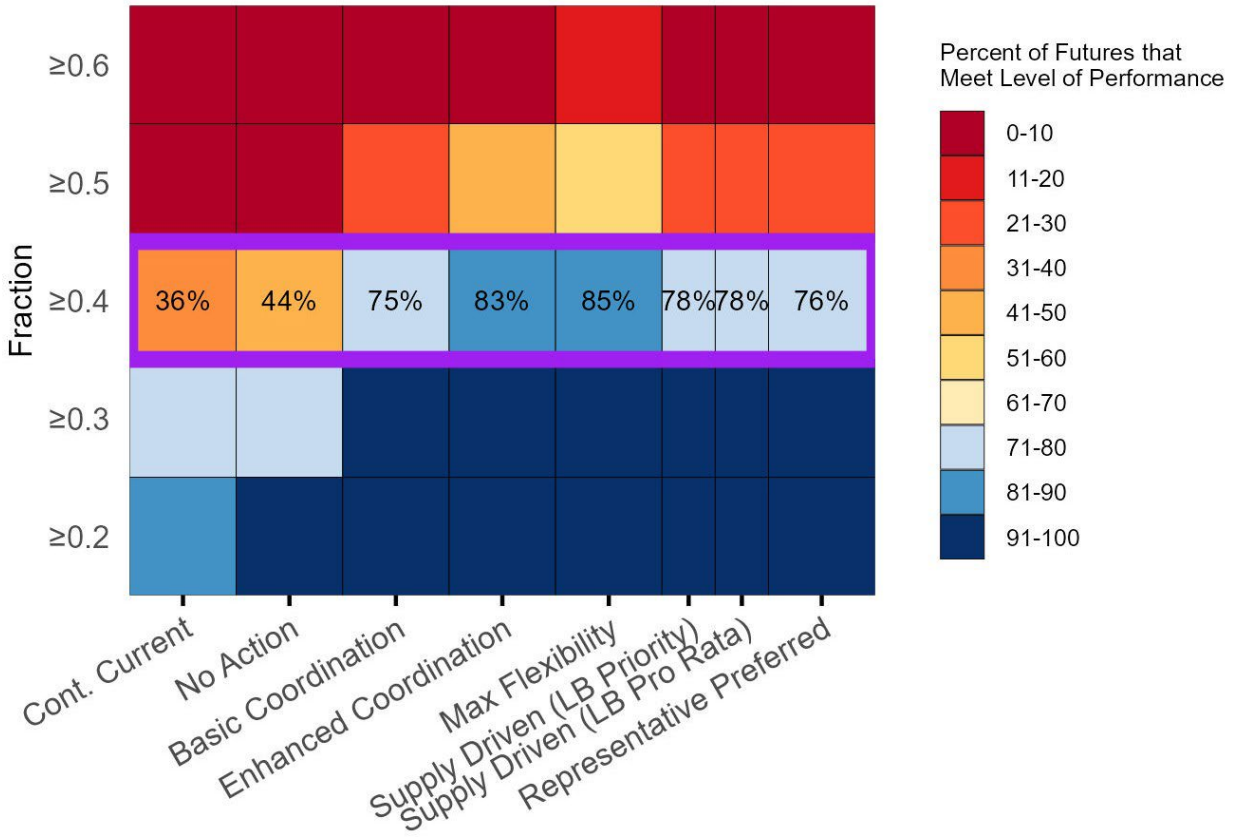


Figure TA 12-10 evaluates how robustly each alternative supports sandbar formation by showing the percentage of futures in which at least 40 percent of total sand mass is transported during sandbar-forming flows. This 40 percent threshold was selected as an indicator of conditions likely to support adequate sand deposition to retain sandbars. Due to modeling constraints, this figure only depicts robustness for the entire modeling period and does not include decadal subperiods.

The Enhanced Coordination and Maximum Operational Flexibility Alternatives exhibit the highest robustness; each achieves successful outcomes—defined as meeting or exceeding the 40 percent threshold—in 83 percent and 85 percent of futures, respectively. Under these alternatives, sediment transport dynamics would generally support sandbar deposition at satisfactory levels, which would indirectly result in desirable levels of sand for fossil reburial.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) meets the threshold in 78 percent of futures, while the Representative Preferred and Basic Coordination Alternatives perform moderately lower at 76 percent and 75 percent, respectively. These three alternatives perform similarly to the Enhanced Coordination and Maximum Operational Flexibility Alternatives because their robustness is within 10 percent of each other, and all five action alternatives reach 91-100 percent robustness within one row of the heatmap. It is notable that the Representative

Preferred Alternative meets the threshold similarly to the highest performing alternative, indicating that sandbar building would continue to occur at rates beneficial to fossil reburial.

Under both the No Action Alternative and the CCS Comparative Baseline, fewer than half of futures meet the 40 percent sandbar-forming flow threshold, with the CCS Comparative Baseline exhibiting the lowest success rate of all alternatives. These outcomes indicate that sand would be transported at rates less favorable for sandbar building and that fossils would be at greater risk of exposure during the erosion of sandbars and less frequently buried during sandbar-building events under the No Action Alternative.

Aeolian Sediment Transport

As discussed above in **Section TA 12.2.1**, Methodology, the aeolian transport model looks at favorable conditions for wind-borne sand to be present to protect paleontological resources over long periods of time using projected vegetation cover and exposed sand area or sandbar volume (Kelley et al. 2026). The vegetation and sandbar volume modeling used is from the Marble Canyon sub-reach from Lees Ferry to the Little Colorado River. The exposed sand modeling was conducted for the portion of the river from Lees Ferry to Bright Angel Creek. But the general conclusions are pertinent to the entire river.

The results of the annual vegetation cover modeling are presented in **Section TA 9**, Vegetation Including Special Status Species. Overall, less vegetation is better for aeolian sand transport because it leaves sand exposed to be picked up by the wind. As discussed in **Section TA 9.2.2** and seen in **Figure TA 9-13**, for all modeled scenarios under the wet and moderately wet conditions, there would be less vegetation cover (below observed conditions) from higher water levels and longer HFEs. As conditions grow drier, water flows diminish, HFEs are shorter, and vegetation cover increases (see **Figure TA 9-13**).

For the Average Flow Category, the median for the CCS Comparative Baseline, the No Action Alternative and all action alternatives (including the Representative Preferred Alternative) is at or just below the modeled historical conditions (i.e., the 2007 Interim Guidelines period [WY 2008–2025]) and the interquartile ranges are relatively small. This indicates that the annual total vegetation may be similar to historical conditions under average flows. Conversely, under the dry and critically dry conditions, annual total vegetation cover increases and differentiation between alternatives can be seen. For the Critically Dry Flow Category, the medians and interquartile ranges are above the modeled historical conditions (dashed line) for all sub-reaches and all alternatives except the interquartile range for the CCS Comparative Baseline, which drops just below the dashed line (see **Figure TA 9-14** in **TA 9**). This indicates that there may be more annual total vegetation cover, especially under critically dry flows.

The results of the sandbar volume modeling are presented in **TA 5**, Geomorphology and Sediment. As discussed in **TA 5**, for an HFE to be triggered, enough sand needs to be available in Marble Canyon and enough water needs to be available in Lake Powell (as measured by water level), with both the required amounts of sand and water being dependent on the selected HFE duration. Additionally, HFE releases can only be implemented when Lake Powell water levels are 3,500 feet, with sandbar deposition occurring most rapidly during the first 4 days of an HFE event. Lastly,

sandbar volume modeling uses the assumption that HFEs are implemented as often as possible (see **Section TA 5.2.1**, Modeling Criteria and Assumptions). For the aeolian transport model, increased exposed sandbar volume (or the amount of "useable" sand) means more sand is available to protect paleontological resources. In general, as conditions get drier and the amount of water flowing through the river decreases, exposed sandbar volume increases (see **Section TA 5.2.4**, Issue 4: Sandbar Volume, in **TA 5**, Geomorphology and Sediment). Differences in performance among the alternatives also increase as hydrological conditions become drier, with the Enhanced Coordination and Maximum Operational Flexibility Alternatives performing the best for the Critically Dry Flow Category (see **Figure TA 5-12** in **TA 5.2.5**).

Figure TA 12-11 shows the results of the water year average of exposed sand area modeling, with the 90th percentile and median (50th percentile) of modeled sand areas depicted as the two dashed lines. As with exposed sandbar volume, increased exposed sand area is beneficial for the aeolian transport of sand to protect paleontological resources. In the Average Flow Category, the median exposed sand area is around the 90th percentile (upper dashed line) and the median (50th percentile, lower dashed line) of modeled sand area (in million square meters). As conditions become drier, all modeled scenarios perform similarly with the forecasted median exposed sand area above the observed median with the Enhanced Coordination Alternative having a slighter higher median than the action alternatives. In the Critically Dry Flow Category, the Maximum Operational Flexibility Alternative exhibits the most variability with the greatest interquartile range. The Representative Preferred Alternative generally performs in the middle of the action alternatives, indicating that the exposed sand area will be conducive to the protection of paleontological resources through aeolian transport.

Figure TA 12-12 shows the results of the aeolian sand modeling, in which the percentage of futures meet one of two criteria: either the annual sand volume is greater than the median observed sand volume over the last 20 years and the vegetation cover area is less than the median observed area over the last 20 years, or the sandbar volume is greater than 1.5 times the initial condition. The highlighted row shows when those conditions are met at least 1 out of every 3 years, which is the optimal time frame for enough sand to be available for aeolian transport, based on previous studies.

Over the full modeling period, the Enhanced Coordination and the Maximum Operational Flexibility Alternatives are the most robust; they meet the desired conditions of at least 1 out of every 3 years in 19 percent and 18 percent of futures, respectively, followed by the No Action Alternative only in 14 percent of futures. The Basic Coordination Alternative meets the preferred minimum of performance in only 9 percent of futures, with the Representative Preferred Alternative meeting it in only 6 percent of futures. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the least robust, meeting the desired conditions in only 3 percent of futures. If the year interval is lengthened (that is, to 1 out of 4, 5, or 6 years), the models perform in a similar overall pattern; the Enhanced Coordination and the Maximum Operational Flexibility Alternatives perform the best.

Figure TA 12-11
Water Year Average of Exposed Sand Area

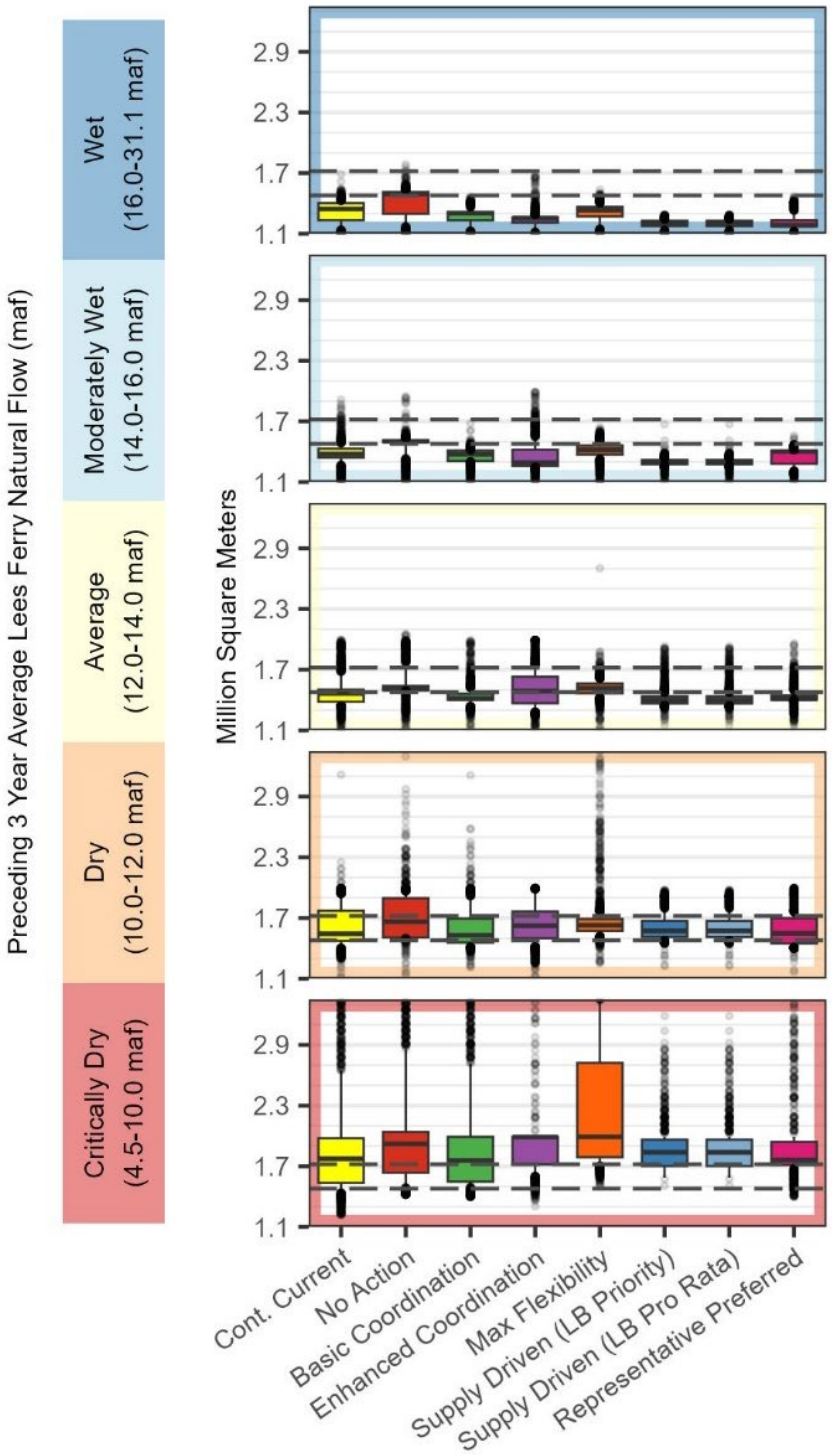

Figure TA 12-12
Multi-modal Aeolian Transport Condition: Robustness.
Percentage of Futures in Which Annual Sand Area Is >50th Percentile and Vegetation Cover Is <50th Percentile, or Sandbar Volume Is >1.5 Times the Initial Condition in the Frequency Specified in Each Row

It is notable that the Representative Preferred Alternative meets the desired conditions in 17 percent of futures between 2027 and 2039, indicating that the conditions required for aeolian transport will not occur frequently, exposing paleontological resources to erosion and other weathering mechanisms.

When results are split over intervals from 2027–2039, 2040–2049, and 2050–2060, the percentage of futures meeting the desired conditions increase for both the Enhanced Coordination and the Maximum Operational Flexibility Alternatives from 35 percent to 55 percent and 53 percent and from 30 percent to 57 percent and 56 percent, respectively. These results seem to indicate an increase in acceptability over time, which may correlate to increased available sand over time; however, the perceived increase is driven by an increase in sandbar volume over time in the modeling, with the understanding that HFEs would continue as planned. In reality, the decision to conduct HFEs depends on annual review.

Summary Comparison of Alternatives

Fossils and other paleontological resources that become exposed to oxygen, wind, and erosion are vulnerable to degradation. Sediment transport, by both aeolian and fluvial processes, can better preserve paleontological resources through burial. Changes in river flows and HFEs can affect the amount of sediment available for transport and indirectly impact the stability and preservation of fossils and other paleontological resources.

Based on the modeling, the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative were the most robust for sand transport during HFEs. Under these alternatives, the rate of sand transport would generally support sandbar building and indirectly contribute to the burial and preservation of paleontological resources. In contrast, the No Action Alternative was the least robust, and HFEs would not support sandbar building in more than 44 percent of futures.

The Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative were also the most robust for aeolian transport of sediment. Although the robustness modeling results showed only 19 and 18 percent of successful futures for these alternatives, respectively, the Basic Coordination Alternative and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) produced values of 9 percent or lower.

The Representative Preferred Alternative generally performs in the middle of the action alternatives, never outperforming the best alternative with regard to paleontological resources. This means that paleontological resources will be vulnerable to altered fluvial and aeolian sediment transport, particularly between 2027 and 2039. Paleontological resources are likely to be exposed rather than buried, and may be degraded by multiple weathering mechanisms over time.

The river corridor, from below Hoover Dam to the SIB, is not well mapped by PFYC. Classifications in the corridor are mostly PFYC W (water). While possible, the presence or impacts on scientifically important vertebrate fossils are not anticipated within the river corridor when compared with the potential for known or undiscovered fossils in the reservoirs. The Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative are the most robust alternatives with regard to sediment transport in the river corridor. Sediment transport would indirectly preserve and stabilize the known and unknown fossil localities.

TA 12.2.4 Issue 3: How will adjustments to dam operations and water levels alter human access to newly exposed fossil sites, and what are the potential risks of increased disturbance, unauthorized collection, and recreational impacts on paleontological resources?

The Paleontological Preservation Risk Model does not include the indirect impacts of human disturbance. However, the model does correlate with lake elevations at Lake Powell and Lake Mead. As lake elevations drop, more of the reservoir becomes accessible to visitors, particularly in flatter areas that are easy to access. The longer amount of time lake elevations remain low, the more vulnerable paleontological resources become to increased rates of disturbance, unauthorized collection, and recreational impacts. The DMDU analysis used for lake elevations in **TA 3**, Hydrologic Resources, is used in conjunction with the paleontological preservation risk to conduct the analysis of indirect impacts on paleontological resources from the alternatives.

Lake Powell

This section presents a comparison of the No Action Alternative, CCS Comparative Baseline, and action alternatives with respect to increased disturbance of, unauthorized collection of, and recreational impacts on paleontological resources at Lake Powell. For a more detailed analysis of

recreation at Lake Powell, please refer to **TA 14**, Recreation. For a more detailed analysis of hydrologic conditions at Lake Powell, please refer to **TA 3**, Hydrologic Resources.

The alternatives perform similarly with respect to maintaining lake elevations and achieving desirable paleontological preservation risk ranks. The Maximum Operational Flexibility Alternative and Enhanced Coordination Alternative are the most robust at staying above 3,500-foot elevation in 100 percent of months over the full modeling period, doing so in 86 percent and 74 percent of futures, respectively. This result is similar to the robustness of both alternatives with regard to achieving the historically derived preservation risk threshold in 90 percent of months.

The No Action Alternative is the least robust at maintaining 3,500-foot elevation in 100 percent of months, doing so in 4 percent of futures over the full modeling period. The No Action Alternative is only 61–70 percent robust at maintaining this elevation in 60 percent of months. The CCS Comparative Baseline, Basic Coordination Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) perform similarly, maintaining the 3,500-foot elevation in 100 percent of months in 18 percent, 13 percent, and 18 percent of futures, respectively.

The Representative Preferred Alternative meets this robustness criteria in 28 percent of modeled futures in the full modeling period. Based on the planned length of this alternative, it is important to note that it meets the preferred minimum performance level in 49 percent of futures between 2027 and 2039. The Representative Preferred Alternative is much less robust than the Maximum Flexibility and Enhanced Coordination Alternatives, but it is much more robust than all other alternatives and the CCS Comparative Baseline.

Alternatives that keep Lake Powell at or above 3,500 feet more often will keep most sites below that level underwater (and protected) more of the time. Therefore, the risk of human disturbance would be for resources above 3,500 feet. The preservation risk rank's historically derived threshold is achieved at approximately 3,500-foot elevation at Lake Powell. Under the Maximum Operational Flexibility Alternative, elevations at Lake Powell would be most consistently at or above 3,500 feet, which would result in the inundation of the most paleontological resources and the least amount of shoreline expansion for visitors to access resources.

Lake Mead

This section presents a comparison of the No Action Alternative, CCS Comparative Baseline, and action alternatives with respect to increased disturbance of, unauthorized collection of, and recreational impacts on paleontological resources at Lake Mead. For a more detailed analysis of recreation at Lake Mead, please refer to **TA 14**, Recreation. For a more detailed analysis of hydrologic conditions at Lake Mead, please refer to **TA 3**, Hydrologic Resources.

The alternatives perform similarly with respect to maintaining lake elevations and achieving desirable paleontological preservation risk ranks. The Supply Driven Alternative (LB Pro Rata) and Maximum Operational Flexibility Alternative are similarly robust at keeping Lake Mead elevation above 975 feet in 100 percent of months, doing so in 73 percent and 70 percent of futures, respectively. The Enhanced Coordination Alternative and Supply Driven Alternative (LB Priority) are also similarly

robust, maintaining Lake Mead elevation above 975 feet in 65 percent and 61 percent of futures, respectively.

The Representative Preferred Alternative meets this robustness criteria in 50 percent of modeled futures in the full modeling period. Based on the planned length of this alternative it is important to note that it meets the preferred minimum performance level in 66 percent of futures between 2027 and 2039.

The No Action Alternative is the least robust, keeping Lake Mead elevation above 975 feet in 100 percent of months in 21 percent of futures over the full modeling period. Robustness of the CCS Comparative Baseline is 38 percent; robustness of the Basic Coordination Alternative is 50 percent.

Summary Comparison of Alternatives

Lake Powell and Lake Mead

Changes in dam operations that lower reservoir levels can expand the extent of exposed shorelines and channel margins, increasing human access both by land and by small watercraft. Recreational activities such as off-highway vehicle use, hiking, camping, and boating at and around the reservoirs can inadvertently disturb fragile paleontological materials through trampling, erosion from trail formation, or sediment displacement. Additionally, unauthorized fossil collection, either intentional or opportunistic, may increase as new sites become visible and accessible to the public. Once displaced or removed, contextual information critical for scientific study and resource management may be lost.

Increased public presence also raises the likelihood of secondary impacts, such as looting, vandalism, or inadvertent exposure through surface collection. These impacts are particularly concerning in areas lacking monitoring or signage that would otherwise deter unauthorized activities. Conversely, rapid reburial of exposed sites during subsequent water level rises may offer temporary protection from ongoing disturbance, although repeated exposure and burial cycles can weaken fossil integrity over time.

Under the Maximum Operational Flexibility Alternative, the paleontological preservation risk rank would be maintained at or near the historically derived threshold in both Lake Powell and Lake Mead. Additionally, critical lake elevations would be maintained at 3,500 feet in Lake Powell and 975 feet in Lake Mead in 87 percent and 80 percent of futures, respectively. The operations proposed under the Maximum Operational Flexibility Alternative would result in the least amount of time paleontological resources below critical elevations are exposed to human disturbance and associated impacts.

Under the Representative Preferred Alternative, critical lake elevations would be maintained at 3,500 feet in Lake Powell and 975 feet in Lake Mead 28 percent and 50 percent of futures, respectively. The operations proposed under the Representative Preferred Alternative only result in better conditions for the preservation of paleontological resources when compared with the CCS Comparative Baseline, No Action Alternative, and the Basic Coordination Alternative in both reservoirs.

The Basic Coordination Alternative would result in greater stretches of time where the paleontological preservation risk threshold is exceeded, and greater stretches of time where lake

elevations drop below critical thresholds. This would result in increased accessibility to vulnerable paleontological sites, and more opportunities for human disturbance.

Management challenges include identifying and monitoring newly exposed areas in real time, implementing site protection measures (such as signage, education, and enforcement), and coordinating with agencies and research institutions to document and recover significant finds before they are lost. Adaptive management strategies—such as targeted public outreach, remote sensing, and rapid site assessment protocols—could mitigate potential damage while accommodating necessary operational changes to the dams.

Statistical Summary Tables

Table TA 12-4
Water Year Maximum Paleontological Preservation Risk at Lake Powell

Alternative	Flow Category (maf)	Max	90th percentile	75th percentile	Median	25th percentile	10th percentile	Min
CCS Comparative Baseline	16.0–31.11	3.17	**2.85**	**2.45**	**2.44**	**2.39**	**2.39**	**2.26**
CCS Comparative Baseline	14.0–16.0	3.32	3.04	2.93	**2.85**	**2.44**	**2.39**	**2.26**
CCS Comparative Baseline	12.0–14.0	3.71	3.25	3.17	2.93	**2.91**	**2.45**	**2.26**
CCS Comparative Baseline	10.0–12.0	3.71	3.32	3.32	3.17	3.04	**2.92**	**2.35**
CCS Comparative Baseline	4.46–10.0	3.71	3.71	3.49	3.32	3.17	3.04	**2.35**
No Action	16.0–31.11	3.17	**2.45**	**2.44**	**2.39**	**2.39**	**2.39**	**2.26**
No Action	14.0–16.0	3.41	3.04	2.93	**2.45**	**2.44**	**2.39**	**2.26**
No Action	12.0–14.0	3.71	3.32	3.25	2.93	**2.45**	**2.44**	**2.26**
No Action	10.0–12.0	3.71	3.49	3.41	3.32	3.17	**2.85**	**2.35**
No Action	4.46–10.0	3.71	3.71	3.71	3.41	3.32	3.04	**2.35**
Basic Coordination	16.0–31.11	3.04	**2.45**	**2.45**	**2.44**	**2.39**	**2.39**	**2.26**
Basic Coordination	14.0–16.0	3.32	2.93	2.93	**2.45**	**2.45**	**2.39**	**2.26**
Basic Coordination	12.0–14.0	3.71	3.17	3.04	2.93	**2.87**	**2.45**	**2.35**
Basic Coordination	10.0–12.0	3.71	3.41	3.32	3.17	3.04	**2.92**	**2.35**
Basic Coordination	4.46–10.0	3.71	3.71	3.56	3.32	3.17	3.06	**2.87**
Enhanced Coordination	16.0–31.11	2.93	**2.45**	**2.45**	**2.44**	**2.39**	**2.39**	**2.26**
Enhanced Coordination	14.0–16.0	3.17	**2.85**	**2.45**	**2.45**	**2.44**	**2.38**	**2.13**

TA 13. Tribal Resources

The Colorado River, its canyons, and its associated ecosystems figure prominently in the cultural traditions of many tribal communities. For these tribes, the river and canyons are living entities consisting of sacred spaces, the homes of their ancestors, the residence of the spirits of their dead, and the source of culturally important resources. Indigenous worldviews do not separate cultural and natural environments, as Western science often does; instead, they view all resources—whether considered cultural or natural in Western frameworks—as interconnected and interdependent. Many tribes see themselves as stewards of the Colorado River and its canyons, which are a vital part of the living and spiritual world; caring for the river and the canyons is their responsibility.

Tribal resources can include archaeological resources, structures, topographic features, habitats, plants, wildlife, and minerals that Indigenous peoples, tribes, or other groups consider essential for the preservation of traditional culture and traditional values. For many tribes, the trails used to access the river are also considered culturally important landscape features. Tribal interests also include values and resources reflected in other sections of this Final Environmental Impact Statement (Final EIS), including water for drinking water and agriculture, recreational resources, and many other socioeconomic and environmental aspects that overlap other sections. These resources are not just those that are essential for the preservation of traditional culture and values but for contemporary use and exercise of tribal sovereignty.

Traditional values of living communities can be manifested at locations called traditional cultural places (TCPs), Indian sacred sites, or cultural landscapes. The Colorado River and its canyons are considered by many tribes to be a TCP. As described by National Park Service guidance on TCPs (NPS 2024:7), a TCP is "a building, structure, object, site, or district that may be listed or eligible for listing in the National Register for its significance to a living community because of its association with cultural beliefs, customs, or practices that are rooted in the community's history and that are important in maintaining the community's cultural identity." Of the groups concerned, the Hualapai Tribe (Coulam 2011), Hopi Tribe (Hopi CPO 2001), Navajo Nation (Maldonado 2011), and Pueblo of Zuni (Dongoske 2011) have prepared National Register of Historic Places (NRHP) nomination forms for the Colorado River and its canyons as a TCP. The Bureau of Reclamation (Reclamation) is actively consulting with tribes regarding the Colorado River and its canyons, including associated Traditional Ecological Knowledge, that will be incorporated as it becomes available.

TA 13.1 Affected Environment

The study area for tribal resources is identical to that discussed in **TA 11**, Cultural Resources, and **TA 18**, Indian Trust Assets. It extends from the northern extent of Lake Powell to the Southerly International Boundary (SIB) and consists of the Colorado River channel from bank to bank except from Glen Canyon Dam to Lake Mead, where it stretches from canyon rim to canyon rim, as well as a 0.5-mile buffer on either side of the riverbank or canyon rim. The study area coincides with the

search area used for a Class I records search conducted for this Final EIS document (Tremblay et al. 2024a, 2024b; Eddy et al. 2024; Winslow et al. 2024; Eskenazi et al. 2024).

Fourteen Native American tribes consider portions of the study area to be part of their homelands. Of these, eight tribes—A:shiwi (Zuni), Ndee (Western Apache), Diné (Navajo), Havasupai, Hualapai, Hopi, Nüümü (Southern Paiute), and Yavapai—are associated directly with the Grand Canyon. Five tribes—Cocopah, Pipa Aha Macav (Mojave), Piipaash (Maricopa), Quechan, and Xalchidom (Halchidhoma)—have homelands along the lower Colorado River where it flows south to the Gulf of California, and one group, the Núuchi (Ute), used northeastern portions of the river and study area. Contemporary Native American communities face a host of common issues, such as widespread poverty, health disparities, and housing shortages. For the Native American tribes discussed here, water shortages and the potential impact on agricultural endeavors are a significant concern. The brief summaries provided below focus on Indigenous cultural connections to the Colorado River landscape and are derived primarily from the multivolume Class I cultural resources literature review conducted in support of this analysis (Tremblay et al. 2024a, 2024b; Eddy et al. 2024; Winslow et al. 2024; Eskenazi et al. 2024).

TA 13.1.1 A:shiwi (Zuni)

The Zuni (A:shiwi) origin story recounts that the People emerged from the fourth underworld via a hole at *Chimik'yana'kya dey'a*, (Ribbon Falls) on a tributary drainage of Bright Angel Creek which flows south from the North Rim of the Grand Canyon into the Colorado River. From the Grand Canyon, groups spread in four directions, leaving behind glyphic symbols on rocks and structural signs that the Zuni recognize today. Some continued to Chavez Pass, others into Mexico, the San Francisco Peaks, the present-day Bandelier National Monument in the Fremont archaeological area, and ultimately to *Halona:wa* "Anthill" where they created Zuni Pueblo, *A:shiwi,* at the central or Middle place. Zuni religion is focused on water, and the waters of the Colorado River are described as sacred. Even dry washes are important—Zuni deem them "passageways" for water, whether water flows there year-round or not. Long before Europeans first saw and named the Colorado River, the Zuni named this watercourse *K'yawan' A:honanne.*

The lands through which the Zuni migrated were never abandoned; their ancestors still inhabit the land. Each ancestral site is incorporated into a broad cultural landscape that encapsulates the Zuni pilgrimage experience and the lessons learned therefrom. The Zuni have provided the following account regarding the Zuni cultural landscape within the study area considered in this document:

> To *A:shiwi*, Chaco Canyon is known as *Heshoda Bitsulliya/Ki:whihtsi Bitsulliya* and in the name *K'yakwe: A:mossi*, or "House of Puebloan High Priests." The greater *A:shiwi* Chaco traditional cultural land/waterscape is simultaneously a dynamic and diverse and inter-functional and unified geographical area densely lined and dotted with multiple intensive zones of historical significance and ongoing traditional religious and cultural importance. The interconnected and interrelated layers and dimensions of multiple intensive middle zones of the district both circularly and circuitously pivot—in space and time—on *Heshoda Bitsulliya/Ki:whihtsi Bitsulliya*, Chaco Canyon, while always connecting and radiating to and from the spatial anchors of *Idiwana'a*, the Zuni Pueblo, and *Chimik´yana´kya dey´a* and *Kuhnin A´l´akk´wa*, the Grand Canyon. The connective umbilical tissues and relations of *Heshoda Bitsulliya/Ki:whihtsi*

> *Bitsulliya* are vast for *A:shiwi* and can be topographically diagrammed and understood to extend at least from *Kuhnin A´l´akk´wa*, Grand Canyon, in Arizona to the west to *Shiba:bulim´a*, Bandelier National Monument, in New Mexico to the east. The historic district's northern reach extends at a minimum to the areas of Abajo (Blue) Mountains and Montezuma Canyon in southeast Utah and Alkali Canyon in southwest Colorado, and its southern reach to the area of *K'yak'yali an Yalanne*, or Eagle Peak, in the central western region of New Mexico. Each of these intensive center or middle spatial zones that help diagram the outlines of the greater *A:shiwi* Chaco traditional cultural land/waterscape and historic district connect and convey three delineable "time periods" that are simultaneously layered and intersecting in their discernability (Curti et al. 2023: Executive Summary).

Thus, the Zuni have a deep and personal interest in the Colorado River and its tributaries since their emergence in this world. In addition to the emergence place, Chimik'yana'kya dey'a, (Ribbon Falls) on Bright Angel Creek, K'yawan' A:honanne (Colorado River), and Ku'nin A'l'akkwe'a (Grand Canyon) are considered to be Zuni TCPs. The Zuni also recognize Gold Strike Canyon-Sugarloaf Mountain near Boulder City, Nevada, as an important ceremonial location that has been listed on the NRHP as a TCP. The Colorado River is important to modern tribal communities as the Zuni continue to make pilgrimages to the Grand Canyon for religious purposes and to gather willow, herbs, sands, clays, and minerals including salt and pigments.

TA 13.1.2 Cocopah

The Cocopah are the southernmost Yuman Tribe along the lower Colorado River, living on both sides of the river from its delta to the Yuma area. They often aligned with Piipaash and Xalchidom, against the Quechan—their nearest neighbor to the north along the river. Cocopah creation stories tell of twin gods who began under the waters of the lower Colorado River and emerged to form the earth and its creations. The Ripley Intaglios near Blythe, California have been listed on the NRHP as a TCP.

TA 13.1.3 Diné (Navajo)

The Navajo Nation (Diné) views the Colorado River and the Grand Canyon as sacred, with the river considered a living being. Spanning from the Animas River to the Pacific Ocean, this landscape holds significant cultural and ceremonial importance, with the Colorado and Little Colorado Rivers playing key roles in Navajo practices. They perform prayers and rituals to honor these waters, which are integral to their spiritual practices and subsistence. Deities are believed to reside in the river canyons, and various ceremonies are associated with the Colorado River, highlighting the importance of preserving these resources and the Navajo's sovereignty.

Historical trails, such as the Salt Trail, Lees Ferry, and the Havasupai Trail, were used for hunting, gathering, and trading. The Salt Trail is particularly culturally significant due to Salt Woman's journey and offerings at a sacred rock. The Grand Canyon also provided refuge during conflicts, and the junction of the Colorado and Little Colorado Rivers is a sacred place in Diné culture.

The Diné people's activities and settlements in the Grand Canyon include cornfields, grazing areas, livestock corrals, former homesites, sweathouses, and ceremonial hunting landscapes. Numerous locations important to Navajo history and culture exist within the Grand Canyon. Significant sites

along the river corridor include Big Sand Dune, hogans at Lees Ferry, and beaches formerly used as cornfields.

Navajo traditions underscore the profound connection between the Navajo people and their land, illustrating how their cultural heritage is deeply intertwined with the natural landscape. The Navajo have nominated several locations along the Colorado and Little Colorado Rivers at TCPs to the NRHP. Additionally, ethnohistoric research conducted during the 1990s identified many locations and resources that would likely qualify.

TA 13.1.4 Havasupai

The Havasupai Tribe, also known as *Havasu 'Baaja* (People of the Blue Green Water), are from the region near Havasu Falls at the bottom of the Grand Canyon and are sometimes referred to as the guardians of the Grand Canyon. The Havasupai's historical territory extended from the southern bank of the Colorado River to the San Francisco Peaks, east to the Little Colorado River, and west to the Hualapai reservation. The San Francisco Peaks are central to Havasupai cosmology. In 1975, their reservation was expanded to include the Havasupai Traditional Use Lands, an area within Grand Canyon National Park acknowledged to be important to the Havasupai people. The Havasupai were regarded by the Hopis as guardians of the Grand Canyon and its sacred sites.

Water holds immense cultural and religious significance, with sacred springs and the Colorado River being integral to the tribe's worldview. All springs are considered sacred, and offerings are made before using the water. Spirits are believed to inhabit various geographic locations in and around the Colorado River corridor, including Gray Mountain, the Great Thumb peninsula, the San Francisco Peaks, and Mount Sinyella. These sites play a significant role in their spiritual practices, particularly rain-making rituals. No TCPs associated with Havasupai cultural places have been formally documented.

TA 13.1.5 Hopi

The Hopi Tribe consists of clans from the Four Corners region, the Southwest, Mexico, and possibly South America. They speak the Uto-Aztecan language of Hopi. The ancestral Hopi, known as the *Hisatsinom*, migrated extensively across the southwestern United States before settling at the Hopi Mesas. During their travels, many resided in the canyons. The Hopi people believe they emerged into the present world from the *Sipapuni*, a spring located in the Little Colorado River gorge near its confluence with the Colorado River. The Hopi Tribe's presence in the Grand Canyon region spans over 1,000 years, with archaeological evidence dating their use of the canyons to at least AD 700–800. By AD 1000, numerous small pueblo sites were established. These sites, which include kivas and shrines, are of profound religious and cultural importance. The Hopi consider these sites to be active and sacred, with a spiritual responsibility to protect them.

Currently, the Hopi live in pueblos on and below the Hopi Mesas, growing crops like corn, beans, squash, and peaches. Water is central to their ceremonies, symbolizing the most precious resource, the source of all life, and their connection to ancestors. TCPs identified by the Hopi include *Öngtupqa* (Grand Canyon), *Palavayu* (Little Colorado River), and *Pisisvayu* (Colorado River). Additional locales include the Hopi origin location *Sipapuni*; Hopi Salt Mine *Öönga*; Lees Ferry; archaeological sites and shrines along the Colorado River within the Grand Canyon, with the canyon

rim as the boundary beginning at the Colorado River confluence with Kanab Creek on the west, downstream of Glen Canyon Dam on the east, and up Little Colorado River Gorge to the Cameron area.

TA 13.1.6 Hualapai

The Hualapai, also known as *Hwal 'baia*, are an upland Yuman people related to the Havasupai Tribe. Their reservation is adjacent to the south bank of the Colorado River and the Grand Canyon. The tribe consists of 12 bands, each named after significant topographical features within their land. The Grand Canyon and Colorado River, from the Little Colorado River to the Bill Williams River confluence, are significant to the Hualapai. Additionally, the Hualapai have a rich origin story that begins at Spirit Mountain and includes the Grand Canyon.

Historically, the Hualapai were hunter-gatherers and agriculturalists, moving seasonally and cultivating crops like corn, beans, and squash. They were skilled hunters and traded with neighbors; they have historically engaged in trade, social interactions, and conflicts with neighboring tribes and European Americans. The Hualapai regard all archaeological and cultural resources within their traditional territory as sacred TCPs. These include plants, wildlife, rock writings, artifacts, and traditional use areas. The Hualapai have nominated several locations along the Colorado River for listing on the NRHP as TCPs.

TA 13.1.7 Ndee (Western Apache)

At the time of contact with Spanish and Euro-American people, the Ndee occupied much of central and northern Arizona and were loosely organized in three to five subtribes based on family lineages and slight differences in language. Oral histories tell of a place located north of the Little Colorado River where the Ndee lived near the Navajo and Hopi. This place is called place "camp beneath the water," "camp beside the water," or "dance camp." Many Ndee bands state that it is a place of emergence from beneath the earth's surface into this world. From this place, bands crossed the Little Colorado River and split into different areas of central Arizona, below the Mogollon Rim. Ndee bands roamed broadly across this region, including the Grand Canyon. The area surrounding the Grand Canyon provided pinyon nuts, sumac berries, and medicinal herbs, as well as hunting grounds for antelope and deer.

The Ndee refer to the Grand Canyon as *Che Da* or *Ge Da Cho*, which roughly translate to the "Rock Cliff" or the "Big Edge." The Colorado River is *Tule'chee*—"Red River"—describing the color of the water in its natural state. Ndee stories recount the creation of the Grand Canyon by a deity named *Naa Ye' Nas Ghane'*. Because of this association with a deity, the canyon is considered a sacred place. Although Western Apache use of the Grand Canyon and Colorado River are well documented by tribal oral tradition, they have not formally identified any TCPs to date.

TA 13.1.8 Núuchi (Ute)

Ute are the easternmost of the Numic-speaking peoples thought to have migrated from southeastern California/southern Nevada in a northeastern arc across the Great Basin. The Núuchi occupied what is now eastern Utah and western/central Colorado. Núuchi gathered roots (wild onion, Indian potato), seeds that were eaten raw or ground into meal, chokecherry and berries, the interior bark of ponderosa pine, prickly pear, and other plants for medicines and tools. They hunted game such as

rabbits, elk, and deer, and traded with Puebloans and later, the Spanish for horses, cattle, and sheep. Ute use of the Colorado River is not well documented, nor have they identified any TCPs to date.

TA 13.1.9 Nüümü (Southern Paiute)

The Southern Paiute inhabited the Colorado River Basin in northwestern Arizona, southern Nevada, and the north and west bank of the Colorado River. Their traditional territory extended north and west of the Colorado River. The nation was divided into the western *Paranayi* and the eastern *Yanawant*, each with different bands. Individuals with knowledge of water sources were highly regarded, and there was a belief in supernatural beings called Water Babies associated with springs and underground water. They practiced small-scale agriculture, gathered wild resources, and believed in supernatural forces, particularly near Charleston Peak in the Spring Mountains.

They have a strong cultural and spiritual connection to the land and its resources, especially the Colorado River (*Piapaxa*). The Southern Paiute Tribes have a profound cultural connection to the Colorado River, viewing it as a powerful natural resource that must be respected and preserved. Paiute elders documented important cultural practices and locations within the Grand Canyon and Colorado River, including the sacredness of agave roasting sites, the use of red pigment for protection and rituals, and the inherent power of rocks and burials. Artifacts are believed to belong to their original owners and should remain undisturbed.

The San Juan Paiutes used specific crossing locations on the Colorado River, and the Kaibab Paiute had trails leading to their winter camps. The Southern Paiute Chemehuevi Salt Song Trail traveled from southern Nevada through the Mojave valley to the lower Colorado River valley. The Southern Paiute have declared the entire Colorado River region a TCP due to its cultural significance. Additionally, the Southern Paiute have identified Gold Strike Canyon-Sugarloaf Mountain, which is a ceremonial location near Boulder City, Nevada, as a TCP.

TA 13.1.10 Piipaash (Maricopa) and Xalchidom (Halchidhoma)

The Piipaash and Xalchidom are Yuman-language speakers who migrated from the lower Colorado River area and ultimately joined the Akimel O'odham on the Salt and Gila ivers near Phoenix. The Piipaash were located along the Lower Gila River when they encountered the Spanish in the late 1600s but likely had previously resided on the lower Colorado River. The Xalchidom occupied both sides of the lower Colorado River south of the Aha Macav and north of the Quechan; they may have been farther south on the river in earlier times, but they were pressured by their neighbors and frequently relocated their villages. Once they were driven from the Colorado River, their former territory was occupied by the Chemehuevi. Due to pressure from the Aha Macav and Quechan, both groups emigrated eastward up the Gila River, and by 1830, joined the Akimel O'odham. They were supported by the O'odham in a final victorious battle against the Quechan/Aha Macav at Pima Butte in 1857. Specific TCPs along the lower Colorado River have not been reported for either tribe. Piipaash and Xalchidom origin stories are similar to that of the Ahi Macav and they, too, consider Avi Kwa Ame to be their sacred origin place.

TA 13.1.11 Pipa Aha Macav (Mojave)

The Pipa Aha Macav (people by the river) are the northernmost Yuman Tribe. Their tribal territory is found along both sides of the Colorado River in the Mojave Valley, and at times, in portions of

the Mojave Desert to the northwest. Traditionally the Pipa Aha Macav lived in earth-covered houses in large seasonal settlements on the terraces above the Colorado River floodplain during the winter and spring. Once waters had receded, extended families established camps with small brush shelters near their crops on the floodplain where they dry-farmed corn, pumpkin, tepary beans, gourds, cotton, and sunflowers. They were renowned traders, carrying goods between the Pacific Ocean and the Pueblos via the Mojave Trail westward from the river through the western Mojave Desert, and eastward via the Moqui Trail through the Grand Canyon to the Hopi, trading with tribes along the way. Tribal origins center on Avi Kwa Ame (Spirit Mountain), which was designated a National Monument in March 2023, and oral tradition tells of *Mutavilya* who is said to have created the Colorado River, its plants and animals, and instructed the Pipa Aha Macav in the arts of civilization.

The Colorado River and Avi Kwa Ame are sacred places to all Yuman Tribes, including the Pipa Aha Macav. Indeed, the Colorado River Indian Tribes have enacted a Tribal Resolution under Tribal law that states, in part, "the Colorado River is a living being carrying and sustaining life as it flows through the reservation and our ancestral lands." This statement reflects the basic core values of the Colorado River Indian Tribes, including the cultural, spiritual, and religious connection between the Colorado River and the welfare of the Colorado River Indian Tribes and its members. Other locations considered sacred include springs, caves, sleeping circles, trails along the river that were traveled via dreams or by walking them, offerings placed among rock cairns along trails, large geoglyphs created on the surface of the desert by removing stones from areas of desert pavement or by placing stones atop areas lacking desert pavement (e.g., the Ripley Intaglios), and pictographs and petroglyphs. Many of these features have yet to be publicly identified by tribal members or formally recorded.

TA 13.1.12 Quechan

The Quechan originally lived near the river delta at the Gulf of California, later moving to the Gila and Colorado Rivers junction and expanding into the Palo Verde Valley. Their creation story, similar to the Pipa Aha Macav, involves the god *Kukumat* creating the Quechan and other tribes on the sacred mountain *Avikwame'*. After *Kukumat's* death, his body and house were burned. *Kumastamxo*, the divine son of the creator, is a central figure, credited with creating the keruk ceremony to commemorate *Kukumat's* death. The Colorado River region is vital to their cultural and ethnic identity, with various landmarks and natural features holding spiritual significance.

In addition to Avi Kwa Ame, other TCPs associated with the river include the trail taken by the Quechan from Avi Kwa Ame south toward the delta; it is called the *xam kwatcám* ("another going down") and is the inspiration for the tribal name. It is the major north–south trail along the west bank of the lower Colorado River and leads to Pilot Knob, another sacred landform, near the Gulf of California. The trail has also been identified as the Keruk Trail, which is the path taken by the dead as part of the cremation ceremony. As with the Pipa Aha Macav, many legendary figures are commemorated within Quechan territory as large geoglyphs on terraces along the banks of the lower Colorado River; smaller geoglyphs are located farther inland on either side of the river.

TA 13.1.13 Yavapai

The Yavapai people traditionally inhabited the area north of the Gila River, between the Colorado and Verde Rivers. They belong to the Pai branch of the Yuman language family and are divided into

four subgroups: western Apache or Tolkapaya, northwestern Wipukpaya, northeastern Yavapai or Apache-Mojaves, and southeastern Yavapai or Kewevkapaya. The Yavapai intermarried with the Tonto Apaches and have various origin theories, including connections to Hakatayan patterns, Sinagua peoples, or a Yuman migration. They first encountered the Spanish in the Verde River Valley in the early 1580s.

Before their removal to reservations in the late 19th century, they lived west of the Verde River. Their origin story includes sacred sites such as San Francisco Peak and Montezuma's Well. Yavapai families traveled in bands, hunting and gathering seasonally available foods. They hunted deer, jackrabbits, rabbits, quail, and woodrats, and planted crops like corn, squash, and beans, which they harvested in the fall. The western Yavapai traded animal skins, baskets, and agave for agricultural products from the Pipa Aha Macav and Quechan. There are no specific Yavapai TCPs recorded within the Grand Canyon or Colorado River, but their use of the canyon is similar to that of the Western Apache.

TA 13.1.14 Ethnographic Resources and Traditional Cultural Places

Several known or documented TCPs within or adjacent to the study area have been listed or are eligible for listing in the NRHP (**Table TA 13-1**). One each is recorded for the A:shiwi and Hopi within Grand Canyon; Sugarloaf Mountain to the west of the lower Colorado River is identified as a TCP by the A:shiwi, Diné, Hopi, Hualapai, Nuwuvi, Pipa Aha Macav, and Yavapai; and the Ripley Intaglios are considered sacred by all Yuman Tribes. The Yuman Tribes consider their origin place, Avi Kwa Ame (Spirit Mountain), to be sacred; it is beyond the project study area but within the newly created Avi Kwa Ame National Monument.

Through ongoing consultation with tribes, the locations of several additional places that are considered sacred have been disclosed to Reclamation cultural resources staff. At the request of these tribes, descriptions and locations of those sacred places are confidential. Tribes discussed in this section revere the Colorado River. The Grand Canyon itself is an NRHP-eligible TCP for multiple tribes. Plants and animals, among other entities, are considered contributing elements to the TCP. Some, like aquatic beings, are considered significant elements unto themselves, often representing the ancestors of the living people. Several important locations within the Grand Canyon TCP have been formally recorded in the canyon for the A:shiwi and Hopi and documented in ethnographic studies for the Diné and Hualapai.

Tribes consider places associated with origin stories, migrations, songs, and ceremonies to be sacred TCPs, as well as ancestral sites, trails, cairns, and rock writing/petroglyphs/pictographs/geoglyphs. All water sources, especially those that come from below ground, are sacred. Plants, animals, and minerals are considered traditional cultural resources, often associated with specific locations. Reclamation is in ongoing consultation with tribes to identify specific locations/resources important to each tribe.

Table TA 13-1
NRHP-Listed or Eligible TCPs

Tribe	TCP Description
A:shiwi (Zuni)	*Chimik'yana'kya dev'a* (Place of Emergence), Ribbon Falls on Bright Angel Creek, *K'yawan' A:honanne* (Colorado River), and *Ku'nin A'l'akkwe'a* (Grand Canyon) Listed 2004: Gold Strike Canyon-Sugarloaf Mountain, a ceremonial location near Boulder City, Nevada
Hopi	*Öngtupqa* (Grand Canyon), *Palavayu* (Little Colorado River), and *Pisisvayu* (Colorado River). Additional locales include the origin location *Sipapuni* (NA 10536 MNA*); Hopi Salt Mine *Öönga* (NA 10537/AZ C:13:3[GCNP]);** Lees Ferry; archaeological sites and shrines, with the canyon rim as the boundary beginning at the Colorado River confluence with Kanab Creek on the west, downstream of Glen Canyon Dam on the east, and up Little Colorado River Gorge to the Cameron area Listed 2004: Gold Strike Canyon-Sugarloaf Mountain, a ceremonial location near Boulder City, Nevada
Diné (Navajo)	None formally recorded within Grand Canyon; ethnohistoric research in the 1990s identified many locations and resources that would likely qualify Listed 2004: Gold Strike Canyon-Sugarloaf Mountain, a ceremonial location near Boulder City, Nevada
Ndee (Western Apache)	None formally recorded
Núuchi (Ute)	None formally recorded
Nüümü (Southern Paiute)	Listed 2004: Gold Strike Canyon-Sugarloaf Mountain, a ceremonial location near Boulder City, Nevada
Havasupai (Yuman – Pai Branch)	None formally recorded
Hualapai (Yuman – Pai Branch)	None formally recorded in Grand Canyon; archaeological and botanical surveys in 1990s identified traditional use areas, sacred places, and traditional resources of concern that would likely qualify Listed 2004: Gold Strike Canyon-Sugarloaf Mountain (near Boulder City, Nevada) as a ceremonial destination
Yavapai (Yuman – Pai Branch)	Listed 2004: Gold Strike Canyon-Sugarloaf Mountain, a ceremonial location near Boulder City, Nevada
Cocopah, Piipaash, Pipa Aha Macav, Quechan, Xalchidom (Yuman – River Branch)	Listed 1975: Ripley Intaglios Listed 2004: Gold Strike Canyon-Sugarloaf Mountain, a ceremonial location (claimed by Pipa Aha Macav)
Fort Mojave Indian Tribe of Arizona, California, and Nevada	Determined eligible 2018: Amut Ahar TCP

* MNA = Museum of Northern Arizona, incorporated into the state-assigned site number
** GCNP = Grand Canyon National Park, incorporated into the state-assigned site number issued by the Arizona State Museum for the Hopi Salt Mine located on National Park Service-managed lands within the national park

TA 13.2 Environmental Consequences

TA 13.2.1 Methodology

Of primary concern is how the alternatives affect the integrity and sacredness of tribal resources. Because these resources attain significance through tribal cultural customs, and because many of these resources are sacred and their locations confidential, the tribes are best situated to understand how the alternatives might affect them. Accordingly, the impact analysis is primarily qualitative and informed by ongoing tribal consultation.

There are many federally recognized tribes with entitlements to Colorado River water or who may be affected or have interests in the proposed federal action. There are 30 federally recognized tribes within the geographic Basin. Reclamation consults regularly with these tribes regarding Colorado River issues. Additionally, the Ten Tribes Partnership is a coalition of 10 federally recognized tribes with rights and unresolved claims to Colorado River water. The partnership was created in 1992 and has an ongoing consultation relationship with Reclamation. Of the 22 federally recognized tribes in Arizona, 4 have quantified water rights, or partially quantified rights to water from the mainstream Colorado River through the Consolidated Decree. Another 10 tribes in Arizona have entered water rights settlements that include Central Arizona Project (CAP) water, one source of which is Priority 4 Arizona Colorado River water. Several more tribes hold CAP contracts.

Reclamation has a long-standing and ongoing consultation relationship with CAP Tribes. Reclamation consults not only with tribes who hold water rights or are located within the Basin's geographic boundary but also with a total of 43 tribes who may be affected or have interests in actions on the Colorado River (**Table TA 13-2**). Consultation and coordination with these tribes are ongoing.

Table TA 13-2
Tribes Invited to Consult on Colorado River Issues

• Ak-Chin Indian Community of the Maricopa Indian Reservation	• Pueblo of Pojoaque
• Chemehuevi Indian Tribe of the Chemehuevi Reservation	• Pueblo of San Felipe
• Cocopah Tribe of Arizona	• Pueblo of San Juan
• Colorado River Indian Tribes of the Colorado River Indian Reservation	• Pueblo of Sandia
• Fort McDowell Yavapai Nation	• Pueblo of Santa Ana
• Fort Mojave Indian Tribe of Arizona, California, and Nevada	• Pueblo of Santa Clara
• Gila River Indian Community	• Pueblo of Tesuque
• Havasupai Indian Tribe of the Havasupai Reservation	• Pueblo of Zia
• Hopi Tribe of Arizona	• Quechan Tribe of the Fort Yuma Indian Reservation

• Hualapai Indian Tribe of the Hualapai Indian Reservation	• Salt River Pima-Maricopa Indian Community of the Salt River Reservation
• Jicarilla Apache Nation	• San Carlos Apache Tribe of the San Carlos Reservation
• Kaibab Band of Paiute Indians of the Kaibab Indian Reservation	• San Juan Southern Paiute Tribe of Arizona
• Las Vegas Tribe of Paiute Indians of the Las Vegas Indian Colony	• Southern Ute Indian Tribe of the Southern Ute Reservation
• Moapa Band of Paiute Indians of the Moapa River Indian Reservation	• Tohono O'odham Nation of Arizona
• Navajo Nation	• Tonto Apache Tribe of Arizona
• Paiute Indian Tribe of Utah	• Ute Indian Tribe of the Uintah and Ouray Reservation
• Pascua Yaqui Tribe of Arizona	• Ute Mountain Tribe of the Ute Mountain Reservation
• Pueblo of Acoma	• White Mountain Apache Tribe of the Fort Apache Reservation
• Pueblo of Cochiti	• Yavapai-Apache Nation of the Camp Verde Indian Reservation
• Pueblo of Jemez	• Yavapai-Prescott Tribe of the Yavapai Reservation
• Pueblo of Laguna	• Zuni Tribe of the Zuni Reservation
• Pueblo of Nambe	

Impact Analysis Area

The study area for tribal resources is identical to that discussed in **TA 11**, Cultural Resources. It includes the Colorado River corridor from the upper limits of Lake Powell in Utah, through the Grand Canyon in Arizona and Lake Mead in Arizona, and from Hoover Dam to the SIB.

Assumptions

Assumptions for the following analysis are:

- Information regarding specific tribal resources and potential impacts on those resources will be provided by the tribes during consultation.

Impact Indicators

Impact indicators for this analysis are:

- Qualitative assessment of potential impacts on TCPs informed by tribal consultation.
- Qualitative assessment of potential impacts on culturally important resources informed by tribal consultation and by reference to relevant quantitative analysis sections of this Final EIS (e.g., **TA 9**, Vegetation Including Special Status Species, **TA 8**, Biological Resources – Fish and Other Aquatic Resources, etc.)

TA 13.2.2 Issue 1: How will any changes in dam operations affect TCPs?

TCPs are historic properties that are eligible for listing on the NRHP principally for their association with culturally significant events as told through Indigenous oral history or with individuals named by those traditions. Impacts on TCPs would consist primarily of changes to the natural environmental context resulting from continued active management of reservoir levels and water releases to downstream river segments. Impacts could also occur as reservoir elevations change and expose TCPs to increased visitation. Because TCPs are a specific category of historic property, adverse impacts on TCPs would be addressed through the project's programmatic agreement developed in compliance with Section 106 of the National Historic Preservation Act or through ongoing consultation with affected tribes.

Exposure of TCPs as lake levels fluctuate as a result of management actions described by the alternatives would facilitate access to these culturally important locations by tribal members but would also increase access for non-Native visitation. End of year lake elevations for each alternative are explored in detail in **TA 3**, Hydrologic Resources, and are summarized here in discussion of impacts on TCPs.

Across all alternatives and the Continued Current Strategies (CCS) Comparative Baseline, Lake Powell's median water year elevations are generally similar under wet hydrologic conditions, except for the Supply Driven Alternative (both Lower Basin [LB] Priority and LB Pro Rata approaches), which show lower median elevations. As conditions become drier, Lake Powell's elevations decrease and differences among alternatives become more pronounced, with operations varying widely at lower water levels.

In the two driest flow categories, the Enhanced Coordination Alternative maintains the highest median reservoir elevations, followed by the Maximum Operational Flexibility Alternative. Both of these alternatives keep median reservoir elevations well above the critical threshold of 3,500 feet, even during dry periods exposing the fewest number of TCPs to increased visitation. In contrast, the No Action Alternative and the Basic Coordination Alternative have median elevations that fall below this critical threshold in dry conditions, and these alternatives would facilitate greatest access to TCPs. Under the Representative Preferred Alternative, Lake Powell elevations remain relatively stable compared to other alternatives. In both the Dry Flow and Critically Dry Flow Categories the Representative Preferred Alternative maintains median elevation above 3,500 feet. The Critically Dry Flow Category shows greater variability in median elevations.

For Lake Mead, median calendar year elevations also decline as conditions become drier, but the relative performance of each alternative remains consistent. The Supply Driven Alternative (LB Pro Rata approach) consistently has the highest median reservoir elevations across all flow categories, followed by the LB Priority approach exposing the fewest number of TCPs to increased visitation. The No Action Alternative consistently has the lowest median elevations, with the CCS Comparative Baseline having the second lowest and these alternatives would facilitate greatest access to TCPs. Most action alternatives show wide variability in Lake Mead's elevations, except for the Maximum Operational Flexibility Alternative, which reliably remains above 975 feet. Under the Representative Preferred Alternative, Lake Mead elevations show moderate variability in dry

conditions and somewhat lower variability in critically dry conditions staying above 975 feet in most years.

TA 13.2.3 Issue 2: How will any changes in dam operations affect lake elevations and river flows downstream which may impact archaeological sites sacred sites?

Sacred sites are specific locations that have been identified by a tribe as sacred because of its traditional religious significance or as a discrete location for ceremonial use. Sacred sites often overlap significantly with TCPs and with Indigenous archaeological sites. Accordingly, impacts on sacred sites are qualitatively similar to impacts on archaeological sites. Here, of primary concern are direct impacts like wave action and wet-dry cycling that could occur from changes in lake levels or from changes to river flows caused by annual releases. Impacts on archaeological sites are analyzed in detail in **TA 11**, Cultural Resources, and that discussion is summarized here.

At Lake Powell and Lake Mead, continuous inundation of sacred sites or Indigenous archaeological sites helps preserve them better than cycles of flooding and exposure, which increase risks from wave action. The main concern is that dropping lake elevations could expose such sites that were previously underwater, making them vulnerable to wet-dry cycles and wave impacts. As water levels fall, more sites become exposed to these risks at lower elevations. Sites at higher elevations may be less affected by wet-dry cycling and wave action but could become more accessible depending on their location.

Hydrological models show that during wet conditions, Lake Powell's water levels are projected to remain above 3,660 feet in all scenarios. As conditions get drier, the Enhanced Coordination and Maximum Operational Flexibility Alternatives maintain the highest median water levels during the Average Flow Category, staying at or above 3,620 feet. These alternatives also perform best in the Critically Dry Flow Category, but projected medians are still below 3,580 feet, meaning sacred sites or archaeological sites—and any unknown sites—at these elevations would be exposed.

For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) maintains the highest water levels during both the Average and Critically Dry Flow Categories, followed by the Enhanced Coordination and Maximum Operational Flexibility Alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has projected median elevations up to 1,150 feet in the Average Flow Category, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives have medians around 1,100 feet. In the Critically Dry Flow Category, all scenarios would expose sacred sites or archaeological sites and any unknown sites, but the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches)could protect more sites, with upper interquartile ranges reaching about 1,120 feet. Under the Representative Preferred Alternative, Lake Powell and Lake Mead elevations are comparable to other alternatives though Lake Mead elevations show greater variability across alternatives for the driest flow categories.

This pattern is reflected in the Preservation Risk Model analysis (**TA 11.2.2**). For Glen Canyon, the Enhanced Coordination Alternative is most robust, and will impact the fewest sites, with 30 percent of modeled futures in the initial modeling period staying below the preservation threshold, followed

by the Maximum Operational Flexibility Alternative at 25 percent. Under the Representative Preferred Alternative the preservation threshold is met in 16 percent of modeled futures. For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust during the initial modeling period, with 5 percent of modeled futures meeting or staying below the threshold. The Maximum Flexibility Alternative and Representative Preferred Alternative both stay below the preservation threshold in 3 percent of modeled futures.

For the Colorado River stretches between Glen Canyon Dam and Lake Mead, and between Hoover Dam and Lake Mohave, water release volumes in Wet and Average Flow Categories generally remain within the range of past annual releases. However, in the Critically Dry Flow Category, median annual release volumes drop below 7.0 million acre-feet (maf) below Glen Canyon Dam, with the Enhanced Coordination Alternative reaching as low as 5.1 maf. Below Hoover Dam, median annual flows fall below 8.0 maf, with the Enhanced Coordination and Maximum Operational Flexibility Alternatives dropping to 6.5 maf. As a result, in critically dry conditions, lower water levels increase the likelihood of sacred sites or archaeological sites near the riverbanks being exposed. The Representative Preferred Alternative has one of the narrowest interquartile range under critically dry hydrological conditions, with an upper limit around 6.0 maf, which is still below the bottom of the range of past flow volumes at 7.0 maf.

Below Davis Dam, impacts are expected to be minimal or nonexistent in any flow category. This is because the dams below Lake Mohave are managed to maintain lake elevations or meet targeted water deliveries, and many sections have channelized banks that further reduce exposure risks.

TA 13.2.4 Issue 3: How will changes in dam operations impact natural resources important to Native Americans including riparian vegetation and wildlife?

Indigenous worldviews do not differentiate between cultural and natural environments as does Western science. Under many Indigenous perspectives, resources considered separately as cultural or natural are all interconnected and interdependent (Berkes 2018). Human interventions that disrupt these interconnections are considered adverse impacts. This Final EIS discusses many of these resources such as water quality, air quality, and terrestrial wildlife among others. Although all resources are considered interconnected, Indigenous oral histories and ongoing consultation with Native American groups have identified riparian vegetation communities and aquatic wildlife as resource categories of particular concern along the Colorado River corridor. Accordingly, we consider riparian vegetation and aquatic wildlife (native and nonnative fish) below. Adverse impacts on these resources important to Native Americans would be addressed through ongoing consultation with affected tribes.

Quantitative impacts on riparian vegetation communities and evaluations of which alternatives best support historical vegetation community conditions are presented in detail in **TA 9**, Vegetation Including Special Status Species. Historical vegetation communities are those that prevailed in the decades prior to reservoir inundation and from Indigenous worldviews are the preferred condition. Those quantitative analyses from **TA 9** are summarized here. Woody riparian vegetation is moderately tolerant of water fluctuations, but if variability increases over a 5-year period, these areas

tend to decrease. Conversely, if water level variability decreases annually or over 5 years, woody riparian vegetation may expand.

For Lake Powell, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would maintain woody riparian vegetation most similar to historic conditions. For Lake Mead, the Maximum Operational Flexibility Alternative would best match historic vegetation patterns. However, in the stretch from Hoover Dam to the SIB reach, these two alternatives would cause vegetation to differ most from historic conditions, leading to greater changes in that area. The Basic Coordination Alternative would be least similar to historic conditions for Lake Powell but would be closest to historic vegetation patterns for Lake Mead and the Hoover Dam to SIB reach. The Representative Preferred Alternative would be least similar to historic conditions for Lake Powell and Lake Mead. This means no single alternative matches historic vegetation across all areas.

Most alternatives provide variability closer to historic conditions than the CCS Comparative Baseline in most reaches, except for Hoover Dam to SIB, where only the Basic Coordination Alternative does so. This suggests that changing current management strategies would benefit much of the analysis area.

For the stretch between Glen Canyon Dam and Lake Mead, which alternative best maintains historic vegetation depends on whether starting conditions are wet or dry. Under dry and critically dry conditions, differences between alternatives become more noticeable, especially in the lowest, median, and peak flows. However, across all alternatives, sub-reaches, and evaluation criteria (habitat area, native species richness, proportion of native species cover, and total annual vegetation cover), the interquartile ranges often overlap, making it hard to identify a clear best or worst alternative for preserving historic vegetation.

In all alternatives for Lake Powell, Lake Mead, and Hoover Dam to SIB, the first decade is expected to have greater variability and reduced woody riparian habitats compared to historic conditions. Conditions improve in the second and third decades, allowing vegetation to recover and reestablish. If variability prevents woody riparian habitats from forming, the area may shift to another habitat type.

Quantitative impacts on aquatic wildlife are considered in detail in **TA 8**, Biological Resources – Fish and Other Aquatic Resources, and those quantitative analyses are summarized here. Decreased water levels at Lake Powell affect lake and river habitats for culturally important native and nonnative fish. Among the alternatives, the No Action Alternative stands out because it increases the amount of exposed river habitat for endangered Colorado pikeminnow and razorback sucker, which is beneficial for these species. However, this also means less lake habitat for sportfish, which could negatively affect recreational fishing.

All alternatives except the Enhanced Coordination and Maximum Operational Flexibility Alternatives keep Lake Powell below critical elevation thresholds (3,598 feet for the Colorado River and 3,600 feet for the San Juan River), thereby increasing river habitat. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are less effective in this regard, as they tend to flood critical habitats and reduce the value of riverine habitat.

None of the alternatives are particularly successful at maintaining Piute Farms Waterfall as a barrier to prevent nonnative fish from moving upstream. On the other hand, all alternatives support native fish passage over the waterfall when it is inundated. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and the CCS Comparative Baseline are the most effective at maintaining the waterfall as a barrier, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives are more likely to allow inundation and fish passage.

For Lake Powell, the Representative Preferred Alternative provides moderate protection of riverine critical habitat but does not perform as well as the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches). Overall, it represents a moderate balance but is less robust than the best-performing alternatives for specific indicators.

For Lake Mead, the alternatives would affect tributary inflow habitats of culturally important fish populations. The No Action Alternative and CCS Comparative Baseline are the most effective at keeping Lake Mead below 1,090 feet for at least 90 percent of months. This helps restrict nonnative fish and maintain the current species composition in the Grand Canyon. However, these lower elevations also hinder native species—such as razorback sucker, flannelmouth sucker, and humpback chub—from moving upstream into Grand Canyon habitats.

The Basic Coordination Alternative performs moderately well in balancing these outcomes. In contrast, the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven Alternatives (both LB Priority and LB Pro Rata approaches) are less effective, as they more often allow Lake Mead to rise above critical thresholds. This can make it easier for both native and nonnative fish to move upstream.

Among the alternatives, the Supply Driven Alternative (LB Pro Rata approach) is the most reliable for keeping Lake Mead above its historical minimum elevation, which supports greater habitat stability.

TA 13.2.5 Summary Comparison of Alternatives

TCPs are historic properties significant to Indigenous communities, mainly due to their association with culturally important events or individuals, as described in oral traditions. The main impacts on TCPs come from changes in the natural environment caused by managing reservoir levels and water releases, as well as increased exposure and visitation when water levels drop. Adverse impacts on TCPs are addressed through a programmatic agreement and ongoing consultation with tribes, in compliance with the National Historic Preservation Act.

As lake levels fluctuate, TCPs may become more accessible to both tribal members and non-Native visitors. Under wet conditions, most alternatives keep Lake Powell's water levels high and exposure of TCPs low, except for the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), which has lower elevations. In dry conditions, the Enhanced Coordination and Maximum Operational Flexibility Alternatives maintain the highest water levels, limiting TCP exposure, while the No Action and Basic Coordination Alternatives result in lower elevations and greater access to TCPs. For Lake Mead, water levels also drop as conditions get drier. The Supply Driven Alternative (LB Pro Rata approach) keeps the highest water levels and limits TCP exposure,

while the No Action Alternative and CCS Comparative Baseline have the lowest levels, increasing access to TCPs. Under the Representative Preferred Alternative, Lake Powell and Lake Mead elevations remain relatively stable compared to other alternatives with increasing variability in the driest flow categories.

Sacred sites are locations identified by tribes for the sites' religious or ceremonial significance, and they often overlap TCPs and Indigenous archaeological sites. Impacts on sacred sites are similar to those affecting archaeological sites, with the main concerns being damage from wave action and wet-dry cycling caused by fluctuating lake and river levels. Continuous inundation helps preserve these sites, while exposure due to falling water levels increases risks.

During wet conditions, Lake Powell's water levels are expected to remain high, minimizing exposure. As conditions become drier, the Enhanced Coordination and Maximum Operational Flexibility Alternatives maintain higher water levels than others but still fall below critical thresholds in extremely dry scenarios, exposing more sites. For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) maintains the highest water levels and protects more sacred sites, especially in dry conditions. For river stretches between Glen Canyon Dam and Lake Mead, and between Hoover Dam and Lake Mohave, annual water releases in wet and average years generally match historical volumes. In critically dry years, releases drop significantly, increasing the risk of exposing sacred and archaeological sites near riverbanks. Below Davis Dam, impacts are minimal due to managed lake elevations and channelized banks.

Indigenous perspectives view cultural and natural resources as interconnected, so any disruption to these links is a potential impact. Along the Colorado River, riparian vegetation and aquatic wildlife are especially important to Native Americans. Woody riparian vegetation is moderately resilient to water fluctuations, but increased variability over several years can reduce these habitats. For Lake Powell, the Enhanced Coordination and Maximum Operational Flexibility Alternatives best maintain vegetation similar to historic conditions. For Lake Mead, the Maximum Operational Flexibility Alternative performs best, while the Basic Coordination Alternative is closest to historic conditions for Lake Mead and the Hoover Dam to SIB reach. No single alternative matches historic vegetation patterns across all areas, but most alternatives perform better than the CCS Comparative Baseline in most reaches. The Representative Preferred Alternative would be least similar to historic conditions for Lake Powell and Lake Mead.

Lower water levels at Lake Powell benefit endangered river species (Colorado pikeminnow and razorback sucker) by increasing their habitat, especially under the No Action Alternative, but this reduces lake habitat for sportfish. Most alternatives (except the Enhanced Coordination and Maximum Operational Flexibility Alternatives) keep Lake Powell below critical thresholds, favoring river habitats. The Enhanced Coordination and Maximum Operational Flexibility Alternatives tend to flood critical habitats, reducing river habitat value. For Lake Mead, the No Action Alternative and CCS Comparative Baseline maintain lower water levels, helping restrict nonnative fish but also limiting upstream movement of native fish. The Basic Coordination Alternative offers a moderate balance. Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives more often allow Lake Mead to rise above critical thresholds, which can facilitate movement for both native and nonnative fish. The Supply Driven

Alternative (LB Pro Rata approach) is most reliable for maintaining Lake Mead above its historic minimum, supporting habitat stability. Overall, the Representative Preferred Alternative provides moderate protection of riverine critical habitat but does not perform as well as the Supply Driven Alternative (LB Pro Rata approach).

TA 14. Recreation

TA 14.1 Affected Environment

This Final Environmental Impact Statement (EIS) identifies and describes in detail the following key recreation resources or issues:

- Shoreline public use
- Reservoir boating
- River and whitewater boating
- Sportfishing

TA 14.1.1 Shoreline Public Use

The following sections describe shoreline public use associated with boating facilities (marinas, boat docks, and boat launch ramps), access to points of interest, and other opportunities within each Colorado River reach. Recreational boating in the study area depends on these major shoreline access points. While fluctuations in pool elevations are a normal aspect of dam operations, increased frequency or severity of these variations could result in changes in recreational facility operational costs and temporary closures. Below critical pool elevations and river flows, certain facilities may be rendered inoperable or require relocation to maintain operation.

Lake Powell and Glen Canyon Dam

Lake Powell is entirely within the Glen Canyon National Recreation Area (NRA), which receives approximately three to five million visitors each year (NPS 2025a). **Table TA 14-1** summarizes visitation to Glen Canyon NRA from 2019 through 2024.

Table TA 14-1
Glen Canyon NRA Recreational Visitors

Year	Recreational Visitors
2019	4,330,563
2020	2,553,392
2021	3,144,318
2022	2,842,776
2023	5,206,934
2024	4,725,610

Source: NPS 2025a

Table TA 14-2 summarizes the total number of recreational visits to Glen Canyon NRA by district for 2024, which is the most recent year for which data are available.

Table TA 14-2
Glen Canyon NRA Visits by District for 2024

District	Recreational Visitors
Wahweap District	1,612,518
Antelope Point District	532,202
Bullfrog District	101,627
Halls Crossing District	139,234
Hite District	261,725
Lees Ferry District	2,065,278
Horseshoe Bend District	831,631
Escalante District	13,029

Source: NPS 2025b

Lake Powell, with its many side canyons and related natural, cultural, and geological resources, is Glen Canyon NRA's primary recreational feature. Recreation that occurs at Lake Powell includes swimming and sunbathing, power boating, waterskiing, fishing, off-beach activities associated with boat trips (such as hiking and exploring archaeological sites), house boating, personal watercraft use, canoeing, kayaking, sailing, wildlife viewing, photography, sightseeing, and other activities. Visitors can enjoy a wide range of camping options, from remote and undeveloped campsites to fully developed campgrounds. Visitors can also see archaeologically and culturally important sites throughout Glen Canyon NRA.

Boating Facilities

Recreational boating is the most important recreational activity on Lake Powell, with nearly two million visitors accessing the reservoir by either private boat or rental (NPS 2025c). **Table TA 14-3** lists critical lake elevations for Lake Powell, identified by the National Park Service (NPS), below which certain marinas, boat docks, or boat launch ramps become inoperable. Water-based recreational facilities at Lake Powell include the marinas at Wahweap, Halls Crossing, Bullfrog, and Antelope Point. Declining water levels have rendered the Dangling Rope Marina inoperable since 2021; prior to its closure, it was the busiest gas station in Utah, despite lacking road access, because it served as the only refueling location in the middle of the lake. The Hite Launch Ramp has also been closed since 2012 due to the ramp being out of the water as a result of low reservoir levels (NPS 2025d).

Changes to the shoreline affect the usability of boat launch ramps throughout the year, especially in warmer months. Launch ramp closures due to declining water levels have resulted in longer lines, limited parking, and congestion at boat ramps and docks (NPS 2025d).

Table TA 14-3
Critical Elevations for Lake Powell by Boating Facility

Lake Elevation (feet)	Impact and Facility
3,700	Full pool
3,650	Hite Public Launch Ramp closed
3,588	Antelope Point Public Launch Ramp closed
3,583	Castle Rock Cut closed
3,578	Bullfrog Main Launch Ramp and Spur closed
3,565	Utah Department of Transportation (UDOT) Ferry and Launch Ramp closed
3,564	Wahweap Stateline Launch Ramp closed
3,556	Hall's Crossing Main Launch Ramp closed
3,550	Wahweap Main Launch Ramp closed; Rainbow Bridge National Monument closed
	Bullfrog Main Launch Ramp Spur closed
3,540	Antelope Point Business Ramp closed
3,529	Bullfrog North Launch Ramp closed
3,520	Wahweap Stateline Auxiliary Launch Ramp closed
3,515	Antelope Marina closed; Bullfrog Marina closed; Hall's Crossing Marina closed
3,430	Wahweap Boat Rental closed; Wahweap Boat Tour Dock closed

Source: Nicole Gibney, Assistant Colorado River Coordinator, NPS, personal communications, May 15, 2024

In 2022, the NPS received $26 million in Disaster Supplemental Funding to provide additional boating access at Lake Powell. Design work is underway for a north Lake Powell ramp that provides access down to an elevation of 3,450 feet in the Stanton Creek area near Bullfrog. The NPS is also working to develop schematic designs for the Antelope Point Public Ramp, Halls Crossing Public Ramp, and a primitive ramp and take-out area at the Hite Marina. The NPS continues to seek funding necessary for potential reconstruction. The NPS is also continuing to seek funds to replace the services previously offered at Dangling Rope Marina and for a navigable waterway congestion study in south Lake Powell (NPS 2023a).

State Route 276 runs through Glen Canyon NRA and crosses Lake Powell via the Charles Hall Ferry, which the UDOT operates. The ferry's southern port is at Hall's Crossing, and the northern port is at Bullfrog. The ferry does not operate if Lake Powell elevation levels drop below 3,565 feet (UDOT 2025).

Access to Points of Interest

Since 2021, the courtesy dock access to the Rainbow Bridge National Monument trail has been intermittently unavailable due to changes in the water level. When water levels fall below 3,544 feet, visitors have to leave boats and small vessels at the shoreline and traverse through mud, debris, sand, and water before reaching the established trail. While no longer connected to the shoreline, the Rainbow Bridge dock system is accessible with restroom facilities. The concessionaire-operated

tours to the monument are no longer able to access the area, thus removing access for most Glen Canyon NRA visitors. Visitors can also access Rainbow Bridge National Monument by obtaining a permit from the Navajo Nation Parks and Recreation Department to backpack for multiple days on Navajo Tribal lands from Navajo Mountain; however, this is not possible for many visitors (NPS 2021).

Harmful Algal Blooms

Warming water temperatures and increased inputs of nutrients from monsoonal storms create conditions that are more conducive to harmful algal bloom growth in freshwater bodies, also known as cyanobacterial blooms. Harmful algal blooms produce toxins that pose serious health risks to humans and animals (NPS 2019). Harmful algal blooms may necessitate temporary closures of water-based recreation to protect public health (Deemer et al. 2023). Water quality concerns are described in detail in **TA 6**, Water Quality.

Quagga Mussel Shells on Shorelines

Quagga mussels were first detected at Lake Powell in 2012. Quagga mussels have colonized practically all areas of the lake, as indicated by water sampling for veligers (NPS 2023b). Seasonally low water levels are now exposing mussel-encrusted shoreline. Sharp quagga mussel shells eventually wash up on beaches and can cut through skin, clothing, and pet paws (NPS 2016).

Hiking and Sightseeing in Glen Canyon

Declining water levels have exposed approximately 100,000 acres of Glen Canyon that were previously inundated by Lake Powell, creating new opportunities to view landscapes that have been underwater since the late 1960s (Baker 2022; Kolbert 2021). These include arches, side canyons, other rock formations, and lush desert ecosystems. This has created new hiking and sightseeing opportunities for Glen Canyon NRA visitors over the last several years. At the same time, these landscapes and archaeological sites are fragile, and exposure could result in their degradation and vandalism.

TA 14.1.2 Glen Canyon Dam to Lake Mead

The 15.5-mile river reach downstream of Glen Canyon Dam to Lees Ferry is within Glen Canyon NRA; it is used by anglers, campers, commercial float trip operators, kayakers, and other boaters. Fishing opportunities for rainbow and brown trout also occur downstream of this reach. In the last 5 years, warming water temperatures have made this reach more attractive for day and overnight use by paddleboarders, kayakers, and canoeists, resulting in increased visitation.

The NPS manages most of the reach, except where it is bordered on the east by the Navajo Indian Reservation and on the south by the Hualapai Indian Reservation. Grand Canyon National Park (GCNP) staff regulates visitor use of the Colorado River downstream of Lees Ferry in accordance with the Colorado River Management Plan (NPS 2006a, 2006b).

GCNP begins downstream of the Lees Ferry boat ramp at the confluence of the Colorado and Paria Rivers. Designated as a United Nations Educational, Scientific and Cultural Organization World Heritage Site in 1979, GCNP is valued for its superlative natural and cultural resources as well as its varied recreational experiences. Approximately 94 percent of GCNP (1,143,918 acres) qualifies as

wilderness, as described in the 1964 Wilderness Act (Public Law 88-577) and NPS Management Policies 2006 (NPS 2006b). This includes 10,919 acres of potential wilderness along the Colorado River corridor.

The Colorado River corridor borders tribal lands for nearly half the distance from the put-in at Lees Ferry to the last takeout at Pearce Ferry. The Navajo Indian Reservation borders GCNP along the eastern bank of the Colorado River from near Lees Ferry to the confluence with the Little Colorado River at river mile (RM) 61.8. The Hualapai Indian Reservation borders the river corridor for approximately 108 miles from upstream of National Canyon (RM 167) to approximately RM 274. The Hualapai Indian Reservation offers camping, fishing, hiking, and big game hunting. Tribal enterprises offer rafting trips on the Colorado River between Diamond Creek and Pearce Ferry. The NPS coordinates with tribal neighbors to address resource management and visitor use concerns along shared boundaries. Access permits from the Navajo Nation, Havasupai Tribe, or Hualapai Tribe are required by each respective tribe to access and recreate on tribal lands.

GCNP receives four to six million visitors each year (NPS 2025e). **Table TA 14-4** summarizes visitation to GCNP from 2019 to 2024.

Table TA 14-4
GCNP Recreational Visitors

Year	Recreational Visitors
2019	5,974,411
2020	2,897,098*
2021	4,532,677
2022	4,732,101
2023	4,733,705
2024	4,919,163

Source: NPS 2025e
*Park closure April–May due to the COVID-19 pandemic

The Lees Ferry to Diamond Creek reach has relatively low-use densities (attributed to the competitive lottery system) and low levels of development, providing opportunities for solitude on the Colorado River; this reach also offers many camps and attraction sites. This section of the Colorado River is where the majority of whitewater boating occurs. Takeouts are at Diamond Creek and Pearce Ferry. The reach downstream of Diamond Creek offers different recreational opportunities than the upstream reach, as it transitions to a more populated, developed setting. Whitewater boating trips become intermingled with very high levels of general boating and recreational use in the Quartermaster area (RM 260). **TA 16**, Socioeconomics, describes the social and economic importance of whitewater boating in the Grand Canyon.

Helicopter operations authorized by the Hualapai Tribe transport people into the Grand Canyon and connect them with motorized pontoon boats that give 20-minute tours of the Quartermaster area. These helicopters also fly out boaters who complete commercial motor day trips from Diamond Creek.

Boating Facilities

No boating facilities are within GCNP. Development along the Colorado River within the park is limited to the development at Phantom Ranch (RM 88) and Pipe Creek (RM 89.5). Other focal points include the launch ramp at Lees Ferry (within Glen Canyon NRA), the helipad near Whitmore Wash (RM 187) on the Hualapai Reservation, road access and minor structures operated by the Hualapai Tribe at Diamond Creek (RM 226), and the tourist area near Quartermaster Canyon (RM 260).

Camping between the Lees Ferry boat ramp and Lake Mead occurs in GCNP on undeveloped sandbars along the Colorado River. The number and usability of campsites diminish between depositional high-flow experiments, due to vegetation encroachment, sandbar erosion from hydropeaking operations, erosion from tributary flooding, aeolian sand remobilization, and recreational use.

Ongoing Glen Canyon Dam operations have resulted in encroachment of vegetation onto sandy beaches. One species that poses particular problems related to campsite encroachment is arrowweed (*Pluchea sericea*), a native shrub that can readily colonize open sandbars used as campsites. Further information on arrowweed and vegetation encroachment can be found in **TA 9**, Vegetation Including Special Status Species.

Sites can also be closed to protect sensitive resources (NPS 2006a). Further information on sedimentation and beach building can be found in **TA 5**, Geomorphology and Sediment. Of the 276 campsites referenced in Section 3.12.1.1 of the Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead Final EIS (2007 Final EIS), 195 sites (71 percent) are still classified as "camps";[1] 68 sites (25 percent) have been classified as "noncamps" due to sand erosion, vegetation overgrowth, or both; 2 sites could not be ascertained based on the float-by methodology used during the November 2022 NPS Colorado River Management Plan monitoring trip; and 10 campsites were not evaluated (Kearsley 2023).

TA 14.1.3 Lake Mead and Hoover Dam

Lake Mead NRA encompasses 1.5 million acres. It encompasses the 110-mile-long Lake Mead, the 67-mile-long Lake Mohave, the surrounding desert, and the isolated Shivwits Plateau in Arizona. Recreation such as camping, boating, fishing, and hiking occurs on upper Lake Mead. The Overton Wildlife Management Area provides opportunities for wildlife viewing and photography, waterfowl and upland game-bird hunting, hiking, and fishing. The Overton Wildlife Management Area averages 4,226 annual visitor use days.[2]

Lake Mead NRA extends along the lower Colorado River from GCNP's western border to Davis Dam. The primary recreational activities on Lake Mead include cruising/sailing, personal watercraft usage, waterskiing, fishing, and swimming. A number of campgrounds and picnic areas, including Boulder Beach, Calville Bay, Echo Beach, Las Vegas Bay, and Temple Bar, provide additional

[1] Campsite area is defined as any region of smooth substrate (most commonly sand) with no more than an 8-degree slope and little or no vegetation (Kaplinski et al. 2014).
[2] Nevada Department of Wildlife, personal communication, 2023

recreational opportunities. Lake Mead NRA had approximately 6.4 million visitors in 2024 (NPS 2025f).

Table TA 14-5 summarizes recreational visits to Lake Mead NRA for 2019 to 2024.

Table TA 14-5
Lake Mead NRA Recreational Visitors

Year	Recreational Visitors
2019	7,499,049
2020	8,016,510
2021	7,603,474
2022	5,578,226
2023	5,798,541
2024	6,412,854

Source: NPS 2025f

Water quality concerns are increasing and are described in detail in **TA 6**, Water Quality. In the spring and summer of 2015, Lake Mead experienced notable concentrations of harmful blue-green algae, which triggered harmful algal bloom advisories for various locations across the lake (NPS 2023b). In 2022, a swimmer was fatally infected with a brain-eating amoeba (*Naegleria fowleri*) at Lake Mead. Brain-eating amoebas are commonly found in bodies of warm, fresh water, such as lakes, rivers, and geothermal water (NPS 2022). These trends may continue to increase as water temperatures warm.

Declining reservoir elevations at Lake Mead in recent years have exposed mudflats along several areas of the shoreline. These have created dangerous conditions where recreationists have periodically become stuck in wet, muddy deposits. Some of these areas have access roads that previously enabled visitors to drive close to the shoreline when reservoir elevations were higher. As reservoir elevations have declined over recent years, visitors have often attempted to chase the shoreline both in their vehicles and on foot to gain access to the changing shoreline for such purposes as fishing, hiking, and other recreational activities. In doing so, they and their vehicles have created unauthorized vehicle routes toward the lowering water levels, and they have become stuck in these muddy conditions, requiring assistance from NPS personnel and others to extract themselves and/or their vehicles.

Boating Facilities

Lake Mead NRA is considered one of the nation's premier water-based recreation areas. Most visitors participate in water-based recreational activities, primarily between May and September. These recreational activities are supported by marina and launch ramp facilities developed along the Lake Mead shoreline. On average, the majority of boats are personal watercraft. Water-based recreational facilities at Lake Mead are located at Callville Bay, Hemenway Harbor, Temple Bar, Echo Bay, South Cove, and Pearce Ferry boat ramps. Pearce Ferry is used as a takeout by Colorado River boaters.

Table TA 14-6 shows critical elevations identified by the NPS for Lake Mead, below which marinas, boat docks, or boat launch ramps become inoperable. The Pearce Bay launch ramp, a take-out point for rafts and whitewater boats, is closed at 1,175 feet. This results in rafts and other whitewater boats having to continue downstream to South Cove, which is an additional 16 miles.

Table TA 14-6
Critical Elevations for Lake Mead by Boating Facility

Lake Elevation (feet)	Impact and Facility
1,221	Full pool
1,075	Boulder Harbor closed
1,035	South Cove Ramp closed
1,000	Echo Bay public launch ramp closed
950	Hemenway Harbor public launch ramp closed; Callville Bay public launch ramp closed; Temple Bar public launch ramp closed

Source: Nicole Gibney, Assistant Colorado River Coordinator, NPS, personal communications, May 15, 2024; December 3, 2024; and December 10, 2025

Since the publication of the 2007 Final EIS, the Echo Bay, Boulder Harbor, and South Cove boat ramps have closed due to low water levels. The NPS facilities at the Temple Bar Marina are also inoperable; however, the concessionaire's launch operations remain operable. The Pearce Bay launch ramp, a take-out point for rafts and whitewater boats, previously closed at elevation 1,175 feet. Access to Lake Mead was closed at Pearce Ferry in 2001 when the water elevation dropped to 1,175 feet. In 2010, the NPS extended Pearce Ferry Road 2 miles to the Colorado River to provide for river take-out operations for private and commercial river runners (NPS 2010).

Changes to water levels affect the usability of the remaining boat launch ramps throughout the year, especially in warmer months. Launch ramp closures due to declining water levels have resulted in longer lines, limited parking, and congestion at boat ramps and docks. In addition, ongoing maintenance and construction at ramps have resulted in temporary closures.

TA 14.1.4 Hoover Dam to Davis Dam

Visitation and recreational use at Lake Mohave have increased in response to more variable Lake Mead levels and the closure of associated boating infrastructure. Recreational opportunities at Lake Mohave include boating, canoeing on the northern parts of the lake, camping, exploring, fishing, photography, picnicking, swimming, parasailing, and waterskiing. There are also hundreds of beaches accessible only by boat. As with Lake Mead, harmful blue-green algal blooms occurred at Lake Mohave in 2015, leading to advisories for multiple locations across the lake (NPS 2023b).

The main shoreline access points for Lake Mohave are Katherine Landing, Cottonwood Cove, and Willow Beach. Facilities for public use and boat launching are located at Katherine's Landing in Arizona near Davis Dam and at Cottonwood Cove, which is east of Searchlight, Nevada. Boats and jet skis can be rented at both locations. Public campgrounds are available at both locations, where concessionaires provide trailer parks, restaurants, lodging, docking facilities, boat and fishing tackle

equipment, and fishing licenses. Facilities for public use and boat launching are also at Willow Beach, 31 miles upstream on the Arizona shore.

TA 14.1.5 Davis Dam to Parker Dam

The Davis Dam to Parker Dam reach includes several recreational areas along the Colorado River, including Laughlin, Bullhead City, Davis Camp, Needles, Havasu National Wildlife Refuge (NWR), Lake Havasu State Park, and Bill Williams River NWR. Relevant recreational areas are briefly described in the following sections.

Davis Camp. Davis Camp contains a campground and day use area. It has boat launching facilities, picnic areas, numerous campsites, and recreational vehicle hookups. Davis Camp offers many river-oriented recreational opportunities, including fishing and water sports.

Havasu NWR. The Havasu NWR, managed by the United States Fish and Wildlife Service (FWS), covers 30 RMs (300 miles of shoreline) from Lake Havasu City, Arizona, to Needles, California. Typical activities include canoeing, fishing, boating through the scenic Topock Gorge, and hiking in the Havasu Wilderness Area. The 4,000-acre Topock Marsh offers excellent canoeing, fishing, and bird-watching. Other activities offered at the Havasu NWR include camping and hunting.

Lake Havasu State Park. Formed by Parker Dam, Lake Havasu contains several coves and inlets and is a popular spot for fishing. Lake Havasu's waters are also used for canoeing, houseboating, riding watercrafts, kayaking, sailing, speedboating, swimming, and waterskiing. Camping and hiking also occur along the more than 400 miles of the lake's shoreline. Additional visitor opportunities include viewing the London Bridge. Lake Havasu is a popular destination for spring break and family vacations.

Lake Havasu is the premier attraction area within the Davis Dam to Parker Dam reach. **Table TA 14-7** lists the visitation from 2019 to 2024 at Arizona's Lake Havasu and Cattail Cove State Parks.

Table TA 14-7
Visitation at Arizona's Lake Havasu and Cattail Cove State Parks

Year	Lake Havasu State Park Visitation	Cattail Cove State Park Visitation
2019	488,597	111,262
2020	598,403	116,822
2021	492,074	95,179
2022	494,318	86,385
2023	484,716	79,978
2024	468,535	83,992

Source: Arizona Hospitality Research and Resource Center 2025

Bill Williams River NWR. Managed by the FWS, the Bill Williams River NWR is along the Bill Williams River near its confluence outlet into Lake Havasu. The refuge offers a variety of recreational opportunities, including hiking, bird-watching, and other wildlife viewing. Hunting is

permitted for dove, cottontail, quail, and desert bighorn sheep. Other activities include boating and fishing.

Boating Facilities. The Davis Dam to Parker Dam reach includes shoreline public use facilities at Laughlin, Bullhead City, Davis Camp, Needles, Havasu NWR, Lake Havasu State Park, and Bill Williams NWR. Recreational activities within this reach include canoeing, fishing, houseboating, riding watercrafts, kayaking, sailing, speedboating, swimming, and waterskiing.

TA 14.1.6 Parker Dam to Cibola Gage

The Parker Dam to Cibola Gage reach includes several recreational areas, including Parker Strip Recreation Area, Palo Verde Diversion Dam, Blythe, and the Cibola NWR. The following are brief descriptions of the relevant recreational areas on this reach.

Parker Strip Recreation Area. The Parker Strip Recreation Area includes an 11-mile road along the Colorado River. Recreation includes boating, camping, fishing, hiking, rock hounding, swimming, and wildlife viewing.

Palo Verde Diversion Dam. There are approximately 95 miles of navigable waters between Imperial Dam downstream of Yuma and Palo Verde Diversion Dam upstream of Blythe. Activities include canoeing, fishing, hunting, power boating, and other water sports.

Cibola NWR. The Cibola NWR, including Cibola Lake, is managed by the FWS and located about 15 miles south of Blythe. Visitors to the refuge engage in canoeing, fishing, hiking, hunting, photography, and wildlife viewing.

Boating Facilities. The Parker Dam to Cibola Gage reach includes shoreline public use facilities at Parker Strip Recreation Area, Palo Verde Diversion Dam, Blythe, and the Cibola NWR. Typical water activities within this reach include canoeing, power boating, fishing, swimming, and other water sports.

TA 14.1.7 Cibola Gage to Imperial Dam

The Cibola Gage to Imperial Dam reach includes the following few recreational areas: Picacho State Recreation Area, Imperial NWR, and Martinez Lake. Brief descriptions of these recreational areas follow.

Picacho State Recreation Area. This area is popular for camping, desert exploring, river running, and sportfishing. It received approximately 10,763 visitors in 2022 (including day and overnight use),[3] and it has a group boat-in area, three individual boat-in camp areas, and large group camping areas. Bird-watching and small-game hunting for doves, ducks, and quail are among the other recreational opportunities.

Imperial NWR. Recreational opportunities at the Imperial NWR include canoeing, fishing, and hunting. Boaters value the refuge for its remote scenery.

[3] T. Unzicker, personal communication, December 5, 2024.

Martinez Lake. Martinez Lake, which adjoins the Imperial NWR, offers opportunities for fishing, bird-watching, boating, hunting, rock hounding, sightseeing, and waterskiing.

Boating Facilities. The Cibola Gage to Imperial Dam reach includes shoreline public use facilities at Picacho State Recreation Area, Imperial NWR, and Martinez Lake. Typical water activities within this reach include river running, boating, canoeing, waterskiing, and sportfishing.

TA 14.1.8 Imperial Dam to the Northerly International Boundary (NIB)

The Imperial Dam to the NIB reach includes a few recreational areas along the Colorado River, including Betty's Kitchen and Mittry Lake Wildlife Area. The following are brief descriptions of these recreational areas.

Betty's Kitchen. This 10-acre wildlife interpretative area provides bird-watching and fishing opportunities.

Mittry Lake Wildlife Area. Mittry Lake, within the Mittry Lake Wildlife Area, covers approximately 600 acres and provides small-game hunting and sportfishing opportunities. There is a three-lane boat launch ramp for motorized boating on the lake. The area is also popular for bird-watching and nature study.

Boating Facilities. The Imperial Dam to the NIB reach includes shoreline public use facilities, including a public fishing pier at Betty's Kitchen and a boat launch ramp for motorized boating and fishing jetties at Mittry Lake Wildlife Area. Typical water activities within this reach include boating, swimming, and sportfishing.

NIB to the Southerly International Boundary (SIB)

The NIB to the SIB reach includes shoreline public use facilities in the city of Yuma, Arizona. Typical water activities within this reach, which is on the edge of the historical floodplain to the east of the Colorado River, include boating, swimming, and sportfishing.

TA 14.1.9 Reservoir Boating

Reservoir boating is affected by fluctuating reservoir elevations; these fluctuations specifically alter exposure to boating navigational hazards and safer boating capacities. Hazards such as exposed rocks may become more evident, and changes in navigational patterns may be necessary as reservoir elevations decline. At low-pool elevations, special buoys or markers may be placed within reservoirs to warn boaters of navigational hazards. In addition, signs may be posted in areas deemed unsuitable for navigation.

Near Hite, a delta has formed that can affect river boaters coming into Lake Powell at low-pool elevations. River boaters from the Colorado River row or motor through Lake Powell to a location where a boat transports them 20 to 25 miles to the Hite Marina. At low elevations, the river boaters must travel farther downstream to reach a location accessible to the transport company's boat. Although this results in more miles to the takeout, there is usually enough current in the river to carry the boats. At lower elevations, additional rapids are exposed in Cataract Canyon. Lower Lake Powell elevations may create additional navigational hazards due to restricted channel widths and subsurface conditions.

Lake Powell

Safe boating navigation. The navigation system on Lake Powell uses regulatory buoys and other marking devices to warn boat operators of hazardous conditions associated with subsurface obstructions or changes in subsurface conditions that could be hazardous for safer passage. Placement of many of these marking devices depends on the lake's elevation.

Lake Mead

Safe boating navigation. Regulatory buoys and other marking devices are used on Lake Mead to warn boat operators of dangers, obstructions, and changes in subsurface conditions in the main channel or side channels. Excursions from Lake Mead into the Grand Canyon are a popular activity. Boats entering the Grand Canyon usually launch at Pearce Ferry, South Cove, or Temple Bar. Many boaters include overnight camping on these excursions.

The upper arms and inflow areas of Lake Mead may be difficult to navigate due to shifting subsurface sediments. Over the years, sediment has built up in the section of the reservoir between Grand Wash and Pearce Ferry. When Lake Mead elevations drop below 1,170 feet, the sediment is exposed as mud flats, and there is no well-defined river channel. As a result, the area is too shallow for motorboats to navigate upstream and into the lower reaches of the Grand Canyon. With fluctuating flows, even smaller crafts may have difficulty accessing the area due to the shifting channel. Based on this information, an elevation of 1,170 feet is considered a threshold elevation for safer boating navigation for Lake Mead's upper end.

Since the publication of the 2007 Final EIS, the NPS has extended the Pearce Ferry launch ramp to provide river take-out operations for private and commercial river runners. However, due to the proximity of the developing Pearce Ferry Rapid, the public launch of boats is prohibited (NPS 2010).

Lake Mohave and Lake Havasu

Because Lake Mohave and Lake Havasu will continue to be operated to meet monthly target elevations, the alternatives will not affect reservoir boating and navigation in these reaches beyond the trends previously described.

TA 14.1.10 River and Whitewater Boating

Whitewater boating is the key recreational activity in the Grand Canyon from Lees Ferry to the Diamond Creek or Pearce Ferry takeouts. Other reaches are not predominantly whitewater localities; therefore, they will not be discussed in this section.

Glen Canyon Dam to Lake Mead

Grand Canyon whitewater boating trips launch at Lees Ferry in Glen Canyon NRA and take out at Diamond Creek on the Hualapai Indian Reservation or at Pearce Ferry in Lake Mead NRA. River trips are conducted using a variety of boats and rafts; group sizes can range up to 32 people (including guides). Trip lengths range up to 25 days and can be run by commercial companies or by private individuals. There are various ways to join trips, including launching from Lees Ferry, hiking into or out of the canyon to join and leave a trip, and gaining limited access by vehicle and helicopter (commercial use only) to join trips in the western portion of the Grand Canyon.

GCNP staff regulates recreational boating in accordance with the Colorado River Management Plan (NPS 2006a). The Colorado River Management Plan prescribes management of recreational use by establishing limits on the number of daily launches, group size, trip length, and periods of motorized and nonmotorized use. Motorized use is permitted between April 1 and September 15. In general, whitewater navigability can be affected by river flows and by large amounts of side canyon debris washed into the river channel. Due to reduced water levels in Lake Mead, rapids like Separation Rapid have returned, and new rapids have formed from the Colorado River scouring a new path in the deltaic sediments, making it more challenging to navigate. While most of the river still follows the old river channel, a new channel has developed near Pearce Ferry, creating a new impassible class VI rapid known as the Pearce Ferry Rapid (Joel 2016). A new waterfall or rapid is expected to form downstream from the North Wash boat ramp that serves as the take-out point for Cataract Canyon rafters (Returning Rapids Project 2023). Intermittent, larger-volume, and higher-magnitude flows could improve navigability at some of these rapids.

River flow levels and fluctuations are important for whitewater boaters (Bishop et al. 1987; Shelby et al. 1992; Hall and Shelby 2000; Stewart et al. 2000; Neher et al. 2017). Past studies have polled commercial and private whitewater trip leaders for their preferences on the minimum levels for running the river safely with passengers. Preferences may vary by experience level and equipment types for different boaters, but a majority have reported that flows below 10,000 cubic feet per second (cfs) and above about 45,000 cfs are considered less than optimal; flows between 20,000 and 26,000 cfs are considered optimum (Shelby et al. 1992; Bishop et al. 1987; Neher et al. 2017). Flows above 8,000 cfs have been identified by commercial guides as the minimum level necessary to safely run the river with passengers (Shelby et al. 1992; Stewart et al. 2000). At low flows (5,000 cfs or less), it often becomes necessary to either walk passengers around some rapids or wait for higher water. The risk of accidents varies by the type of boat employed. At extremely low flows (less than 5,000 cfs), motor rigs have the highest incidence of accidents, followed by small (typically private group) rafts (Jalbert 1992). At flows higher than power plant capacity, smaller craft, such as small rafts, dories, kayaks, and canoes and inflatables, experience more accidents (Brown and Hahn-O'Neill 1987).

Hoover Dam to SIB

The alternatives are not expected to adversely affect river and whitewater boating between Hoover Dam and the SIB.

TA 14.1.11 Sportfishing

No specific reservoir elevation thresholds or river stages related to sportfishing were identified in the literature reviewed. Catch rates for reservoir fishing are assumed to be directly related to reservoir habitat, including water quality. Please refer to **TA 8**, Biological Resources – Fish and Other Aquatic Resources, for more information regarding impacts on fish habitat, and **TA 6**, Water Quality, for impacts on water quality. Fishing satisfaction is assumed to be directly related to (1) the general recreational issues of boating access to water via shoreline facilities, and (2) the potential for boating navigational hazards or reservoir detours due to low reservoir elevations.

Lake Powell and Glen Canyon Dam

Lake Powell supports a popular warmwater sportfishery composed mainly of striped and smallmouth bass. The striped bass depends on threadfin shad for a significant portion of their diet. The threadfin shads in Lake Powell are at the northernmost portion of their range, and they are sensitive to fluctuations in water temperature. Gizzard shads may become an important forage fish for striped bass. In addition to striped and smallmouth bass, Lake Powell supports other nonnative fish species, including largemouth bass, walleye, channel catfish, bluegill, and black crappie. Angler use in 2018 was at a 40-year low, mainly attributed to a decline in the percentage of boat days that were spent angling (Blommer and Gustaveson 2021).

Glen Canyon Dam to Lake Mead

The 15.5-mile Glen Canyon reach of the Colorado River supports a Blue Ribbon recreational rainbow trout fishery that attracts local, national, and international anglers. The NPS, in coordination with the Arizona Game and Fish Department and the FWS, manages fish in all waters within Glen Canyon NRA and GCNP. The intention of Blue Ribbon management is to provide a quality fishing opportunity where anglers can catch larger-than-average trout at a relatively high catch rate in a unique recreational setting. Most angling is from boats or is facilitated by boat access, often provided by guide services. Some anglers also wade or fish from shore.

Fishing in the Glen Canyon reach occurs year-round. Peak usage is in April and May; however, substantial fishing has occurred from March through October in most years (Rogowski and Boyer 2023). An estimated 5,095 anglers used the rainbow trout fishery in 2022; of these, 3,594 were boat anglers, and 1,501 were walk-in anglers (Rogowski and Boyer 2023). Boat and walk-in angler use decreased in 2022 relative to 2021 (Rogowski and Boyer 2023).

The quality of the rainbow trout fishery at Lees Ferry is highly dependent on water quality within the reach, which is a proxy for catch (Bishop et al. 1987). Prior to 2022, fish species from Lake Powell were periodically entrained and survived passage through the dam; however, water temperatures within the Glen Canyon reach were generally cold enough to impede growth and cease reproduction. In 2022, water temperatures within the Glen Canyon reach were the highest on record, which led to higher survival of entrained warmwater and cool-water fish through the dam (Rogowski and Boyer 2023). There is concern that as Lake Powell continues to decline and warm water is subsequently discharged, coupled with low dissolved oxygen, there will be an increase in warmwater fish, successful recruitment of the highly invasive smallmouth bass, and a decrease in rainbow trout (Rogowski and Boyer 2023).

The Glen Canyon Dam Long-Term Experimental and Management Plan Final Supplemental Environmental Impact Statement (2024 LTEMP Final SEIS) was developed to implement water management actions to temporarily control smallmouth bass populations downstream of Glen Canyon Dam from 2024 to 2027 (Reclamation 2024). The Bureau of Reclamation (Reclamation) is planning to continue coordination with stakeholders for future control of smallmouth bass populations. **TA 8**, Biological Resources – Fish and Other Aquatic Resources, provides further information on rainbow trout dynamics in the Glen Canyon reach.

Lake Mead and Hoover Dam

Lake Mead has an excellent warmwater sportfishery composed of largemouth bass, striped bass, channel catfish, rainbow trout, bullhead catfish, sunfish, crappie, and bluegill. Fishing is generally better in September, October, and November. Larger fish are caught by deepwater trolling in spring from March through May.

The Lake Mead Fish Hatchery, operated by the Nevada Department of Wildlife, historically raised rainbow trout, endangered razorback suckers, and bonytail chub. The Lake Mead Fish Hatchery ceased operations in 2022 in response to Lake Mead declining below 1,060 feet, the point at which the hatchery drew its water (Peterson 2022). The Nevada Department of Wildlife and the Southern Nevada Water Authority are currently developing a project to replace the hatchery's water supply line to draw deeper in the water column.

Hoover Dam to Davis Dam

Lake Mohave's fishery is similar to Lake Mead's fishery. In Lake Mohave, there are largemouth bass, striped bass, channel catfish, rainbow trout, bullhead catfish, sunfish, crappie, and bluegill. Largemouth and striped bass are in deep water in the winter and move into shallow water to spawn in the spring. Fishing is open year-round, but the best fishing generally occurs in September, October, and November. For deepwater trolling, March through May tends to provide the best conditions.

Davis Dam to Parker Dam

Striped bass is the dominant sportfish in Lake Havasu. It can be caught throughout the year, but the best fishing locations change with the seasons and water temperature. The largemouth bass population supports tournaments nearly every weekend from September through May. The smallmouth bass population has increased in number over the past couple of years. Channel catfish are abundant and average 2 to 4 pounds in size. Flathead catfish grow to large sizes in Lake Havasu. Only a limited number of anglers fish specifically for catfish. Black crappie numbers are limited due to overharvesting and a lack of habitat.

Parker Dam to SIB

Fishing in Cibola NWR is available in Pretty Water, Cibola Lake, the Colorado River, and the old river channel. Cibola NWR is managed to protect wintering waterfowl that use Cibola Lake. Fishing is permitted March 15–October 1, unless otherwise stated. Sportfishing in Cibola Lake includes largemouth, smallmouth, and striped bass; channel and flathead catfish; crappie; sunfish; tilapia; and common carp.

Imperial NWR is managed as a refuge and breeding area for migratory birds and other wildlife. Hunting and fishing are permitted in some areas, according to state regulations, and fishing by boat is allowed on the mainstream Colorado River at any time of the year.

TA 14.2 Environmental Consequences

TA 14.2.1 Methodology

Reclamation used similar methods for the analysis of potential impacts on recreation as were used in the 2007 Final EIS and 2024 LTEMP Final SEIS to assess the effects on shoreline public use facilities, reservoir boating and navigational hazards, whitewater boating, and sportfishing. This analysis also incorporates additional Decision Making under Deep Uncertainty (DMDU) concepts, specifically robustness heat maps and vulnerability bar plots, developed to provide an indicator of an alternative's performance across many possible hydrologic futures. Refer to **TA 3**, Hydrologic Resources, and **Section 3.2**, Analysis Methods, for additional information on DMDU. Also, see **Appendix E**, DMDU Overview and Approach, for an overview of interpreting the DMDU robustness heat maps and vulnerability bar plots.

Method Used to Assess Shoreline Public Use Facilities

This section analyzes the impacts that reservoir elevations decreasing below critical thresholds would have on selected marinas, boat docks, and launch ramps, as well as whether these elevations could impact access to or use of attraction features. The NPS provided threshold reservoir elevations included in this analysis. The DMDU analysis uses the subset of reservoir elevations used in the regional economic modeling (see **TA 16**, Socioeconomics). The DMDU analysis for shoreline public use facilities analyzes the percentage of selected marinas, boat docks, and launch ramps. Threshold elevations were used as indicators of recreational facilities that might be rendered inoperable or require relocation or modification to remain operational. The narrative of the alternatives' effects is provided below for selected facilities at both Lake Powell and Lake Mead. These facilities are representative of the alternatives' potential effects on shoreline recreational opportunities at each reservoir.

Method Used to Assess Reservoir Boating and Navigational Hazards

This analysis assesses the effects of reservoir elevations falling below critical thresholds, which would result in boating navigational hazards and changing navigable areas and passageways. This methodology is consistent with the 2007 Final EIS and 2024 LTEMP Final SEIS, but with the addition of new modeling and DMDU concepts, it assesses the percentage of futures in which reservoir elevations never drop below identified thresholds. Threshold pool elevations were determined using the methodology identified in the 2007 Final EIS.

Method Used to Assess Whitewater Boating

The assessment of effects on whitewater boating used a similar methodology identified in the 2007 Final EIS and 2024 LTEMP Final SEIS by using river flow data from **TA 3**, Hydrologic Resources, to analyze whether there would be increased exposures to boating navigational hazards, changes in access or use of rest areas and takeouts, or changes in trip durations resulting from the alternatives. The analysis additionally incorporates DMDU concepts and analyzes the percentage of futures in which daytime flows of the Colorado River would not drop below an identified minimum threshold, previously identified as the minimum preferred flow (Shelby et al. 1992; Stewart et al. 2000).

Methods Used to Assess Sportfishing

This analysis assesses the effects on fishing opportunities by river reach under the alternatives, using similar methods identified in the 2007 Final EIS and 2024 LTEMP Final SEIS. There are no specific reservoir elevation thresholds related to sportfishing; therefore, DMDU concepts are not used in the reservoir sportfishing analysis. A general discussion of changes in flow and salinity, and the possible effects on sportfish is also provided.

A more detailed analysis of effects on rainbow trout based on changes in water temperature is used for the Lees Ferry reach of the Colorado River, which incorporates DMDU concepts. Rainbow trout were chosen for the analysis based on the importance of their recreational fishery in the Colorado River reach below Glen Canyon Dam.

TA 14.2.2 Impact Analysis Area

The impact analysis area for recreation aligns with the general analysis area, which encompasses the Colorado River corridor from the full pool elevation of Lake Powell to the SIB. Flows below Hoover Dam are consistently low due to upstream diversions and delivery obligations. As a result, the range of operational changes evaluated across the alternatives would not meaningfully alter flow conditions in a manner that would measurably affect recreational opportunities in this reach. Given the limited variability in flows and the constrained nature of water-based recreation downstream of Parker Dam, a detailed analysis was determined to be unwarranted. Potential effects in this area would be negligible and would not differ substantially among the alternatives.

Assumptions

- The analysis assumes that the demand for recreational opportunities will either remain constant or increase over time, forming the basis for evaluating impacts on activities such as reservoir recreation, fishing, and whitewater boating.
- The analysis considers 5,000 cfs and 8,000 cfs as two levels at which commercial and private boaters may experience navigability challenges (Bishop et al. 1987; Shelby et al. 1992; Stewart et al. 2000).
- While high-flow experiments are not directly incorporated into the recreation modeling, actual high-flow experiment frequency may differ from that assumed or predicted in other modeling efforts.
- Additional assumptions related to modeling are considered in the analysis, contributing to the accuracy and reliability of the hydrologic models used to anticipate impacts resulting from various actions.

Impact Indicators

- Threshold reservoir elevations
- Threshold river flows
- Water temperatures

TA 14.2.3 Issue 1: How would the management of reservoir elevations affect recreation?

This issue examines how different reservoir elevations (Lake Powell and Lake Mead) resulting from different operational strategies would impact shoreline recreational facilities, reservoir boating activities, sportfishing opportunities, and the ferry and taxi boat services at Lake Powell. This analysis first presents and analyzes DMDU figures, and then assesses qualitative impacts on selected recreation activities resulting from changes in reservoir elevations.

Lake Powell

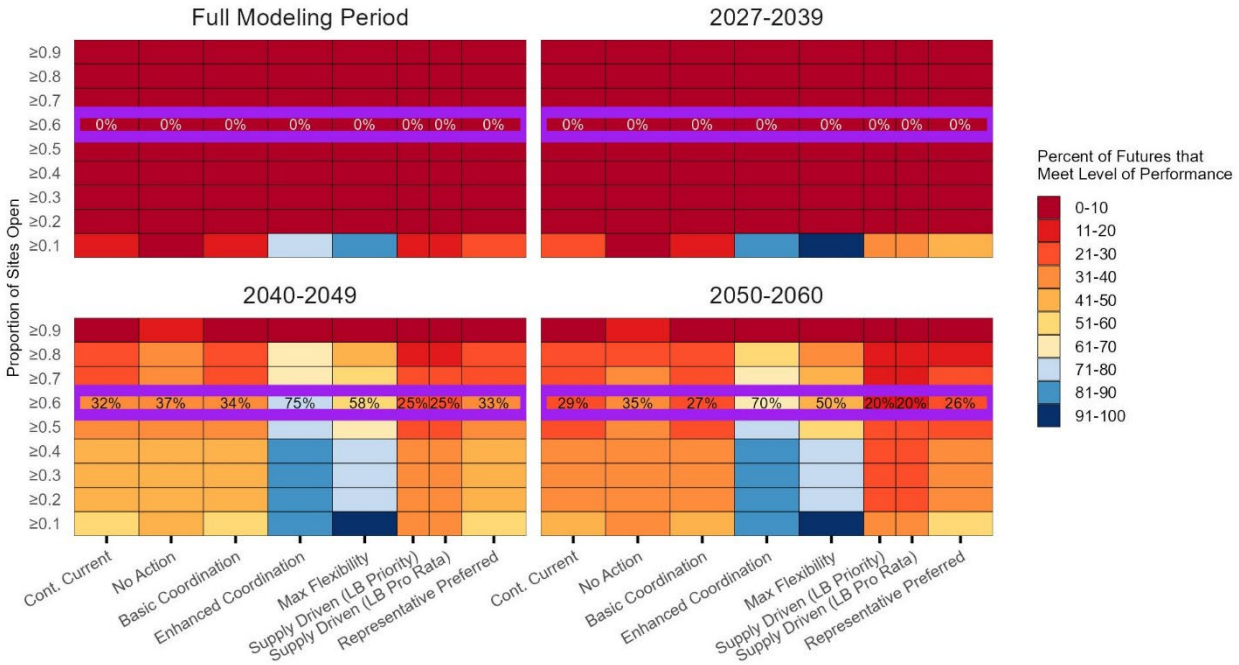

Table TA 14-3 identifies the threshold elevations, or preferred minimum performance levels, below which shoreline recreational facilities at Lake Powell could be affected. Below these elevations, facility adjustments or capital improvements would be required, creating potential impacts on recreation at Lake Powell. The analysis first examines the proportion of Lake Powell recreation sites that would remain open every summer month, then analyzes the performance of alternatives in maintaining Lake Powell elevations above 3,620 feet, which corresponds to the elevation required for safely navigating the Castle Rock Cut; 3,590 feet, the critical threshold for most boat launch facilities; 3,525 feet, below which nearly all current boat ramps would become inaccessible; and 3,500 feet, the critical threshold for planned boat ramp extensions to date.

Figure TA 14-1 below depicts the performance of each alternative with regard to keeping a specified proportion of Lake Powell recreational sites open over every summer month, which corresponds to peak visitation (May 31 – August 31). The figure is divided into four robustness heat maps, each showing a different time period across the analysis. The highlighted row represents the percentage of futures that an alternative achieves maintaining a 0.6 proportion of Lake Powell recreational sites open between May 31 and August 31. The 0.6 proportion row was chosen to be highlighted because it corresponds to approximately the 10th percentile from the historical analysis that informed the thresholds.

Across the full modeling period and the 2027–2039 subperiod, none of the alternatives would maintain keeping at least 60 percent of Lake Powell recreational sites open during the summer months. This indicates that reservoir elevations sufficient to sustain broad recreational site accessibility are unlikely under near-term conditions. Given the planned length of this decision, it is notable that the Representative Preferred Alternative does not meet the preferred minimum performance across the full modeling period or 2027–2039 subperiod, achieving it in only 30 percent of modeled futures in the 2040–2049 subperiod, and 22 percent of modeled futures in the 2050–2060 subperiod.

These results translate to widespread closures of Lake Powell recreation sites and boat launch ramps over the next decade. As access becomes increasingly constrained, use would be concentrated at the remaining operable locations, resulting in longer wait times, limited parking available, and increased congestion at boat ramps and associated facilities. These conditions would reduce the reliability and overall quality of recreation opportunities and may displace some users entirely.

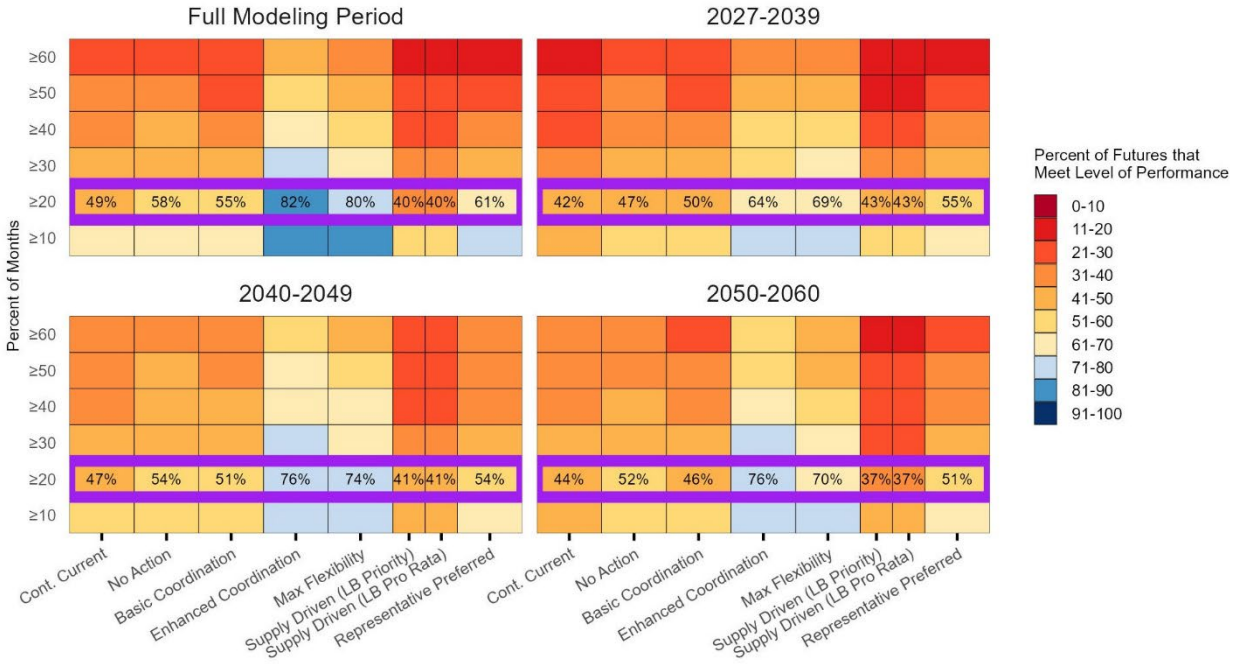

Figure TA 14-1
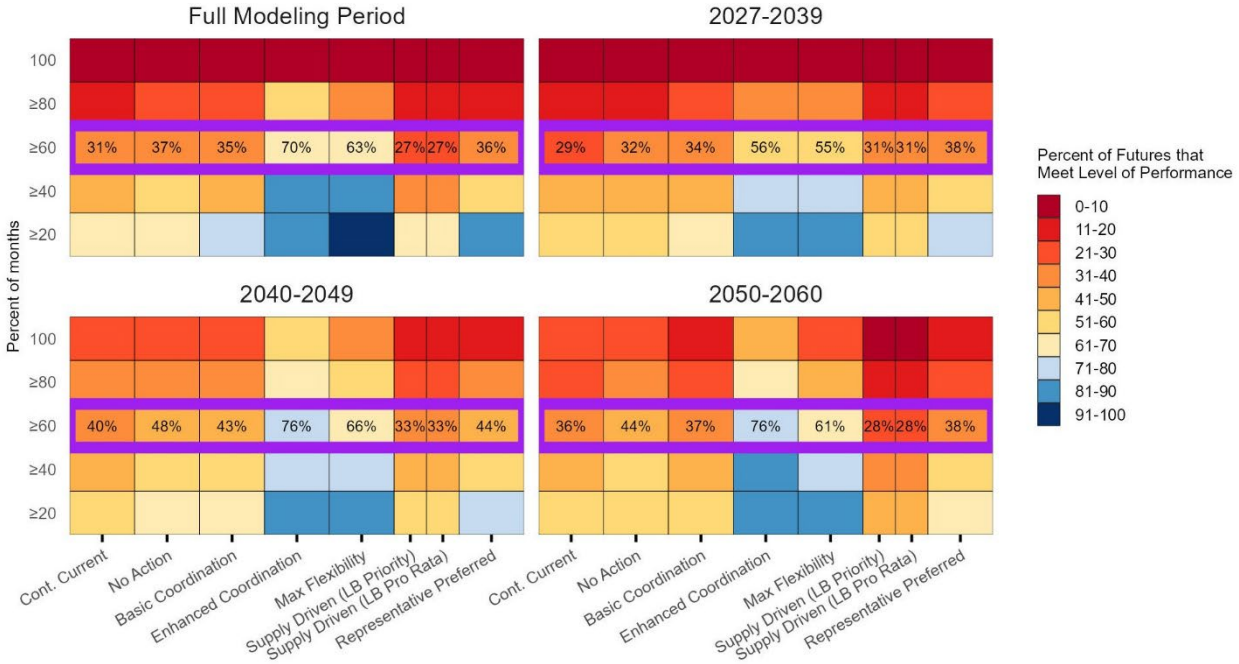
Lake Powell Recreation Sites: Robustness.
Percent of futures in which the proportion of open Lake Powell sites stays above the value specified by each row in every summer month (May 31 – August 31)

In the later subperiods (2040-2049 and 2050-2060), all alternatives show improved performance in maintaining the 60 percent threshold. This is likely attributed to the preferred standard being easier to meet over shorter timespans than over the full 34 years, and also because these subperiods are further removed from the present dry initial conditions. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust at meeting the preferred minimum performance, doing so in 75 percent and 58 percent of futures, respectively, in 2040-2049, and 70 percent and 50 percent of futures, respectively, in 2050-2060. This is considerably more robust than the other alternatives. While these alternatives demonstrate comparatively greater robustness, even their improved performance does not eliminate the risk of access limitations and associated declines in reservoir boating experience under lower reservoir elevations.

Figure TA 14-2 below depicts the performance of each alternative with regard to maintaining Lake Powell above an elevation of 3,620 feet, which corresponds to the elevation required for safely navigating the Castle Rock Cut. The figure is divided into four heat maps, each showing a different time period across the analysis. Rows of the heat map show different frequency ranges (percent of months) for keeping Lake Powell above an elevation of 3,620 feet. The highlighted row shows the percentage of futures that an alternative achieves in maintaining Lake Powell above this elevation in 20 percent or more of months. This row was chosen to be highlighted because, from October 2007 through May 2025, Lake Powell was at or above 3,620 feet in 24.5 percent of months.

Figure TA 14-2
Lake Powell Boating Hazards: Robustness.
Percent of futures in which the elevation of Lake Powell is at least 3,620 feet in the percent of months specified by each row



The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust at maintaining or exceeding a Lake Powell elevation of 3,620 feet in 20 percent or more of months over the full modeling period, as shown in the upper-left heat map. These alternatives perform similarly to one another, doing so in 82 percent and 80 percent of futures, respectively. Over the full modeling period, the Basic Coordination, No Action, and Representative Preferred Alternatives perform similarly, succeeding in 55 percent, 58 percent, and 61 percent of futures, respectively. These alternatives are slightly more robust than the Continued Current Strategies (CCS) Comparative Baseline and the Supply Driven Alternative (both Lower Basin Priority [LB Priority] and Lower Basin Pro Rata [LB Pro Rata] approaches), which only meet the preferred minimum performance in 49 percent and 40 percent of futures across the full modeling period, respectively.

Across the full modeling period, all alternatives exhibit poor performance for the upper rows. Under all alternatives, projected Lake Powell elevations for much of the analysis period would be below the critical threshold for safely navigating the Castle Rock Cut. This would result in a reduction in the quality of or the loss of reservoir boating opportunities on Lake Powell. Under all alternatives, dock access would continue to be unavailable from the Rainbow Bridge National Monument shoreline, which would continue until a long-term access solution is developed. Similarly, under all alternatives, projected Lake Powell elevations for much of the analysis period would be below the critical threshold for the Charles Hall Ferry, which would therefore be unable to operate.

Based on the planned length of this decision, it is important to compare robustness in the 2027–2039 modeling period. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust, meeting the preferred minimum performance level in 82 and 80 percent of futures, respectively. The No Action, Basic Coordination, and Representative Preferred Alternatives perform similarly, meeting the preferred minimum performance level in 55 to 61 percent of futures. The CCS Comparative Baseline and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are less robust, meeting the preferred minimum performance level in 49 and 40 percent of futures, respectively.

Figure TA 14-3 below depicts the performance of each alternative with regard to maintaining Lake Powell above an elevation of 3,590 feet, which corresponds to the critical threshold for most boat launch facilities. The figure is divided into four heat maps, each showing a different time period across the analysis. Rows of the heat map show different frequency ranges (percent of months) for keeping Lake Powell above an elevation of 3,590 feet. The highlighted row shows the percentage of futures that an alternative achieves in maintaining Lake Powell above this elevation in 60 percent or more of months. This row was chosen to be highlighted because it corresponds to approximately the 10th percentile from the historical analysis.

Figure TA 14-3
Lake Powell Boat Ramps 3,590 Feet: Robustness.
Percent of futures in which Lake Powell elevation is 3,590 feet or greater in the specified percent of months

The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust at maintaining or exceeding a Lake Powell elevation of 3,590 feet in 60 percent or more of months over the full modeling period, as shown in the upper-left heat map. These alternatives perform

similarly to one another, succeeding in 70 percent and 63 percent of futures, respectively. Over the full modeling period, the CCS Comparative Baseline, No Action, Basic Coordination, and Representative Preferred Alternatives perform similarly, succeeding in 31 percent, 37 percent, 35 percent, and 36 percent, respectively. These alternatives are slightly more robust than the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), which only meet the preferred minimum performance in 27 percent of futures.

Across the full modeling period, all alternatives exhibit poor performance for the upper rows. This suggests that challenges related to accessing existing Lake Powell boat ramps and associated impacts described above will continue under all alternatives.

Based on the planned length of this decision, it is important to compare robustness in the 2027–2039 modeling period. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust, meeting the preferred minimum performance level in 56 and 55 percent of futures, respectively, followed by the Representative Preferred Alternative at 38 percent. The No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives perform similarly, meeting the preferred minimum performance level between 31 and 34 percent of futures. The CCS Comparative Baseline is least robust, meeting the preferred minimum performance level in 29 percent of futures.

Figure TA 3-9 in **TA 3,** Hydrologic Resources, compares alternatives with respect to maintaining Lake Powell above an elevation of 3,525 feet. This elevation is important to recreation because it corresponds to the threshold that nearly all existing boat ramps become inaccessible. The purple highlighted row shows the percentage of futures that an alternative maintains Lake Powell above 3,525 feet in at least 90 percent of months. Please refer to this figure in **TA 3**, Hydrologic Resources.

In the Full Modeling Period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives can meet the preferred minimum level of performance in 80 percent and 72 percent of the modeled futures, respectively, which is considerably more robust than the other alternatives. The CCS Comparative Baseline and No Action Alternative are only able to meet the preferred minimum performance in 29 percent and 24 percent of futures, respectively. The Representative Preferred Alternative meets the preferred level of performance in 50 percent of modeled futures in the Full Modeling Period. For the more stringent performance standard of keeping Lake Powell above 3,525 feet in 100 percent of months, all alternatives and the CCS Comparative Baseline show poor levels of performance and can only meet the more stringent standard in 0-10 percent of futures.

Based on the planned length of this decision it is important to note that in the first subperiod (2027–2039) the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 72 percent and 64 percent of futures respectively. The CCS Comparative Baseline and Basic Coordination and Supply Driven (both LB Priority and Pro Rata approaches) Alternatives are similarly less robust meeting the preferred minimum performance in 34 percent, 38 percent, and 36 percent of futures respectively. The No Action Alternative is least robust meeting the preferred minimum performance in only 25 percent of futures in the first subperiod.

The Representative Preferred Alternative meets the preferred minimum performance level in 52 percent of futures in the first modeling period (2027–2039).

The alternatives meet the preferred minimum level of performance in greater percentages of futures in subperiods than the Full Modeling Period because the preferred standard is easier to meet over shorter timespans than over the full 34 years. Additionally, the observed data prior to modeling and the initial system state (2027 begins with relatively low reservoir elevations) cause worse performance in the first decade than the following two decades. The robustness ranking across the three alternatives in each subperiod is consistent with the ranking in the Full Modeling Period.

With respect to lower rows in the heatmap, which reflect lower percentages of years where Lake Powell elevation is above 3,525 feet, all alternatives improve.

Figure TA 3-7 in **TA 3,** Hydrologic Resources, compares alternatives with respect to maintaining Lake Powell above an elevation of 3,500 feet. This elevation is important to recreation because it corresponds to the threshold that nearly all planned extensions to boat ramps would become inaccessible. The purple highlighted row shows the percentage of futures that an alternative maintains Lake Powell above 3,500 feet in 100 percent of months. This was chosen as the preferred minimum performance level due to the importance of avoiding critical impacts on water deliveries and hydropower, which, although not directly related to recreation, also aligns with a key recreational infrastructure threshold. Please refer to this figure in **TA 3**, Hydrologic Resources.

In the Full Modeling Period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives can meet the preferred level of performance in 74 percent and 86 percent of the modeled futures, respectively, which is considerably more robust than the other alternatives. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are the least robust and are only able to meet the preferred minimum performance in 18 percent, 4 percent, 13 percent, and 18 percent of futures, respectively.

Based on the planned length of this decision, it is important to note that in the first modeling period (2027–2039) the Enhanced Coordination and Maximum Operational Flexibility Alternatives are most robust, achieving the preferred minimum level of performance in 81 percent and 94 percent of futures respectively. The Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative and the CCS Comparative Baseline are less robust meeting the preferred minimum performance in 35 percent and 30 percent of futures respectively. The No Action and Basic Coordination Alternatives are least robust in the first modeling period meeting the preferred minimum performance in only 4 percent and 19 percent of futures respectively.

In the three subperiods, the alternatives meet the preferred minimum level of performance in greater percentages of futures because the preferred standard is easier to meet over shorter timespans than over the full 34 years. Additionally, the observed data prior to modeling and the initial system state (2027 begins with relatively low reservoir elevations) cause worse performance in the first decade.

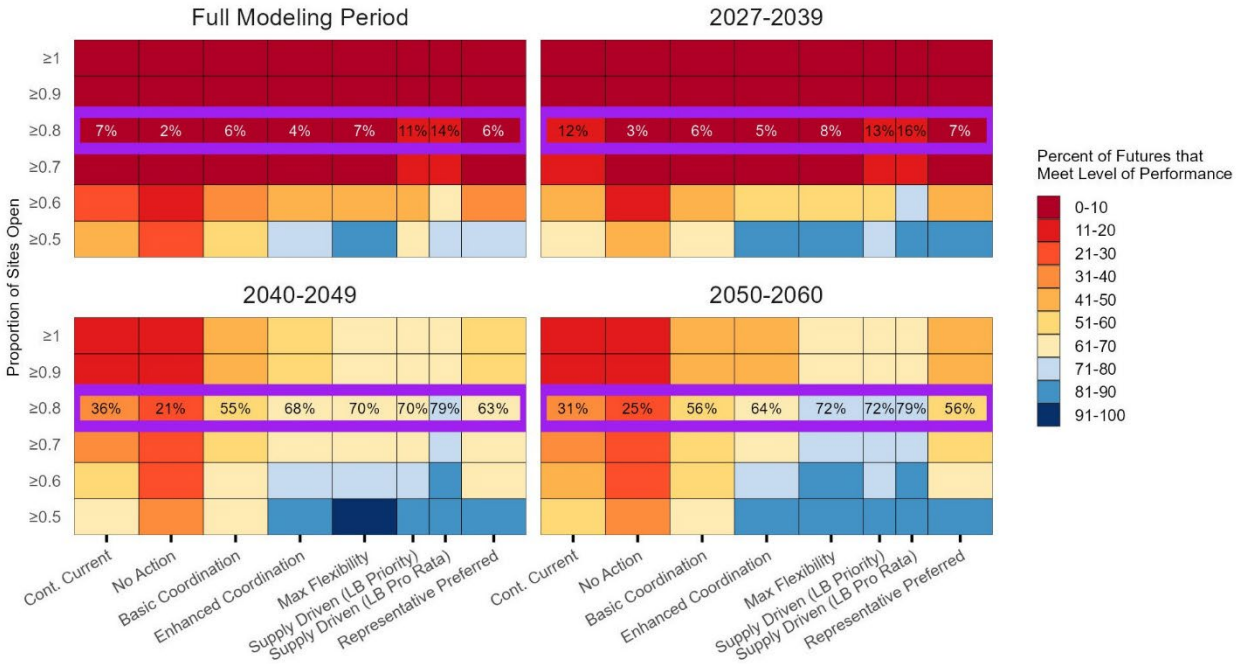
In the lower rows of the heat maps, which reflect lower percentages of months where Lake Powell elevation stays above 3,500 feet, all alternatives improve.

The Representative Preferred Alternative meets preferred level of performance in 40 percent of modeled futures in the Full Modeling Period. Based on the planned length of this decision, it is

important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 58 percent of futures in the first modeling period (2027–2039).

These results indicate a substantial risk that reservoir elevations would drop below the thresholds required for the planned boat ramp extensions to function, particularly over the next decade. This suggests that even with planned infrastructure improvements, access could remain constrained or, in some cases, unavailable without additional modifications to support operations at elevations below 3,500 feet. As a result, Lake Powell reservoir boating access may be intermittent and concentrated at a limited number of locations.

Sportfishing



There are no specific reservoir elevation thresholds or river stages related to sportfishing identified from the literature reviewed. Catch rates for reservoir fishing are assumed to be directly related to reservoir habitat. Generally, lower reservoir elevation also reduces lake habitat for sportfish, which may have a negative impact on recreational sportfishing. Higher lake levels tend to favor popular sportfish, like largemouth bass, bluegill, and crappie, whereas lower levels favor smallmouth bass (Gustaveson 2018). The general trend for the alternatives indicates that the Maximum Operational Flexibility and Enhanced Coordination Alternatives have higher, less variable results centered around 3,600 feet, while the Supply Driven (both LB Priority and LB Pro Rata approaches), Basic Coordination, No Action, and Representative Preferred Alternatives, and the CCS Comparative Baseline, have median elevations around 3,560 feet. Therefore, the Maximum Operational Flexibility and Enhanced Coordination Alternatives would likely be more beneficial for reservoir sportfishing.

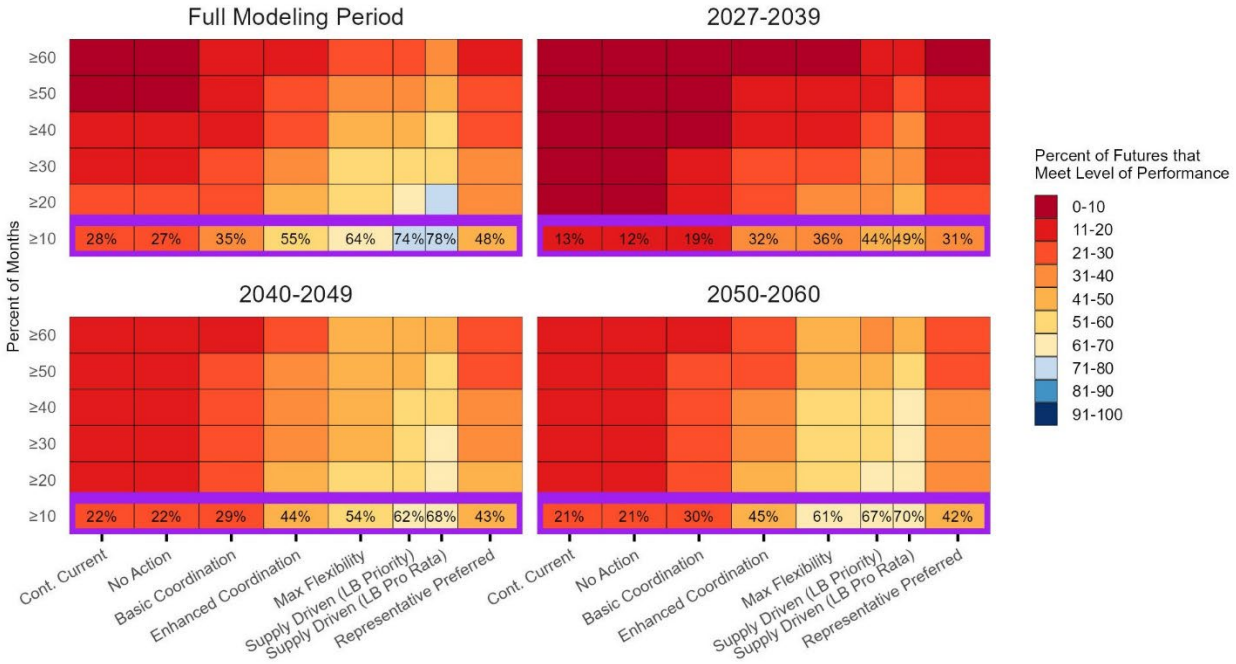
Lake Mead

Table TA 14-6 identifies the threshold elevations below which shoreline recreational facilities at Lake Mead could be affected. Below these elevations, facility adjustments or capital improvements would be required, potentially impacting recreation at Lake Mead. The analysis first examines the proportion of Lake Mead recreation sites that would remain open every summer month, then analyzes the performance of alternatives in maintaining Lake Powell elevations above 1,170 feet, which corresponds to the elevation required for avoiding most navigational hazards; 1,040 feet, the historic low elevation; and 1,000 feet, the elevation at which all existing boat ramp access would be lost.

Figure TA 14-4 below depicts the performance of each alternative with regard to keeping a specified proportion of Lake Mead recreational sites open over every summer month, which corresponds to peak visitation (May 31 – August 31). The figure is divided into four heat maps, each showing a different time period across the analysis. The highlighted row shows the percentage of futures in which an alternative achieves maintaining a 0.8 proportion of Lake Mead recreational sites open between May 31 and August 31. The 0.8 proportion row was highlighted because it corresponds to approximately the 10th percentile from the historical analysis that informed the thresholds.

Figure TA 14-4
Lake Mead Recreation Sites: Robustness.
Percent of futures in which the proportion of open Lake Mead sites stays above the value specified by each row in every summer month (May 31 – August 31)

Note: Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water)



Across the full modeling period, all alternatives exhibit poor performance at maintaining at least 80 percent of Lake Mead recreational sites open during the summer months, indicating that widespread reductions in recreation site availability are likely under a broad range of future conditions. The Supply Driven Alternative (LB Pro Rata approach) is the most robust at achieving the preferred minimum level of performance over the full modeling period but still does so in only 14 percent of modeled futures. The Supply Driven (LB Priority approach) performs similarly, succeeding in 11 percent of futures. All other alternatives perform at or below these levels. The Maximum Operational Flexibility Alternative and CCS Comparative Baseline perform the same over the full modeling period, succeeding in 7 percent of modeled futures, while the Basic Coordination, Representative Preferred, Enhanced Coordination, and No Action Alternatives succeed in only 6 percent, 6 percent, 4 percent, and 2 percent of futures, respectively, over the full modeling period.

Based on the planned length of this decision, it is important to compare robustness in the 2027–2039 modeling period. The CCS Comparative Baseline and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative are most robust, meeting the preferred minimum performance level between 12 and 16 percent of futures. The Basic Coordination, Enhanced Coordination, Maximum Operational Flexibility, and the Representative Preferred Alternatives meet the preferred

minimum performance level in 6 percent, 5 percent, 8 percent, and 7 percent of futures, respectively. The No Action Alternative is least robust, meeting the preferred minimum performance level in 3 percent of futures. These results indicate that reduced access to Lake Mead recreation sites is likely to persist over the next decade. As site availability declines, use would be concentrated at fewer locations, contributing to increased congestion, limited parking, and reduced reliability of recreation opportunities.

Figure TA 14-5 depicts the performance of each alternative with regard to the percent of futures in which the Lake Mead elevation is 1,170 feet or above in the specified minimum percent of months across the full modeling period (2027–2060) and three subperiods. Rows of the heat map show different frequency ranges for keeping Lake Mead above this elevation for a specified percentage of months throughout the full modeling period. Lake Mead has not been at or above an elevation of 1,170 feet between October 2007 and May 2025; therefore, the 10 percent row was chosen to be highlighted.

Figure TA 14-5
Lake Mead Boating Hazards: Robustness.
Percent of futures in which the elevation of Lake Mead is at least 1,170 feet in the percent of months specified by each row

Note: Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water)

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust at maintaining or exceeding a Lake Mead elevation of 1,170 feet in 10 percent or more of months over

the full modeling period, as shown in the upper-left heat map. The LB Pro Rata and LB Priority approaches perform similarly to one another, doing so in 78 percent and 74 percent of futures, respectively. Over the full modeling period, performance is followed by the Maximum Operational Flexibility Alternative, the Enhanced Coordination Alternative, and the Representative Preferred Alternative, which succeed in 64 percent, 55 percent, and 48 percent of futures, respectively. The Basic Coordination Alternative, CCS Comparative Baseline, and No Action Alternative are the least robust at achieving the minimum level of performance, succeeding in 35 percent, 28 percent, and 27 of modeled futures, respectively.

Across the full modeling period, all alternatives exhibit poor performance in the upper rows. The analysis suggests that it is difficult to achieve a Lake Mead elevation above which boating navigational hazards would not occur.

Based on the planned length of this decision, it is important to compare robustness in the 2027–2039 modeling period. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is most robust, meeting the preferred minimum performance level in 44 percent (LB Priority approach) to 49 percent (LB Pro Rata approach) of futures. The Maximum Operational Flexibility Alternative meets the preferred minimum performance level in 36 percent of futures, followed closely by the Enhanced Coordination Alternative (32 percent) and Representative Preferred Alternative (31 percent). The CCS Comparative Baseline and the No Action and Basic Coordination Alternatives are less robust, meeting the preferred minimum performance level in 13, 12, and 19 percent of futures, respectively.

Figure TA 14-6 below depicts the performance of each alternative with regard to the percent of futures in which the Lake Mead elevation is 1,040 feet or above in the specified minimum percent of months across the full modeling period (2027–2060) and three subperiods. This elevation corresponds to the historical low Lake Mead elevation. Rows of the heat map show different frequency ranges for keeping Lake Mead above this elevation for a specified percentage of months throughout the full modeling period. The purple highlighted row shows the percentage of futures that an alternative maintains Lake Mead at or above 1,040 feet in at least 90 percent of months. This row was chosen to be highlighted because it corresponds to approximately the 10th percentile from the historical analysis.

The Supply Driven Alternative (LB Pro Rata approach) is the most robust at maintaining or exceeding a Lake Mead elevation of 1,040 feet in 90 percent or more of months over the full modeling period, doing so in 51 percent of futures. Over the full modeling period, performance is followed by the Enhanced Coordination, Supply Driven (LB Priority approach), Maximum Operational Flexibility, and Representative Preferred Alternatives, which succeed in 42 percent, 39 percent, 33 percent, and 27 percent of modeled futures, respectively. The Basic Coordination Alternative, CCS Comparative Baseline, and No Action Alternative exhibit the worst performance, succeeding in 22 percent, 16 percent, and 8 percent of modeled futures, respectively.

Based on the planned length of this decision, it is important to compare robustness in the 2027–2039 modeling period. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust, meeting the preferred minimum performance level in 22 percent

(LB Priority approach) to 28 percent (LB Pro Rata approach) of futures. The Maximum Operational Flexibility and Representative Preferred Alternatives both meet the preferred minimum performance level in 18 percent of futures, followed by the CCS Comparative Baseline (17 percent), Enhanced Coordination Alternative (16 percent), and Basic Coordination Alternative (12 percent). The No Action Alternative is least robust, meeting the preferred minimum performance level in 5 percent of futures. These results indicate a high likelihood that Lake Mead levels would fall below the historic low elevation over the next decade. Such conditions would constrain access at existing boat ramps, particularly those already operating near minimum functional elevations, potentially rendering some facilities inoperable. As access becomes more limited, this would result in impacts previously described above.

Figure TA 14-6
Lake Mead Boat Ramps: Robustness.
Percent of futures in which Lake Mead elevation is 1,040 feet or greater in the specified percent of months

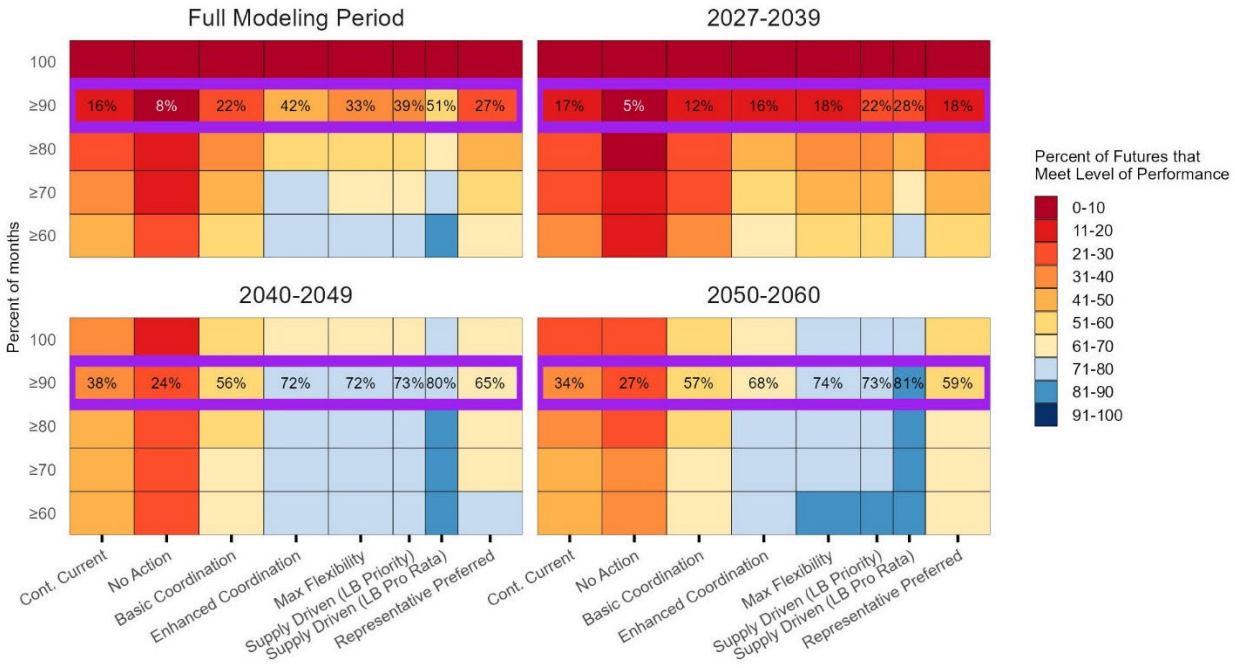


Figure TA 3-14 in **TA 3**, Hydrologic Resources, compares alternatives with respect to maintaining Lake Mead above an elevation of 1,000 feet. This elevation is important to recreation because it corresponds to the threshold that nearly all boat ramps would become inaccessible. The purple highlighted row shows the percentage of futures that an alternative maintains Lake Mead above 1,000 feet in 90 percent of months. Please refer to this figure and rationale for selection of this threshold as the preferred minimum level of performance in **TA 3**, Hydrologic Resources.

In the Full Modeling Period, the Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Supply Driven (LB Pro Rata approach) Alternatives are similarly robust, meeting the preferred minimum level of performance in 71 percent, 71 percent, 64 percent,

and 74 percent of futures, respectively. The CCS Comparative Baseline and No Action Alternative are the least robust, meeting the preferred minimum performance in 46 percent and 20 percent of futures, respectively.

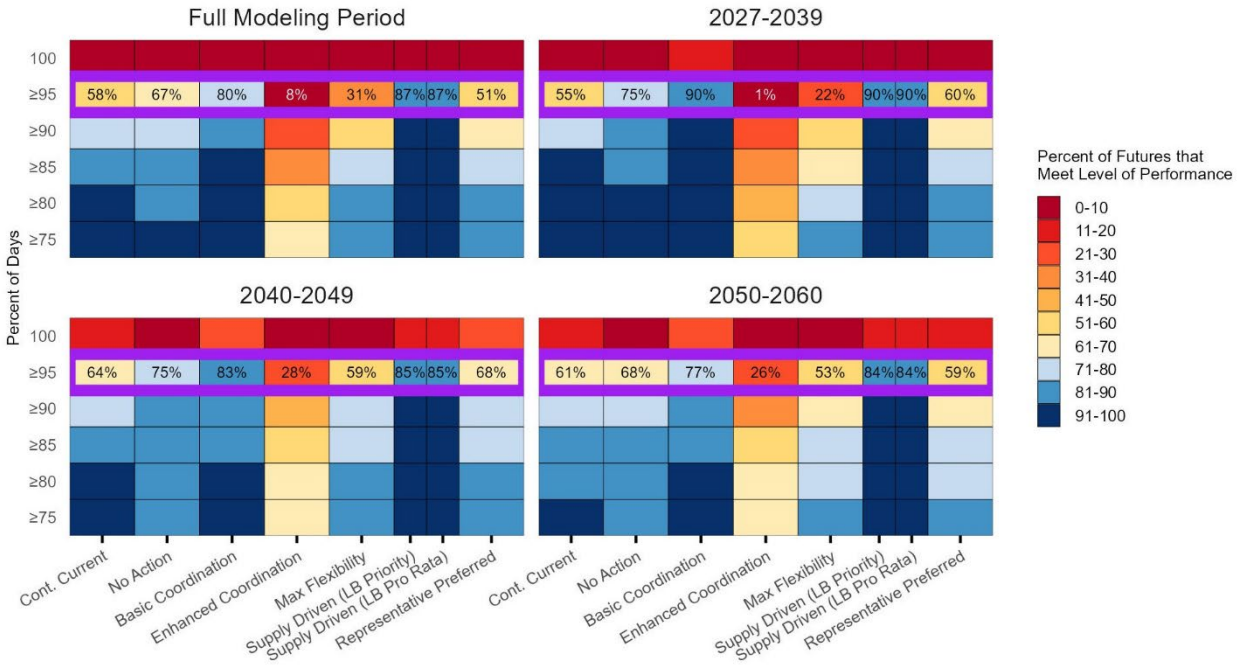
Based on the planned length of decision, it is important to note that in the first decade (2027–2039) Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Supply Driven (LB Pro Rata approach) Alternatives are similarly robust, meeting the preferred minimum level of performance in 70 percent, 67 percent, 64 percent, and 77 percent of futures respectively. The CCS Comparative Baseline and Basic Coordination Alternatives are somewhat less robust, meeting the preferred minimum performance in 54 percent and 55 percent of futures respectively. In the first modeling period, the No Action Alternative is the least robust, meeting the preferred minimum performance in 25 percent of modeled futures.

The Representative Preferred Alternative meets the preferred minimum level of performance in 63 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 62 percent of futures in the first modeling period (2027–2039).

In the three subperiods, the alternatives meet the preferred minimum level of performance in greater percentages of futures because the preferred standard is easier to meet over shorter timespans than over the full 34 years. Additionally, the observed data prior to modeling and the initial system state (2027 begins with relatively low reservoir elevations) cause worse performance in the first decade. The robustness ranking across the three alternatives in each subperiod is consistent with the ranking in the Full Modeling Period.

In the remaining modeled futures in which minimum performance is not achieved, reservoir elevations would fall below the levels required to sustain boat ramp operations, resulting in a complete loss of reservoir boating opportunities at Lake Mead. Such conditions would eliminate launching opportunities until water levels recover or additional infrastructure modifications are implemented, substantially constraining recreation access and use.

TA 14.2.4 Issue 2: How would the management of releases from Glen Canyon Dam affect recreation, including water temperature?



Whitewater Boating

River flow levels and fluctuations are important for whitewater boaters. The minimum daily flow levels of 8,000 cfs were set under the 2016 Glen Canyon Dam Long-Term Experimental and Management Plan Final EIS as the minimally adequate daytime levels for Grand Canyon boating. Levels lower than this may present increasing navigability challenges for the use of large (often 35 feet long) rafts equipped with motors. Extended low flows of 5,000 cfs would adversely affect navigability and trip management because of a greater risk of boating incidents. Commercial and private whitewater trip leaders have reported a preference for steady flows (flows that do not fluctuate by more than 10,000 cfs per day) in the 20,000-26,000 cfs range (Bishop et al. 1987; Neher et al. 2017); thus, there would likely be greater perceived value to rafters when flows are within this range. However, the historical and projected volume range under the alternatives may not align with

these preferences, and the exact impacts on recreation would continue to depend on water availability for releases.

Figure TA 14-7 depicts the performance of each alternative with regard to the percent of futures in which daytime flows (7 a.m. – 7 p.m.) below Glen Canyon Dam are at least 8,000 cfs in the specified percent of days over the full modeling period (2027–2060) and three subperiods. Rows of the heat map show different frequency ranges for keeping daytime flows above this threshold in the specified percentage of days throughout the full modeling period.

Figure TA 14-7
Whitewater Boating Below Glen Canyon Dam, 8,000 cfs: Robustness. Percent of futures in which daytime flows below Glen Canyon Dam are greater than or equal to 8,000 cfs in the percent of days specified by each row

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust at maintaining or exceeding daytime flows of 8,000 cfs below Glen Canyon Dam over the full modeling period, as shown in the upper-left heat map; succeeding in 87 percent of futures. The Basic Coordination Alternative achieves a similar robustness of 80 percent. Over the full modeling period, performance is followed by the No Action Alternative, which would succeed in 67 percent of futures, and the CCS Comparative Baseline, which would succeed in 58 percent of futures. The Representative Preferred Alternative would succeed in 51 percent of futures. The Maximum Operational Flexibility Alternative would succeed in 31 percent of futures, and the Enhanced Coordination Alternative would be the least robust, succeeding in only 8 percent of futures.

Based on the planned length of this decision, it is important to compare robustness in the 2027–2039 modeling period. The Supply Driven (both LB Priority and LB Pro Rata approaches) and Basic

Coordination Alternatives are the most robust, meeting the preferred minimum performance level in 90 percent of futures. The No Action Alternative meets the preferred minimum performance level in 75 percent of futures, and the Representative Preferred Alternative meets this performance level in 60 percent of futures. The CCS Comparative Baseline (55 percent) and Maximum Operational Flexibility Alternative (22 percent) are less robust. The Enhanced Coordination Alternative is least robust, meeting the preferred minimum performance level in 1 percent of futures.

In the remaining modeled futures in which minimum performance is not achieved, daytime flows would fall below the levels required to safely navigate the river for large rafts with motors. Such conditions would eliminate rafting opportunities for large group trips until water levels recover, substantially constraining recreation access and use.

Figure TA 14-8 depicts the performance of each alternative with regard to the percent of futures in which daytime flows (7 a.m. – 7 p.m.) below Glen Canyon Dam are at least 5,000 cfs in the specified percent of days over the full modeling period (2027–2060) and three subperiods. Rows of the heat map show different frequency ranges for keeping daytime flows above this threshold in the specified percentage of days throughout the full modeling period.

The Supply Driven (both LB Priority and LB Pro Rata approaches) and Enhanced Coordination Alternatives are the most robust at maintaining or exceeding daytime flows of 5,000 cfs below Glen Canyon Dam over the full modeling period, as shown in the upper-left heat map. These alternatives would succeed in 97 percent and 98 percent of futures, respectively. The Representative Preferred Alternative would succeed in 92 percent of futures. The CCS Comparative Baseline would succeed in 80 percent of futures across the full modeling period, followed by the Basic Coordination Alternative (79 percent), then the No Action Alternative (76 percent), and finally, the Maximum Operational Flexibility Alternative (33 percent).

Based on the planned length of this decision, it is important to compare robustness in the 2027–2039 modeling period. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is most robust, meeting the preferred minimum performance level in 100 percent of futures. The CCS Comparative Baseline, Enhanced Coordination Alternative, and Representative Preferred Alternative follow closely, meeting the preferred minimum performance level between 96 and 99 percent of futures. The No Action and Basic Coordination Alternatives are less robust, meeting the preferred minimum performance level in 92 and 94 percent of futures, respectively. The Maximum Operational Flexibility Alternative is least robust, meeting the preferred minimum performance level in 40 percent of futures. When flows are above 5,000 cfs, there would generally be fewer navigation challenges and boating incidents caused by a change in river levels. Minor changes in exposure to boating navigational hazards caused by a change in river velocity; changes in access or use of rest areas and take-out points; changes in trip duration caused by changes in river velocity; or the ability to use sportfishing sites caused by changes in flows, may occur under all alternatives.

Figure TA 14-8
Whitewater Boating Below Glen Canyon Dam, 5,000 cfs: Robustness.
Percent of futures in which daytime flows below Glen Canyon Dam are greater than or equal to 5,000 cfs in the percent of days specified by each row

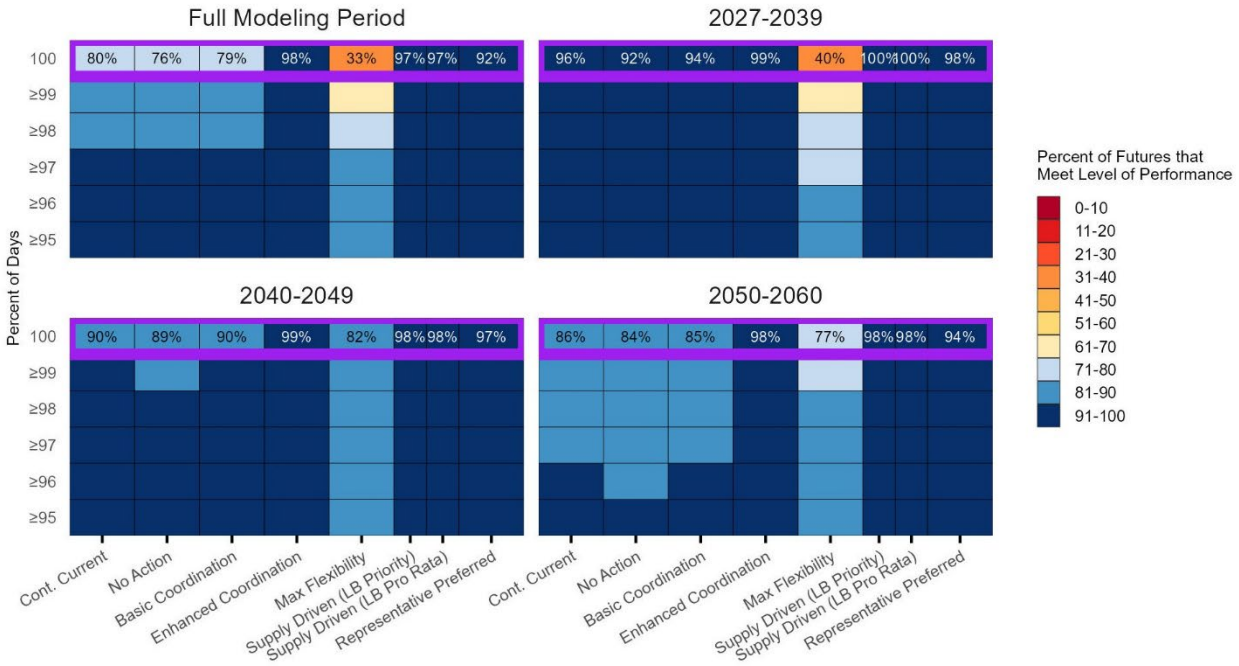


Figure TA 9-11 in **TA 9**, Vegetation Including Special Status Species, depicts arrowweed suitable habitat under each alternative by Grand Canyon sub-reach. Please refer to this figure in **TA 9**, Vegetation Including Special Status Species. Across all three reaches, all alternatives show similar trends. Under the Average Flow Category, the median for each alternative overlaps or nearly overlaps the modeled historic conditions, and the interquartile conditions are relatively small. This suggests that arrowweed suitable habitat may be similar to historic conditions under the Average Flow Category.

Across all three sub-reaches, under the Wet Flow Category and Moderately Wet Flow Category, the median and interquartile ranges are below the modeled historic conditions for all alternatives except for interquartile ranges of the No Action Alternative and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) in the Moderately Wet Flow Category. This suggests that there would be less arrowweed suitable habitat under the Wet and Moderately Wet Flow Categories under all sub-reaches and all alternatives. Under the Dry Flow Category, the median and interquartile ranges are above historic conditions (dashed line), for all alternatives except the CCS Comparative Baseline and Enhanced Coordination Alternatives. Under the Critically Dry Flow Category the median and interquartile ranges are above the modeled historic conditions for all sub-reaches and all alternatives except for the CCS Comparative Baseline, although the median remains above historic conditions. This indicates that there may be more arrowweed suitable habitat under Critically Dry Flow Category for all alternatives across all sub-reaches.

These results indicate that in futures with drier flow category conditions, there may be more arrowweed suitable habitat, which would further encroach on available campsite areas within the Grand Canyon compared to under the average or wet flow categories.

Sportfish Populations

While different water temperature thresholds were considered for native and invasive fish species, this section focuses on impacts on the rainbow trout fishery at Lees Ferry. Water temperatures exceeding 20 °C (degrees Celsius; 68 °F [degrees Fahrenheit]) can cause thermal stress and mortality of rainbow trout while creating conditions more favorable for the growth of nonnative fish and smallmouth bass. Additionally, warmer water temperatures may increase the competitive advantage for brown trout, as this species is more tolerant of elevated temperatures. The percentage of futures for each alternative in which water temperature at Lees Ferry exceeds 20 °C (68 °F) is presented in **Figure TA 8-10** under **TA 8**, Biological Resources – Fish and Other Aquatic Resources.

Over the full modeling period, the Enhanced Coordination Alternative is the most robust, meeting the preferred minimum performance level in 56 percent of futures. The Maximum Operational Flexibility Alternative performs lower than the Enhanced Coordination Alternative at 47 percent but still performs substantially better than the remaining alternatives. The No Action Alternative and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) perform similarly and are the least robust, meeting the preferred minimum performance level in 12 to 18 percent of futures and performing similarly to the CCS Comparative Baseline. Decadal comparisons of robustness reveal similar rankings among the alternatives. Robustness scores tend to be lowest in 2027 due to the low initial reservoir conditions in 2027. Robustness is highest after 2040, with the best-performing alternatives—the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative—nearing or exceeding 80 percent in meeting the preferred minimum performance threshold.

The Representative Preferred Alternative meets the preferred minimum performance level robustness criteria in 20 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Enhanced Coordination (62 percent) and Maximum Operational Flexibility (60 percent) Alternatives are the most robust. The remaining action alternatives (including the Representative Preferred Alternative) and the CCS Comparative Baseline are similarly less robust (27-36 percent). The No Action Alternative is the least robust (19 percent).

Alternatives that support higher Lake Powell elevations and greater river flows generally perform better at maintaining cooler water temperatures. However, under extended drought (low average flows and lower Lake Powell elevation), all alternatives become more vulnerable to undesirable temperature increases, affecting fish habitat and species composition. Please refer to **TA 8**, Biological Resources – Fish and Other Aquatic Resources, Issue 2, for more detailed information on changes in water temperature and quality from Glen Canyon Dam downstream through the Grand Canyon to Pearce Ferry and impacts on rainbow trout, native Grand Canyon fishes, and nonnative predatory fish.

TA 14.2.5 Summary Comparison of Alternatives

The alternatives vary in their potential to affect recreational resources, including shoreline public use facilities, reservoir boating, river and whitewater boating, and sportfishing. The general trend for the alternatives indicates that the Maximum Operational Flexibility and Enhanced Coordination Alternatives have higher, less variable Lake Powell reservoir elevations; therefore, these alternatives would likely be more beneficial for all Lake Powell recreational activities. The general trend for the alternatives indicates the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has higher, less variable Lake Mead reservoir elevations, followed by the Maximum Operational Flexibility and Enhanced Coordination Alternatives; therefore, these alternatives would likely be more beneficial for all Lake Mead recreational activities. The Representative Preferred Alternative generally performs in the middle of the range of alternatives for both Lake Powell and Lake Mead elevations, showing moderate robustness but not outperforming the top-performing option.

However, across the full modeling period, all alternatives have poor levels of performance for maintaining higher elevations for a greater percentage of futures. Under all alternatives, projected Lake Powell and Lake Mead elevations for much of the analysis period would be below the critical thresholds for most boat launch facilities and safe boat navigation, which would result in a reduction in the quality of or the loss of reservoir boating opportunities.

Under the Basic Coordination Alternative, projected flows would be the highest in the Critically Dry Flow Category; however, river flows generally decrease as flow categories get drier. Higher flows would generally yield the greatest benefits to whitewater boating in the Grand Canyon. The Enhanced Coordination and the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are the most robust at achieving daytime flows of 5,000 cfs or greater, which is above the safe whitewater boating minimum for large, motorized watercraft. Again, the Representative Preferred Alternative generally performs in the middle of the range of alternatives, showing moderate robustness. The Enhanced Coordination Alternative is the most robust at maintaining cooler water temperatures at Lees Ferry, which would confer the greatest benefits to the rainbow trout fishery.

TA 15. Dams and Electrical Power Resources

TA 15.1 Affected Environment

This section provides an overview of the four primary dams and reservoirs in the analysis area of the Colorado River corridor from the full pool elevation of Lake Powell to the Southerly International Boundary: Glen Canyon Dam/Lake Powell, Hoover Dam/Lake Mead, Davis Dam/Lake Mohave, and Parker Dam/Lake Havasu. This section provides the context for analyzing the effects of the alternatives on the electrical power capacity and spillway use of Glen Canyon Dam and Hoover Dam, and the power generation at all four dams. This section also provides the context for analyzing the effects of the alternatives on electricity rates.

Other, smaller dams and hydroelectric facilities in the analysis area include Headgate Rock, Senator Wash, Siphon Drop, and Pilot Knob. Changes to these smaller dams and their associated reservoirs are not being proposed in any of the alternatives, and due to the nature of their operations, there are no anticipated substantial effects on the electrical power capacity, generation, spillway, or safety of these dams nor are there any anticipated substantial effects relative to their electricity rates nor the economic value of the power they produce from the alternatives.

The Bureau of Reclamation (Reclamation) operates and maintains the Glen Canyon, Hoover, Davis, and Parker Dams. The Western Area Power Administration (WAPA) is responsible for marketing and transmitting the power generated at these facilities across the Colorado River Basin (Basin; Reclamation 2007a). As established in the 1922 Colorado River Compact, the Upper Colorado River Basin (Upper Basin) consists of the states of Colorado, New Mexico, Utah, and Wyoming; the Lower Colorado River Basin (Lower Basin) consists of the states of Arizona, California, and Nevada; and Lee Ferry is considered the dividing point between the two basins. Lee Ferry is located 1 mile below the mouth of the Paria River in Arizona. The Colorado River Compact established that each basin would receive 7.5 million acre-feet (maf) of water annually. In 1956, the Colorado River Storage Project Act of 1956 (CRSPA) outlined Upper Basin water storage and management processes to facilitate the apportionment of water in the Upper Basin and the delivery of water to the Lower Basin. This water storage system called for the building of four dams, with Glen Canyon Dam and Lake Powell reservoir serving as the primary water storage infrastructure for the Upper Basin.

TA 15.1.1 Hydropower Generation and Capacity Overview

Hydropower generation occurs when water stored in a reservoir passes through a turbine, which converts the energy of the falling water to mechanical energy, which is then converted to electricity as the turbine turns the rotors in the generating units. The amount of electrical power generated is directly related to the amount of water passing through the turbines and the force, or "head," of the water as it moves through the turbines. The higher the reservoir elevation, the more head the water

can exert when passing through the turbines. Capacity is mainly affected by the depth of the reservoir and the number of generators.

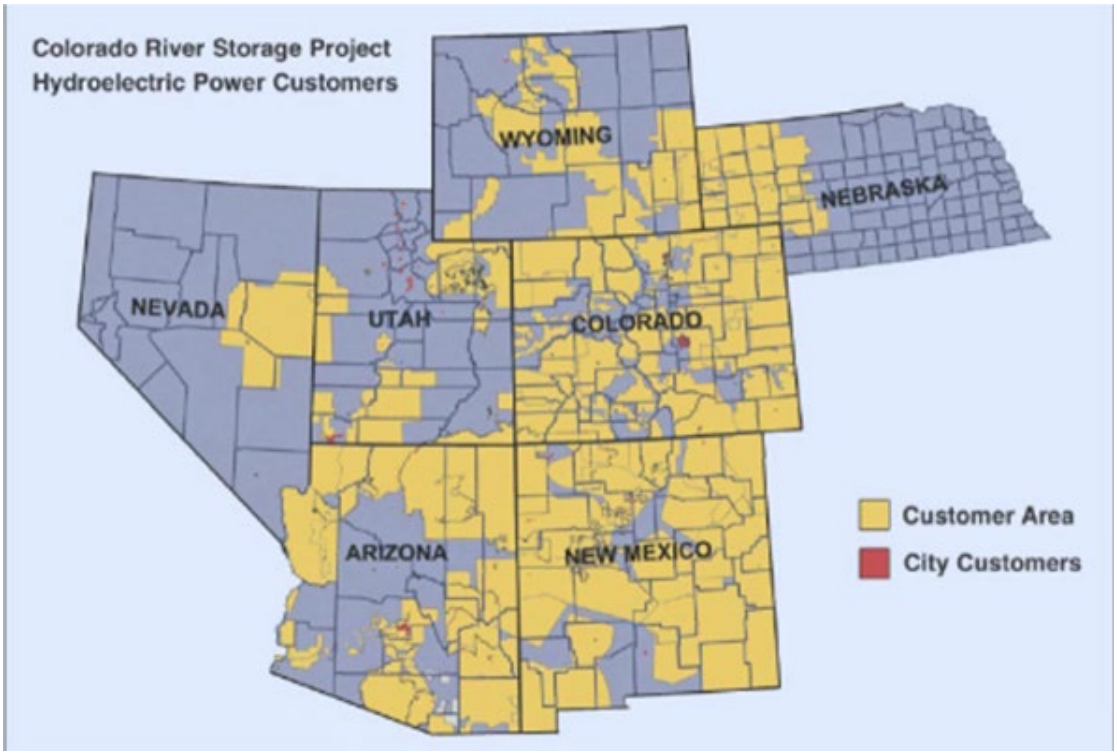
Power generation has two main measurable components: power and energy. Power is the rate at which energy is transferred or consumed, or the amount of electricity produced at a specific time and is measured in megawatts (MW). Energy is the amount of power generated over time and is measured in megawatt hours (MWh). Capacity is the maximum power that can be produced at a specific moment. The physical capacity of a powerplant is the maximum power that results from generator and turbine capacity and reservoir levels. Firm capacity is the reliable, guaranteed amount of power output from a powerplant that accounts for operational constraints such as water releases and ramp rates[1]. Physical and firm capacity are measured in MW. This affected environment portion of this technical appendix describes the physical capacity of the Glen Canyon and Hoover Powerplants, and the environmental consequences portion analyzes the effects of the alternatives on the firm capacity of these powerplants as firm capacity takes into account all of the conditions that WAPA and Reclamation use for operational decisions.

Additional information on power generation, control, regulation, reserves, and ramping can be found in the Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead Final Environmental Impact Statement (2007 Final EIS) Section 3.11.1.1 (Reclamation 2007a); and that information is incorporated here by reference.

TA 15.1.2 Hydropower Marketing and Administration Overview

WAPA markets power and administers power contracts for electricity generated from the dams that are specific to each of the hydropower projects. WAPA sets power rates every few years for each hydropower project. The rates cover the operating costs of WAPA and those of the hydropower project (WAPA 2025a). WAPA power sales and transmission operations are organized by region with Glen Canyon Powerplant operating within the Colorado River Storage Project (CRSP) region and Hoover, Parker, and Davis Powerplants operating within the Desert Southwest Region. WAPA bundles and markets power to a variety of entities including: small and medium-sized municipalities that operate publicly owned utilities; irrigation cooperatives and water conservation districts; rural electrical associations; generation and transmission co-operatives; federal facilities; universities; state agencies; and tribes (Reclamation 2016a) across the following states: Nebraska, Wyoming, Utah, Nevada, Colorado, California, Arizona, and New Mexico.

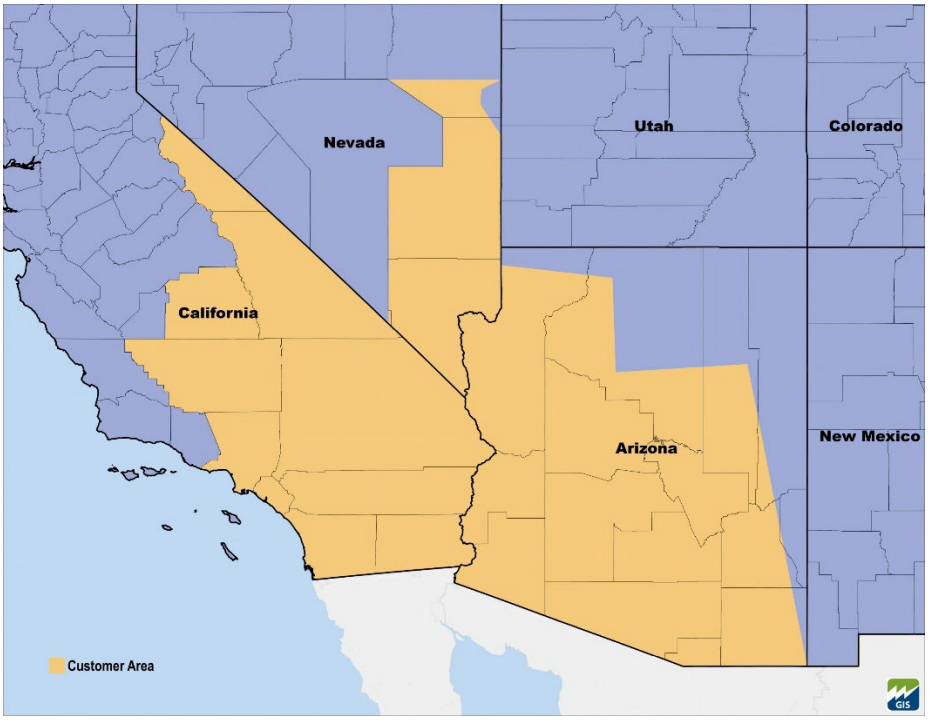
WAPA distributes the power through four types of contracts that are classified as: long-term firm power and other long-term sales; non-firm energy and short-term sales and purchases; seasonal power sales; and purchase power (WAPA 2025a). Firm power contracts guarantee the capacity and energy that will be available 24 hours a day and non-firm contracts come without a guarantee of continuous availability (WAPA 2025a). Firm and non-firm contracts can be short- or long-term.



The contracts for Glen Canyon Dam power are effective 2024 through 2057 (WAPA 2023). There are more than 100 customers for Glen Canyon Dam power, and they provide electricity within the states of Wyoming, Utah, Colorado, New Mexico, Arizona, Nevada, and Nebraska. WAPA markets

[1] The ramp rate is the rate of change in instantaneous output from a powerplant. The ramp rate is established to prevent undesirable effects due to rapid changes in loading or discharge.

Hoover Dam generated power to 46 customers and Parker Dam and Davis Dam generated power to 36 customers within southern Nevada, Arizona, and southern California. Hoover Dam power is marketed as a long-term contingent capacity contract with associated energy. This means that WAPA is obligated to deliver the energy that can be generated from the available capacity. The new contracts for Hoover Dam took effect on October 1, 2017, and expire on September 30, 2067. The Parker Dam and Davis Dam power is marketed as long-term, firm contracts. Contracts for the Parker Dam and Davis Dam were signed prior to 2007 and terminate in 2028. WAPA anticipates signing new contracts that will replace the expiring contracts.



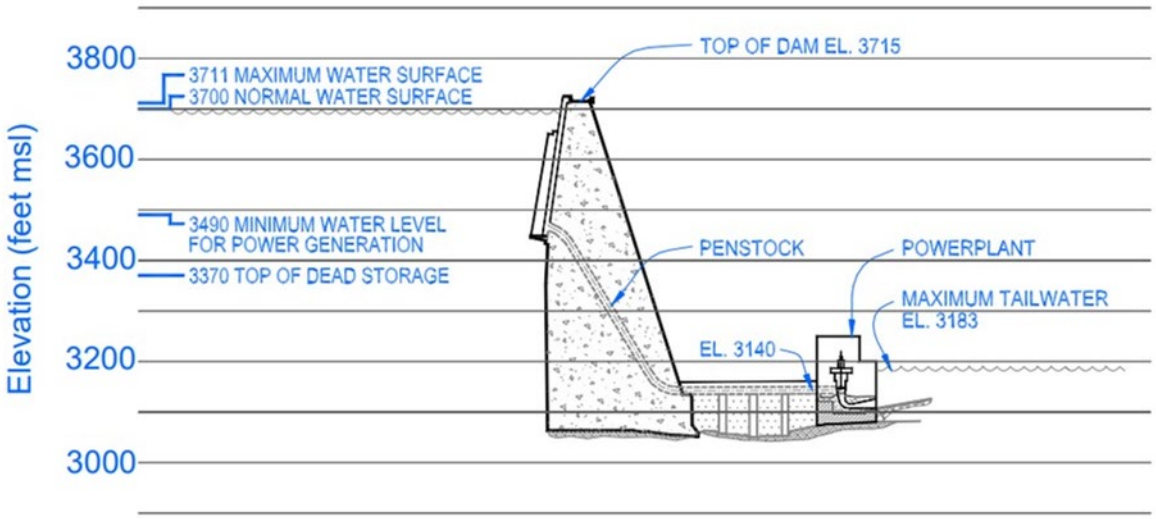
The Basin is within what is referred to as the Western Interconnection region of the Western Electricity Coordinating Council (WECC). The WECC is a regional, non-profit corporation that oversees bulk electrical system reliability planning and assessment. The Western Interconnection area includes two Canadian provinces, 14 western states, and the northern United Mexican States (WECC 2025). The Glen Canyon, Hoover, Parker, and Davis Powerplants account for approximately 2.2 percent of the total electrical capacity within the Western Interconnection region. **Figure TA 15-1** identifies the CRSP hydroelectric power customers located within the Western Interconnection, illustrating the geographic distribution of entities that receive power generated from Basin facilities. Similarly, **Figure TA 15-2** shows WAPA's Desert Southwest Region's service area map which provides electric service to customers in Arizona, southern California, and southern Nevada.

Figure TA 15-1
CRSP Hydroelectric Power Customers

Note: Glen Canyon Dam is a feature of CRSP.

Figure TA 15-2
Desert Southwest Region Hydroelectric Power Customers

Note: Hoover, Parker, and Davis Dams are features of the Desert Southwest Region.



TA 15.1.3 Infrastructure Conditions and Hydroelectric Power Generation and Capacity

This section provides an overview of the infrastructure conditions of the Glen Canyon Dam/Lake Powell reservoir, the Hoover Dam/Lake Mead reservoir, Davis Dam/Lake Mohave reservoir, Parker Dam/Lake Havasu reservoir, and their hydropower capacity and generation.

Glen Canyon Dam/Lake Powell

Glen Canyon Dam is located in Page, Arizona and is a concrete arch dam rising 710 feet with a 35-foot-wide roadway connecting the dam's spillways, see **Figure TA 15-3**. The dam's reservoir, Lake Powell, has a water storage capacity of 25.16 maf and a maximum reservoir elevation of 3,711 feet. The dam and reservoir are operated and maintained by Reclamation's Glen Canyon Field Division in Page, Arizona.

Figure TA 15-3
Lake Powell and Glen Canyon Dam Important Operating Elevations

Water Releases and Operational Considerations

During normal operating conditions, water is released from Glen Canyon Dam through the Glen Canyon Powerplant through intakes on the upstream face of the dam. Eight, 15-foot steel penstocks convey water to the powerplant turbines through an elevation drop of 330 feet to a centerline elevation of 3,140 feet. Water cannot be released from the penstocks below a Lake Powell elevation of 3,490 feet (which is known as the minimum power pool and is 20 feet above the penstock intake centerline). At an elevation of 3,490 feet, it is estimated that vortex formation would begin to occur at the powerplant. As described in **Section 1.8.4.1**, there are also infrastructure concerns associated with the uncertainty of extended operations through the river outlet works as the sole means of sustained water releases from Glen Canyon Dam that could compromise the reliability and operational flexibility of Glen Canyon Dam and affect the ability to meet critical downstream water supply needs. Releases in excess of powerplant capacity are made when flood conditions are caused by high runoff in the Upper Basin or when high-flow experiments (HFEs) are triggered downstream. Historically, these releases are well above 3,490 feet. However, HFEs can be conducted down to an elevation of 3,500 feet.

Four, 96-inch steel pipes comprise the river outlet works at a centerline elevation of 3,374 feet. The outlets have a maximum combined capacity of 15,000 cubic feet per second (cfs) at elevation 3,500 feet. Below 3,500 feet the capacity decreases. Below minimum power pool, the outlet works are the sole means of releasing water. An annual release of 8.23 maf equates to a continuous flow of up to 11,368 cfs. With all four outlets operational, this release can be maintained down to approximately elevation 3,440 feet, however, operations and maintenance constraints may limit these releases or the elevation. Since the construction of Glen Canyon Dam, the river outlet works are typically reserved for flood control, HFEs, augmenting powerplant and spillway discharges, or for periods when the powerplant is not operating.

Dam operations are managed to maintain the water surface elevation near or below 3,700 feet, which is the normal operating level. Operational preference is to maintain a water surface elevation below the top of active conservation, 3,700 feet, to minimize the occurrence of flood operations and the need for additional monitoring. Glen Canyon Dam is designed to safely accommodate the probable maximum flood including operating up to the maximum water surface elevation of 3,711 feet.

Another important operational consideration is maintaining adequate vacant storage around elevation 3,684 feet on January 1, which provides necessary capacity for managing inflows from spring runoff.

In 1983, heavy late-winter mountain snow accumulation within the Basin created 150 percent of normal runoff, causing the first real use of the Glen Canyon spillway. High, extended releases through the spillways (up to 27,000 cfs from the right spillway and 32,000 cfs from the left) caused serious cavitation damage within the tunnel, particularly in the vertical bends. Cavitation is the formation of vapor cavities in a liquid. As the vapor cavities move into a zone of higher pressure, they collapse, sending out destructive high pressure shock waves (Reclamation 2019). The 1983 damage led to the installation of 4-by-4-foot air slots in the spillways to prevent future cavitation damage by introducing air into the water flow.

Current Condition

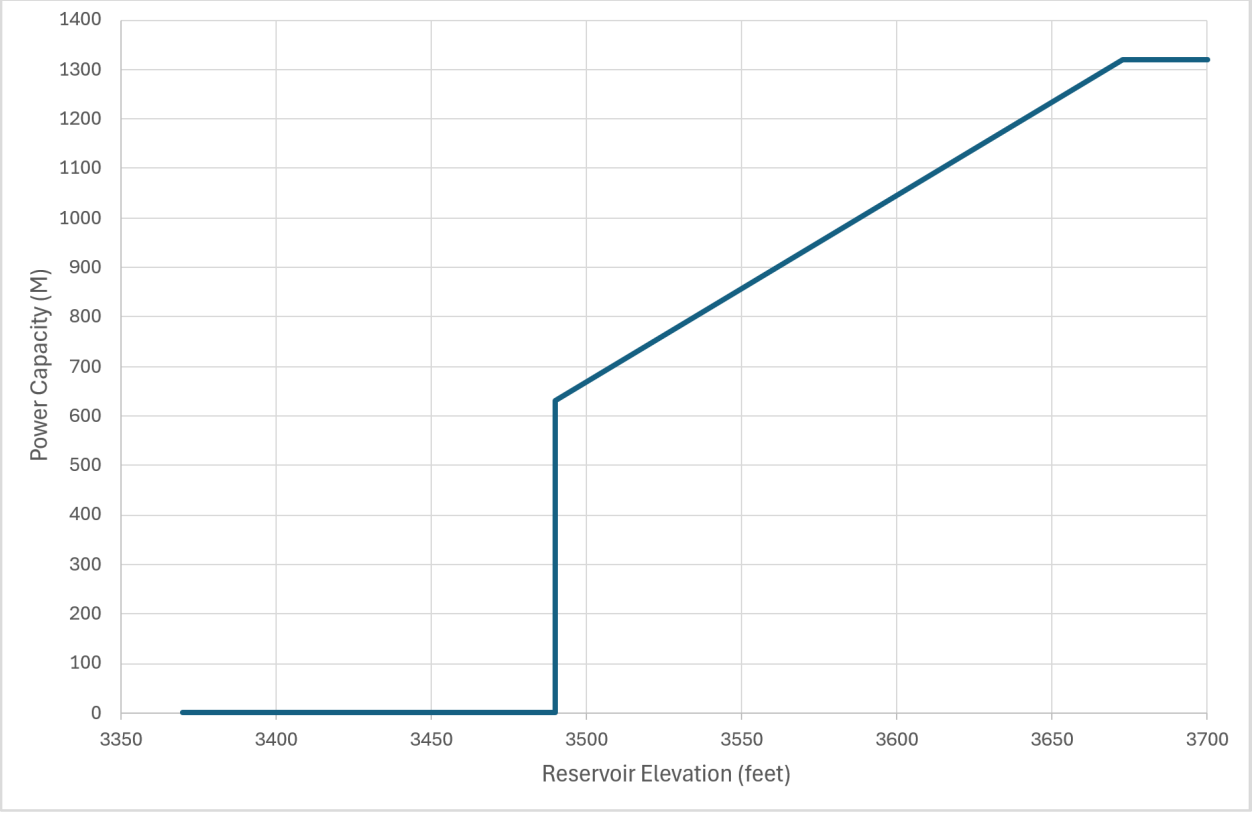
Reclamation, utilizing the Dam Safety Priority Rating (DSPR) system, evaluated Glen Canyon Dam and gave it a DSPR 5 category rating. This is Reclamation's lowest-priority rating from a dam-safety risk standpoint, indicating the facility poses the lowest risk to the public. The total mean annualized failure probability of static, hydrologic, and seismic risks to the dam is 3 orders of magnitude below Reclamation's Public Protection Guideline.

Maintenance tasks for the river outlet works include lining repairs and hollow-jet valve maintenance. The interior of the river outlet works was originally lined with coal tar enamel. Relining of the river outlet works with solvent borne epoxy began in the fall of 2024. The fabrication of the river outlet works hollow-jet valves dates back to the original construction of the dam, with no rehabilitation since that time. In 2023, an inspection of the outlet works found that to continue long-term operation of the outlet works, major repairs or replacement of the hollow-jet valves should be considered, as well as increasing the frequency of regular operation and maintenance tasks. River outlet works conduits were relined between 2024 and 2025. Refurbishment or replacement of the hollow jet valves is in the planning stages.

Operations

The operating criteria for Glen Canyon Dam were published in 1997. The Glen Canyon Powerplant operating regime was modified with the 2016 Glen Canyon Dam Long-Term Experimental and Management Plan (LTEMP) Record of Decision (ROD), which establishes guidelines for allocating annual release volumes and defines a minimum water release rate of 8,000 cfs or more between 7:00 a.m. and 7:00 p.m., and at least 5,000 cfs between 7:00 p.m. and 7:00 a.m.; the maximum hourly increase (that is, the up-ramp rate) of 4,000 cfs per hour; a daily fluctuation limit of 8,000 cfs per 24-hour period; and a water maximum release rate of 25,000 cfs (Reclamation 2016b). The 2016

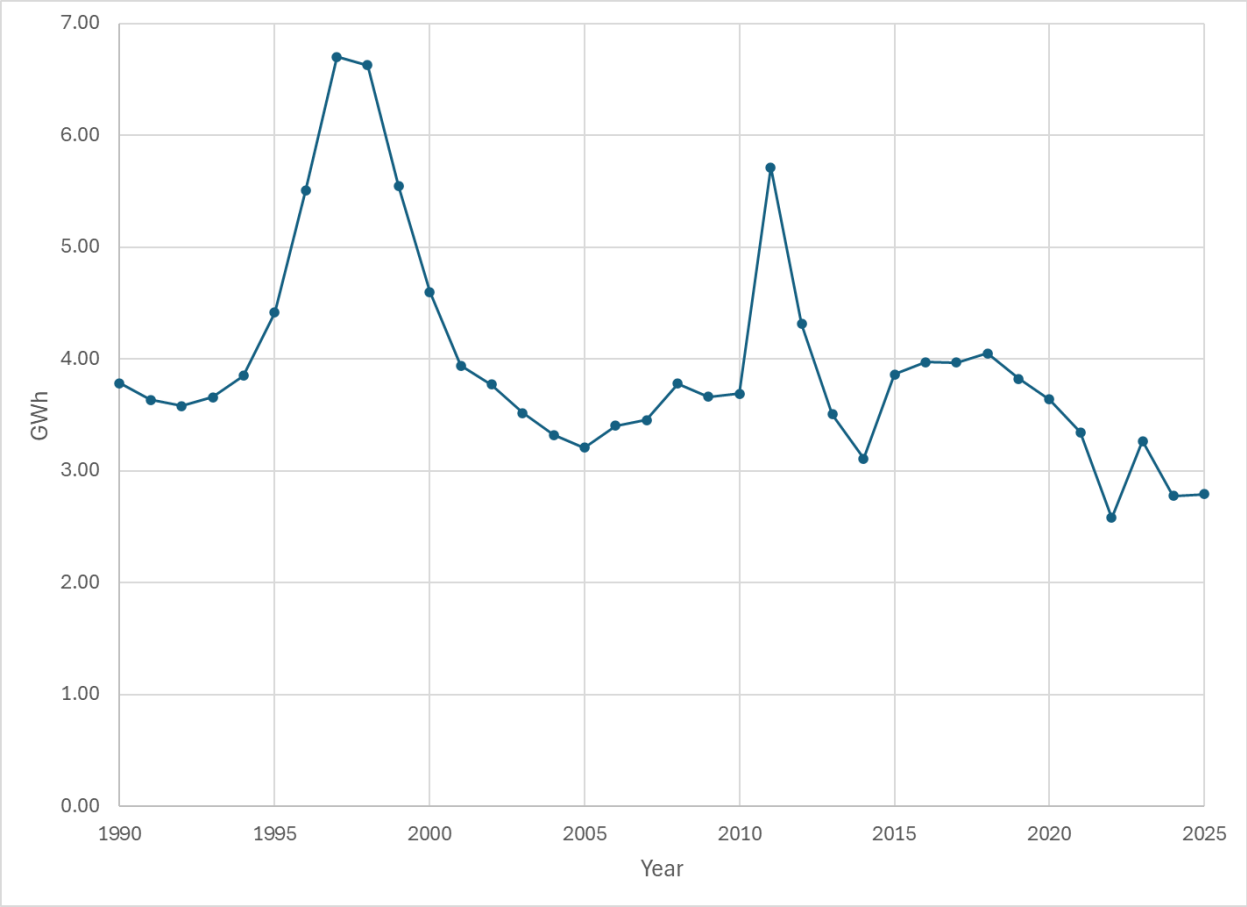
LTEMP ROD modified the daily fluctuation limit, so it is calculated as a function of the monthly volume, and it increased the down-ramp rate to no greater than 2,500 cfs per hour (Reclamation 2016b).



Hydropower Generation and Physical Capacity

Glen Canyon Powerplant has eight generators with a maximum combined physical capacity of 1,320 MW at a reservoir elevation of 3,700 feet (Reclamation 2016a). At minimum power pool, the powerplant has an estimated physical capacity of 630 MW.

Since 2007, the powerplant has undergone updates to improve efficiency, including: replacement of all eight turbines, four generator rewinds, replacement of all step-up transformers, optimization of software within the facility; and continued operations and maintenance (Reclamation 2024).



Despite the improved efficiencies, the powerplant's physical capacity to generate power has been affected by drought conditions and the resulting decreases in Lake Powell reservoir elevations. The decreases in elevation and, therefore, head, combined with reduced annual releases, have reduced power generation since 1997. **Figure TA 15-4** below shows the estimated physical capacity at a range of lake elevations. **Figure TA 15-5** displays the historical annual power generation from 1990 to present.

Hoover Dam/Lake Mead

Hoover Dam is located in Black Canyon on the Arizona-Nevada state line, approximately 35 miles southeast of Las Vegas, Nevada. The dam and its reservoir, Lake Mead, are operated and maintained by Reclamation's Lower Colorado Basin Dams Office. Hoover Dam is a concrete gravity-arch structure standing 726 feet high with a crest length of 1,244 feet, see **Figure TA 15-6**. Lake Mead has a water storage capacity of 30.2 maf and a maximum reservoir elevation of 1,232 feet.

Figure TA 15-6
Lake Mead and Hoover Dam Important Operating Elevations

Water Releases and Operational Considerations

Effective power generation currently requires a minimum water elevation of 950 feet in Lake Mead (Reclamation 2024). Water levels between 895 and 950 feet constitute the inactive pool, where releases can occur but do not generate hydropower. Below 895 feet, water reaches dead pool elevation, at which point releases are no longer possible.

Water is released from Lake Mead to the river through four intake towers. These 395-foot-high towers are positioned two on each side of the canyon and each tower has two openings for water to enter the penstocks, one near mid-height at elevation 1,045 feet and one at the bottom at elevation 895 feet. These openings can be closed by two 32-foot diameter, 11-foot-tall cylindrical gates. The two upstream intake towers release water to the lower main penstocks. The two downstream intake towers release water to the upper main penstocks. Each main penstock has four 13-foot-diameter steel penstocks that connect to the main penstock and supply water to individual generator turbines. The combined discharge capacity of all generator turbines is estimated at 49,000 cfs.

In addition, to passing water through the turbines, at the end of each main penstock are outlet works. At the end of each of the main penstock the penstock pipe branches into smaller diameter penstocks controlled by outlet work valves. Each of the lower penstocks have 4 valves available to discharge water. The discharge capacities for the lower outlet works are 15,300 cfs (Nevada penstock) and 15,400 cfs (Arizona penstock) at a reservoir water surface elevation of 1,219.6 feet, which is the bottom of the exclusive flood control space. Each of the upper main penstocks have 2 valves available to discharge water, the discharge capacities for the upper outlet works are 10,800 cfs (Nevada) and 10,700 cfs (Arizona) at elevation 1,219.6 feet.

There are two spillways at Hoover Dam, each consisting of a concrete overflow crest structure and basin with four spillway drum gates each, and a concrete-lined tunnel that discharges directly into the Colorado River. The original discharge capacity of both spillways was 400,000 cfs, but the maximum safe discharge capacity for each spillway was reduced to approximately 135,000 cfs due to the formation of a hydraulic jump inside the tunnels at those flows or greater.

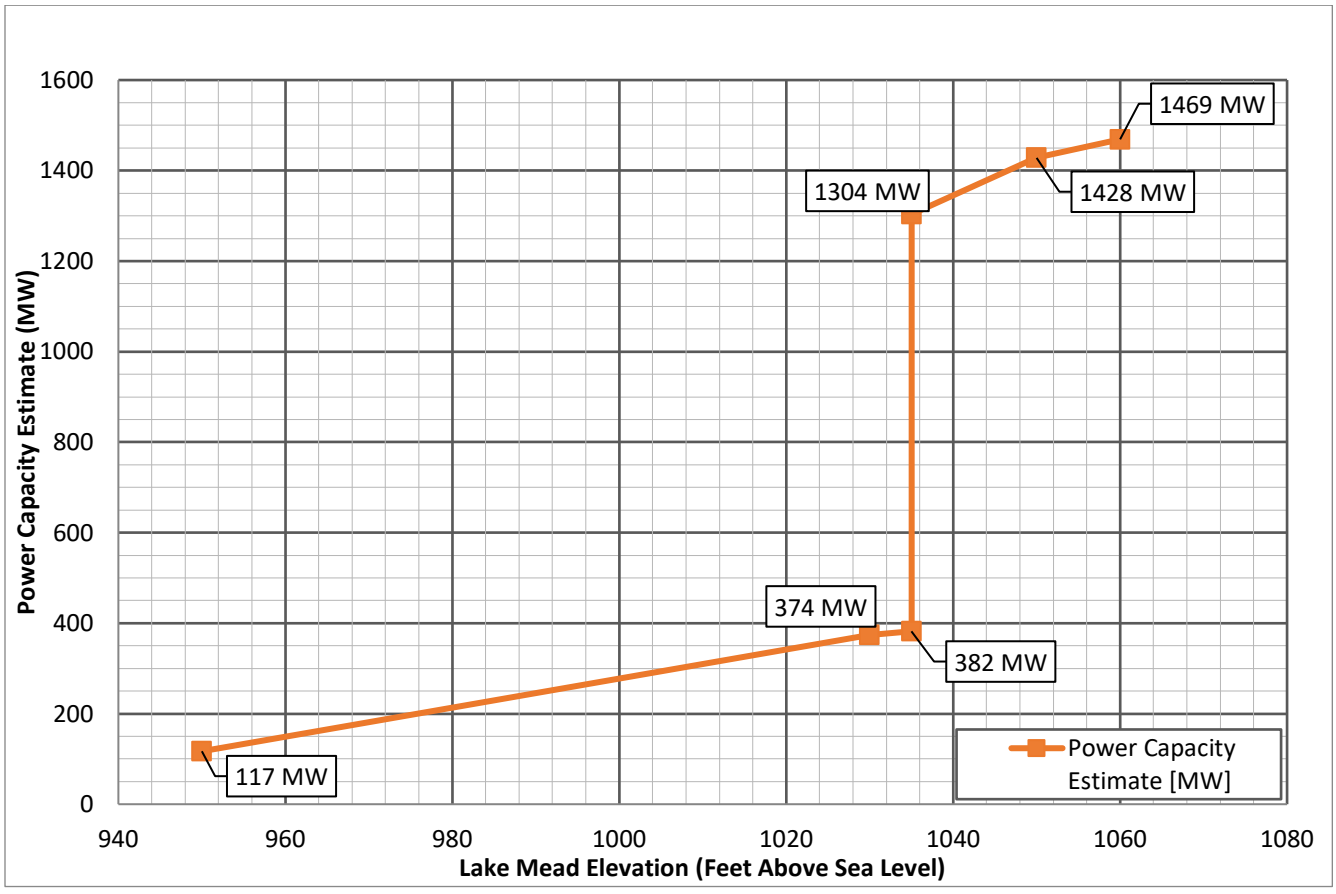
Under normal conditions, nearly all Colorado River flow passes through the turbines, with the spillways and outlet works used only in exceptional circumstances. The maximum safe channel capacity is estimated to be 40,000 cfs. Current operations aim to keep Lake Mead below 1,219.6 feet as much as possible. While limited operation above this level has occurred historically, it is preferred to minimize time spent in the flood control space. The bottom of the spillway drum gate is 1,205.4 feet. Operating below this elevation is desired as elevations above this point rely on mechanical gate function, where risk of failure increases. The most critical elevation threshold is 1,226.9 feet. This elevation corresponds to a spillway discharge exceeding 40,000 cfs and represents an imminent emergency.

Current Condition

The DSPR system evaluated Hoover Dam to be in the DSPR 5 (low priority, normal urgency of action) category. The total mean annualized failure probability for static, hydrologic, and seismic risks remains three orders of magnitude below Reclamation's Public Protection Guideline threshold.

Water conveyance systems at Hoover Dam are generally in good condition. The intake towers and penstocks are more than 85 years old and part of the original construction of Hoover Dam. The intake towers and penstocks cannot be replaced, and routine maintenance is required to maintain structural integrity. As part of the routine maintenance program, the penstocks are drained, inspected, and the coating is repaired as needed.

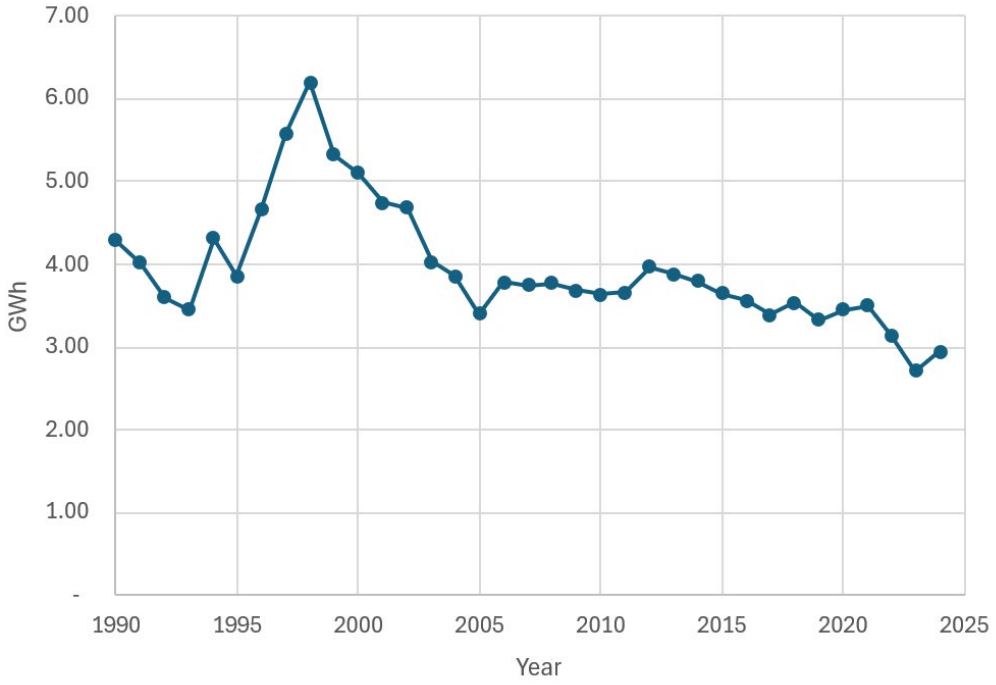
In August 1941, Lake Mead's water level was within 1 foot of the spillway crest when the spillway gates were lowered, allowing flows for the first time. Relatively modest flows, never exceeding 13,000 cfs, were passed through both spillways for 4 months. Velocities reached up to 175 feet-per-second in the Hoover Dam spillway elbow. When halted in early December 1941, an inspection of the Arizona spillway tunnel revealed a 38- by 112-foot eroded section of tunnel lining due to flow cavitation that required repairs. The 1941 damage was attributed to a slight misalignment of the tunnel invert. In response to this finding, the tunnels were patched with special heavy-duty concrete and the surface of the concrete was polished smooth. The spillways were subsequently modified in 1947 by adding flip buckets to eliminate conditions thought to have contributed to the 1941 damage.



Operations

The Hoover Dam water releases are highest in the spring and summer with daily fluctuations made to meet water demands downstream as well as meet hydropower demand. The total range of flood control releases from Hoover Dam are from Step 1 - 0 cfs to Step 6 - 73,000 cfs (Reclamation 2007b). Hoover Dam releases are managed on an hourly basis to maximize the value of generated power by providing peaks during high-demand periods. Releases from Hoover Dam are also based on flood control regulations that are operated by the United States (U.S.) Army Corps of Engineers. Approximately 1.5 maf of space must be reserved at all times exclusively for flood control purposes.

Hydropower Generation and Physical Capacity



The Hoover Powerplant is the largest hydropower-generation facility in the Basin. The Hoover Powerplant has seventeen commercial generators with a maximum combined capacity of 2,074 MW. The powerplant requires a minimum Lake Mead elevation of 950 feet to produce power. At minimum power pool, the powerplant has an estimated physical capacity of 117 MW. The power-generating capacity of Hoover Dam has been affected by drought conditions. The drop in Lake Mead's elevation has reduced head, lowering electric power output. At Lake Mead elevation 1,035 feet, Hoover Dam's generating capacity is drastically reduced from 1,274 MW to 382 MW. At elevations above 1,035 feet or greater in current market conditions, hydropower can be produced at or above market value. With current turbines, if the elevation drops below 1,035 feet, it is estimated that operating costs will exceed the value of the hydropower produced. Please reference **Figure TA 15-7** and **Figure TA 15-8** below.

Figure TA 15-7
Power Capacity Estimates for Hoover Powerplant at Varying Lake Mead Elevations

Source: Reclamation 2025b

Figure TA 15-8
Annual Hoover Powerplant Net Generation from 1990 to 2024

Source: Reclamation 2025c

Since the 2007, Reclamation has replaced five existing turbines at the powerplant with "wide-head" turbines, upgraded wicket gates, modernized unit controls, and conducted typical operations and maintenance of the facility. The upgraded turbines, wicket gates and modernized unit controls have increased efficiency. However, at elevation 1,035 feet Hoover Dam would only be able to use its five wide head turbines. The 12 older turbines are expected to get excessive cavitation damage and would not be used. In May 2026, Reclamation announced $52 million from the Hoover Dam Post Retirement Benefit fund will be used for replacement of up to three older turbines with wide-head turbines designed to operate at lower lake elevations.

Despite the increased efficiencies, the power generating capacity of Hoover Dam has been affected by drought conditions. **Figure TA 15-7** shows the estimated electric power capacity at a range of Lake Mead elevations. **Figure TA 15-8** displays the historical annual power generation from 1990 to present. The decrease in the elevation of the Lake Mead reservoir has led to a decrease in head, which has resulted in a decrease in electric power output.

Davis Dam/Lake Mohave and Parker Dam/Lake Havasu

Davis Dam is a 320-foot-tall rock and earth-fill gravity dam, rising 140 feet above the Colorado River. The dam spans the border of Arizona and Nevada in Pyramid Canyon and is 67 miles downstream from Hoover Dam. Its dam crest is 1,600-feet long and 50-feet wide. Its reservoir, Lake Mohave has a water storage capacity of 1.8 maf and a maximum reservoir elevation of 647 feet. Davis Dam is operated and maintained by Reclamation's Davis Dam Field Division which is part of the Lower Colorado Basin Dams Office.

Parker Dam, commonly known as the "deepest dam in the world," is a concrete arch structure, 320 feet tall, with 73 percent of its height below the original stream bed elevation of the Colorado River. The dam is on the Arizona and California border and 88 miles downstream from Davis Dam. The dam has a crest length of 856 feet and a width of 39 feet. The dam's reservoir, Lake Havasu, has a storage capacity of 646,200 acre-feet and a maximum reservoir elevation of 450 feet. Parker Dam is operated and maintained by Reclamation's Parker Dam Field Division of the Lower Colorado Basin Dams Office.

Water Releases and Operational Considerations

Davis Dam has a rectangular concrete forebay at its eastern end. At the end of the forebay is a spillway that consists of three 50-foot x 50-foot fixed wheel gates and a spillway crest elevation of 597 feet. The river outlet works consist of 22-foot x 19-foot radial gates with a crest elevation of 542 feet. From the forebay, water enters the powerplant through five 22-foot diameter steel lined penstocks to five hydroelectric generators. The powerplant can release up to 26,000 cfs at 120 feet of head and 31,000 at 136 feet of head. Normal releases from Davis Dam are made through the powerplant turbines with the spillway and outlet works in the closed position. The safe downstream channel capacity on the river is 40,000 cfs. Normal operating elevations for the Lake Mohave reservoir are between 630 and 646 feet.

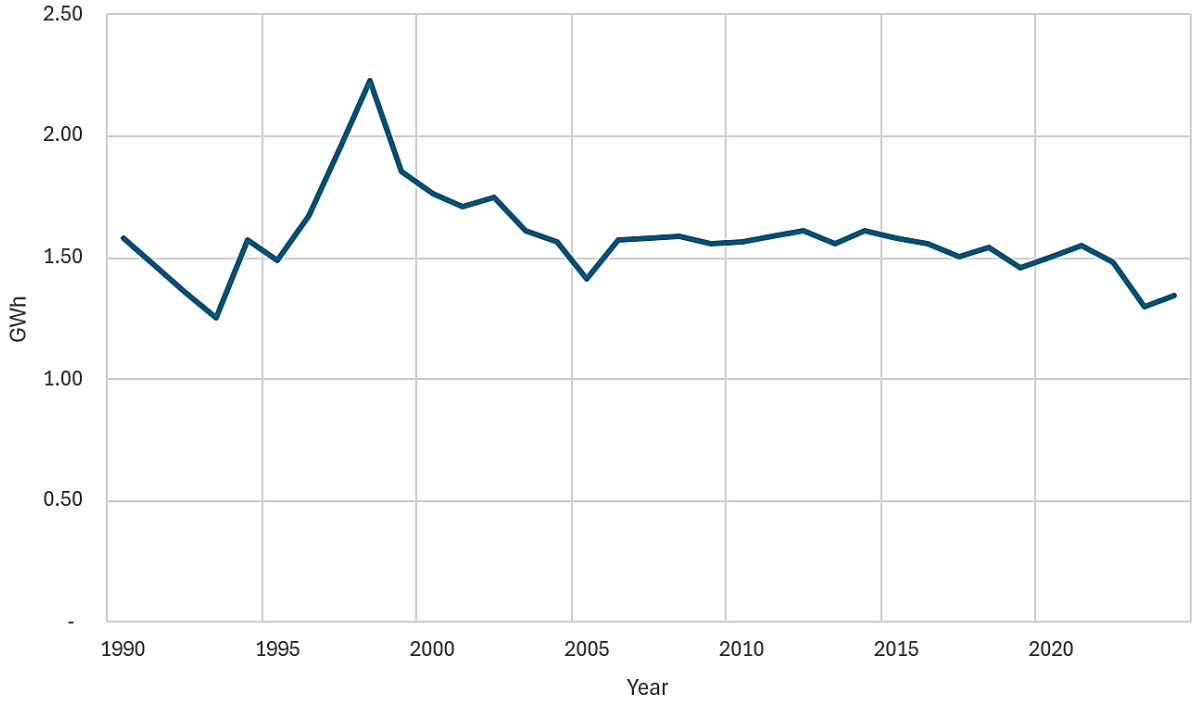
Parker Dam has a forebay on the right downstream abutment. In the center of the dam is a spillway that consists of five 50-foot-wide overflow gate bays at the dam center with a crest elevation of 400 feet. From the forebay water enters the powerplant through four 22-foot diameter steel lined penstocks that convey water to four hydroelectric generators. Their combined discharge capacity is 22,000 cfs. The safe downstream channel capacity on the river is 40,000 cfs. The normal operating elevations for the Lake Havasu reservoir are between 445 and 450 feet.

Current Condition

The DSPR system evaluated Davis and Parker Dams to be in the DSPR 4 (low urgency of action) category, as the total mean annualized failure probability of static and seismic risks to the dams is one-half order of magnitude below Reclamation's Public Protection Guideline threshold value. The dams were determined to be in good condition and performed adequately, and responses of the dams to reservoir loading are predictable, with conditions not appearing to change.

Operations

The Davis Dam fluctuates releases between 4,200 cfs and 23,000 cfs, while Parker Dam fluctuates between 1,800 cfs and 19,000 cfs. The maximum releases for the Parker and Davis Powerplants are 19,000 cfs and 23,000 cfs, respectively. The exact release depends on downstream water demands and tends to be lowest during the winter and highest in spring and summer. Parker Dam is operated under the same rule curve that determines end-of-month target elevations as prior to the Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead, maintaining Lake Havasu's water surface elevation between 445 and 450 feet. Seasonal adjustments to the reservoir's water surface elevation allow for flood control in the fall and higher water levels in the spring. The average annual elevation was 447.5 feet from 1996 to 2007, and approximately 447.7 feet from 2008 to 2022, remaining consistent for the last several decades. Current minimum releases of the Parker Dam are 1,600 cfs daily, 1,400 cfs hourly, and



95,000 acre-feet during a 30-day month. The 2007 Final EIS stated Parker Dam releases from Lake Havasu ranged from 6.19 maf to 10.3 maf (averaged 7.4 maf) from 1996 to 2007 (Reclamation 2007a). Since 2008, annual dam releases ranged from 6.2 maf to 6.7 maf (averaged 6.4 maf) through 2022. The average annual Parker Dam releases have decreased by 1.0 maf since the issuance of the Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead.

Hydropower Generation and Physical Capacity

The Davis Powerplant has four 51.75 MW generators and one 48 MW generator for a total of 255 MW of capacity. The Parker Powerplant has four 30 MW generators, totaling 120 MW, with a discharge capacity of 22,000 cfs (Reclamation 2023).

Since 2007, both the Davis and Parker Dam facilities have undergone typical operations and maintenance. All four turbines at the Parker Powerplant were replaced between 2004 and 2010. Drought conditions have had less impact on the capacity at Davis and Parker Powerplants than the Hoover and Glen Canyon Powerplants because the elevations of Lake Mohave and Lake Havasu reservoirs have remained relatively constant. **Figure TA 15-9** shows the historical combined annual power generation at the Parker and Davis Powerplants. The slight drought induced reduction in river flow has led to a decline in electric power generation.

Figure TA 15-9
Annual Parker and Davis Powerplants Generation from 1990 to Present

TA 15.1.4 Hydroelectrical Power Distribution

Hydroelectric power generation can be adjusted operationally through a coordinated effort between WAPA and Reclamation. This operational flexibility allows WAPA to quickly and efficiently increase or decrease generation in response to customer demand, generating unit or transmission line outages (contingency reserves), unscheduled customer deviations from internally scheduled contracted power usage (regulation and load/generation following) within a specific metered load area known as a balancing authority, integrated power system requirements, and requests for emergency assistance from interconnected utilities. Power operations are the physical operations of an electric power system, including hydropower generation and control, operational flexibility, scheduling, power generation load following, regulation, transmission, and emergency operations. These are discussed in the sections below. Additional information on power generation, control, regulation, reserves, and ramping can be found in the 2007 Final EIS Section 3.11.1.1 (Reclamation 2007a); and that information is incorporated here by reference.

Scheduling[2]

Power scheduling occurs by matching available power generation to seasonal, daily, and hourly system energy and capacity needs. Power scheduling is affected by the temporal distribution of monthly water release volumes, restrictions in water release patterns, availability of generator units (due to maintenance), availability of other regional hydropower units, power allocations, and peak and off-peak power demand period. Glen Canyon Dam scheduling by WAPA to meet power requirements typically results in higher water releases via the powerplants in the peak power demand months of December, January, July, and August. In the Lower Colorado River dams, scheduling is driven by water orders. There is high degree of flexibility in the releases within a month for Hoover Dam, but the amount of power delivered is constrained by monthly water orders. For Parker Dam and Davis Dam the scheduling occurs daily for power based on water orders.

Load Following,[3] *Ancillary Services, Generation, and Regulation*[4]

Hoover Dam and Glen Canyon Dam can change in response to changes in the load (demand) or unanticipated changes in the power generation resources within the operating region. This ability to respond to rapidly changing load conditions is called load or generation following (Reclamation 2016a). Load following creates large fluctuations in water releases, which can have impacts on some downstream environmental resources (Reclamation 2016a). The 1996 Operation of Glen Canyon Dam: CRSP ROD (Reclamation 1996) narrowed the range of operation for CRSPA purposes, thereby reducing the ability of power generation at Glen Canyon Dam to respond to customer load.

Changes in WAPA's scheduling guidelines for Glen Canyon Dam typically occur over a period of months, not only because of the operational constraints originally imposed by the 1996 Glen Canyon Dam ROD (Reclamation 1996) but also due to changing market conditions. Operational conditions for Glen Canyon Dam are further affected by the frequency, season, and time-of-day

[2] Scheduling information is provided for context. The alternatives do not address scheduling and there are no anticipated impacts on scheduling from the alternatives.
[3] Load following are adjustments to power output as demand for electricity fluctuates throughout the day.
[4] Load following, ancillary services, generation, and regulation information is provided for context. The alternatives do not address load following, generation, or regulations and there are no anticipated impacts on them from the alternatives.

limitations that may be in effect; physical and environmental operating restrictions at other CRSP generating facilities and within the interconnected electric system; and the availability and price of replacement power (Reclamation 2016a).

National Regional Reliability Standards[5]

To ensure interconnected system reliability, WAPA follows mandatory reliability standards enforced by the North American Electric Reliability Corporation (NERC) and the WECC. In addition, WAPA follows operational criteria, guidelines, and procedures set in place by the WECC and the contingency reserve sharing group applicable to each balancing authority area. Each WECC utility is located within such a load balancing area, and one utility within the balancing authority area serves as the balancing authority operator. WAPA is the balancing authority operator for the Southwest Power Pool Regional Transmission Organization Balancing Authority Areas and is responsible for ensuring that each load-serving utility within each balancing authority serves its own internal load while meeting its power and reserve obligations. Operating as a balancing authority, WAPA is the provider of last resort should a load-serving entity not be able to fulfill its obligation to the balancing authority area, and it carries all compliance responsibility for the balancing authority function. All CRSP powerplants are within the Western Area Colorado-Missouri Region balancing authority, and the flexibility and load/generation following capability of CRSP hydroelectric powerplants, particularly Glen Canyon Powerplant, are important in meeting NERC/WECC reliability standards and criteria. Hoover, Parker and Davis Powerplants are all within the Western Area Lower Colorado balancing authority area. Hoover provides ancillary services including regulation capability through a dynamic or pseudo tie generation arrangement with four other balancing authority areas including significant capacity allocations that can provide regulation services within the California Independent System Operator.

Colorado River Storage Project Basin Fund[6]

The CRSPA; 43 U.S. Code 620d) established the Basin Fund for the collection of revenues from the operation of the CRSP and participating projects. These funds are available until expended to defray the costs of operation, maintenance and replacements for all facilities of the CRSP and participating projects. Maintaining a sufficient Basin Fund balance is critical to operating and maintaining the reliability of CRSP facilities. Reclamation and WAPA use this fund to repay the federal investment (with interest), operate and maintain facilities, purchase market power, when necessary, provide funding under a Basin States' memorandum of agreement, support environmental and salinity programs, and provide irrigation assistance. WAPA sells wholesale power to preference customers, including public utilities, municipalities, and tribes, which incorporate this power into the rest of their portfolio to fulfill their load requirements. Under WAPA's current rate structure, WAPA provides its long-term firm power customers with a set amount of power on a quarterly basis. The amount of power is based on the amount of water Reclamation forecasts to release from the CRSP units during that quarter. If the CRSP units do not generate enough power to fulfill these quarterly obligations, WAPA purchases power and necessary transmission to make up the difference. Revenues collected through WAPA's firm power rate from the sale of wholesale power are

[5] National/Regional Reliability Standard information is provided for context. The alternatives do not address these standards and there are no anticipated impacts on them from the alternatives.
[6] Basin Funds are discussed for context. The Basin Fund will not be impacted by the alternatives because it is a reimbursable fund. Any changes in generation would be offset by changes in rates.

deposited into the Basin Fund. Changes in generation identified in the alternatives will not impact the Basin Fund. The Basin Fund has historically funded environmental programs like the Glen Canyon Dam Adaptive Management Program and the San Juan River Basin Endangered Fish Recovery Programs. In recent years, appropriations have funded these base programs, while the Basin Fund continues to fund related experiments. Experimental releases that bypass the electrical generators at Glen Canyon Dam reduce hydropower generation. Accordingly, WAPA purchases replacement power to fulfill contractual delivery obligations. Under the Grand Canyon Protection Act of 1992 (Public Law 102-575), WAPA records the financial cost of environmental experiments at Glen Canyon Dam as a non-reimbursable expense. WAPA accounts for such costs as a constructive return to the U.S. Treasury rather than as an operations and maintenance expense to be recovered through WAPA's cost-based power rates.

Colorado River Dam Fund

The Boulder Canyon Project (BCP) Act of 1928 established the Colorado River Dam Fund to pay for the construction, operation and maintenance of the BCP, including Hoover Dam. All revenues generated by the project, primarily from power sales, are deposited into this fund, which is then used to repay the U.S. Treasury for the construction costs, cover operation and maintenance expenses, and fund other beneficial purposes like flood control, water delivery for Reclamation, and payments to Arizona and Nevada. In addition, surcharges are added to the charges of Nevada and California power contractors to contribute money for the salinity program. Arizona power contractors pay a surcharge for the repayment of the Central Arizona Project. BCP power contractors also contribute to the Lower Basin Multi-Species Conservation Program.

Each year WAPA and Reclamation present the proposed budget for the next ten years with a focus on the next fiscal year to the power contractors. The costs for each fiscal year budget amount is collected from the BCP power contractors and is referred to as the base charge. Each power contractor pays their contractual share of the base charge collected as an energy and capacity component. The base charge value, along with the projected energy generation which is derived from projected water deliveries for the next year creates an implied rate that is used for comparative purposes. The funds collected cover the cost of Reclamation and WAPA for operating and maintaining Hoover Dam and all associated project transmission and facilities.

Parker-Davis Project

The Rivers and Harbor Act of 1935 authorized the construction of Parker Dam. The Davis Dam Project was authorized under provisions of the Reclamation Project Act of 1939. The Consolidate Parker Dam Power Project and Davis Dam Project Act of May 28, 1954, 68 Stat. 143 authorized the Parker Dam Project and the Davis Dam Project to be consolidated into the Parker-Davis Project (PDP). As a result of original project funding, Metropolitan Water District of Southern California holds a perpetual contract for 50 percent of the power generated by the Parker Powerplant.

Reclamation Fund

WAPA has Firm Electric Service Contracts with power contractors. Under the PDP marketing plan, a set amount of monthly power is provided to the power contractors and power revenues are collected into the Reclamation Fund. If power from PDP is not generated to fulfill these contractual power obligations, WAPA purchases power to make up any difference. WAPA uses cash through

their receipt authority from the Reclamation Fund to make those purchases. In 1998, Reclamation entered an Advancement of Funds Contract with the majority of the power contractors to directly fund their costs for Davis Dam and half of Parker Dam. In addition, Reclamation receives monthly transfers from WAPA for the surplus revenues collected under the 4-1/2 mills per kilowatt (kW) hour in the rates charged to power contractors in Arizona for repayment of the Central Arizona Project and 2-1/2 mills per kW hour in the rates charged to power contractors in California and Nevada for the Salinity Program pursuant to the Hoover Power Plant Act of 1984, as amended and supplemented. These funds are recorded as a pass though in PDP and are transferred to the Lower Colorado River Basin Development Fund.

Disturbances and Emergencies and Outage Assistance[7]

In the event of a widespread sudden loss of generation resource power outage, or an imbalance in the transmission system element causing a load/resource imbalance requiring an immediate response (i.e. disturbance), NERC contingency reserve standards require that available generation capacity be utilized to return the electric generation and transmission system to normal operating conditions within load/generation balance within 10 minutes following the disturbance. Generally, emergency operations contingency reserves are needed only for periods of an hour or less but can and frequently are activated several times a day.

WAPA may use available generating capacity at Glen Canyon Dam and Hoover Dam to support grid reliability and power system operations. Short-duration changes in releases may occur as part of normal power regulation activities. WAPA's ability to supply emergency assistance is limited by available transmission capacity and available generation capability, while the ability to deliver emergency assistance varies on an hourly basis, depending on firm load obligations and available generation from project resources.

Transmission System[8]

The Hoover, Glen Canyon, Parker, and Davis Powerplants are connected to a transmission system. Each facility's generation can affect transmission limitations when lines do not have enough capacity to transmit electricity from the point of generation to the point of demand. Actual transmission refers to the measured flow of power on the line. WAPA operates 17,000 circuit miles of transmission lines.

Power Marketing

WAPA markets long-term firm capacity and energy, short-term, firm capacity and energy, and non-firm energy. Firm power is capacity and energy that are guaranteed to be available to the customer. Loads are made up of firm load, non-firm sales, and interchanges out of the control area. Firm load and capacity obligations include long- and short-term firm sales, Reclamation project use loads, system losses, balancing authority control area regulation, firm load contingency reserves, and scheduled outage assistance. Capacity is reserved to provide regulation, contingency reserves,

[7] Disturbance and emergencies and outage assistance are discussed for context. The alternatives in this Final EIS do not address disturbance, emergencies, or outage assistance and there are no anticipated impacts on these from the alternatives.

[8] Transmission is discussed for context. The alternatives in this Final EIS do not address transmission and there are no anticipated impacts on transmission from the alternatives.

frequency support and response, meet contractual obligations, and participating project capacity. For Glen Canyon Dam, capacity is also reserved to serve Reclamation's irrigation and drainage pumping plant loads before being marketed as long-term firm capacity.

Colorado River Storage Project

In fiscal year 2025, WAPA marketed 4,268 gigawatt hours (GWh) of wholesale CRSP power to approximately 130 entities serving retail customers in Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming. Customers are small to medium-sized municipalities that operate publicly owned electrical systems; irrigation cooperatives and water conservations districts; rural electrical associations or generation and transmission co-operatives who often act as wholesales to these associations; federal facilities such as Air Force bases, universities, and other state agencies, and tribes. Capacity and energy from Glen Canyon Dam are bundled and marketed by WAPA as the Salt Lake City Area Integrated Projects (SLCA/IP). Electricity generated at SLCA/IP facilities in the Upper Colorado Region is marketed by WAPA under statutory criteria in the Reclamation Project Act of 1939, the Flood Control Act of 1944, CRSPA, and the Department of Energy Organization Act of 1977, along with associated marketing plans and contractual obligations. The majority of CRSP power is sold under long-term firm electric service contracts. If WAPA is unable to supply contract amounts of firm capacity or energy from Reclamation hydroelectric resources, it must purchase the deficit from other (primarily non-hydropower) resources for delivery. The expense for this purchase power is shared by all SLCA/IP customers. Reliance on SLCA/IP capacity and energy varies considerably among customers. In general, rural customers are more reliant on hydropower resources as a percentage of their total resource portfolio compared to urban customers.

Tribal Benefit Crediting

Tribes receive hydropower from WAPA, including hydropower from Glen Canyon Dam. Glen Canyon Dam is one component of a larger hydropower system and is included with other powerplants for marketing purposes. Capacity and energy from Glen Canyon Dam are bundled and marketed by WAPA as the SLCA/IP to consumers across Arizona, Colorado, Nebraska, New Mexico, Nevada, Utah and Wyoming. In the 2016 LTEMP Final EIS, tribal populations with the potential to be affected by project management include those who receive annual SLCA/IP allocations. The 2016 LTEMP Final EIS (Reclamation 2016a, Appendix K, Attachment 12) provides a comprehensive list of the annual SLCA/IP allocations to American Indian tribes and benefit information. When originally allocated in 2002, WAPA anticipated serving about 55.7 percent of total tribal electric use in the summer season and 58.8 percent in the winter season. There are 53 tribes or tribal entities that have signed firm electric service contracts with WAPA to receive power from SLCA/IP, which includes power from Glen Canyon Dam. Over the past 20 years, tribal load growth and reductions in hydropower due to drought have reduced that original percentage. There are currently seven tribes or tribal entities that operate electric utilities and receive power deliveries directly from WAPA. The remaining tribes operate under benefit crediting arrangements. Under a benefit crediting arrangement, the tribe's electric service supplier takes delivery of the SLCA/IP allocation and in return gives an economic benefit or payment to the tribe. In other words, the utility receives WAPA power on behalf of the tribe; subsequently, the utility receives the benefit of the power and transfers the economic benefit of the federal hydropower allocation to the tribe. Ideally, arrangements are made with public power utilities in areas that receive an allocation of power from WAPA such as a rural electric cooperative or municipality (however, exceptions apply

for various reasons). Because benefit crediting arrangements are typically a function of MWh provided, a reduction in energy deliveries from WAPA translates directly into a reduced financial benefit to a tribe.

Desert Southwest Region

WAPA markets 10,600 GWh of wholesale Desert Southwest Region power to 80 entities in Arizona, southern California, and southwest Nevada. Capacity and energy from Hoover Dam are bundled and marketed by WAPA as the BCP and capacity and energy from Parker and Davis Dams are bundled and marketed by WAPA as the PDP to consumers in Nevada, Arizona, and California.

The BCP has delivered power to customers for over 80 years. The BCP Post-2017 remarketing effort was created in 2014 to determine power allocations for the Hoover Powerplant that expired in September 2017 (WAPA 2017). The new BCP contracts were signed in October 2016 and now run from 2017-2067. The existing contract delivers power to 46 direct and 74 total allocations including allocations through state agencies in Arizona, Nevada, and Southern California.

Davis Dam provides all 255,000 kW of operating capacity to the PDP and Parker Dam provides 60,000 kW of operating capacity to the PDP and 60,000 kW to the Metropolitan Water District of Southern California (WAPA 2024). The existing PDP sales contract expires in 2028 and a plan for a future remarketing is underway. At present, there are 36 contractors receiving power allocations from the PDP. The electricity produced by the PDP provides electricity to approximately 300,000 people (WAPA 2025c).

Rates

WAPA sets rates for firm electric service from Federal hydropower projects in its marketing territory based on Department of Energy regulations and applicable Federal statutes. Customers pay rates that align specifically with the project they buy power from.

WAPA has a public rate-setting process that includes collaborative planning, a public comment period, and information and comment forums. A *Federal Register* notice announces proposed rates before the comment periods and then another notice is issued with final rates at the end of the process.

Wholesale Rates

WAPA has various wholesale customers including municipal utilities, federal and state public power facilities, and rural electric cooperatives as well as tribal entities. Power rates are established in order for revenues to be sufficient to pay all costs assigned to power within required time periods. Power revenues also pay annual power operation and maintenance, purchased power, transmission service, and interest expenses on Treasury loans used to finance construction of power and transmission projects, and irrigation assistance beyond the ability of the irrigators to repay. CRSP and Lower Colorado Dam's power revenues also must contribute toward salinity control costs under the Basin Salinity Control Act. CRSP power revenue also contributes to construction costs (with interest) of CRSP-participating projects, as well as certain environmental costs as provided under the Grand Canyon Protection Act. Arizona power customers pay a surcharge for Central Arizona Project construction projects and Multispecies Conservation Program costs. Remaining annual revenues are

used to pay off investment costs assigned to power, so that each investment can be paid within the time allowed (Reclamation 1995).

Retail Rates

Retail rates are those paid by end users (residential, commercial, and industrial customers of WAPA's wholesale customers). The retail rates charged by not-for-profit entities normally are set to cover system operation and capital costs. As costs of these individual components change, the retail rates are adjusted to ensure enough revenue is collected to meet the utility's financial obligations.

TA 15.2 Environmental Consequences

This environmental consequences section analyzes the effects of the alternatives on: the minimum power pool for Lake Powell and Lake Mead; the power capacity of the Glen Canyon and Hoover Powerplants; the power generation of the Glen Canyon, Hoover, Davis, and Parker Powerplants; spillway use of Glen Canyon Dam and Hoover Dam; and electricity rates and the market value of the electricity.

The spillway condition and hydropower capacity of the Davis Dam and Parker Dam are not analyzed because Lake Mohave and Lake Havasu reservoirs have historically remained relatively constant, and their elevations are expected to remain so under all alternatives. Both Lake Mohave and Lake Havasu would continue to be operated under a rule curve that provides specific target elevations at the end of each month (refer to **TA 3.1.8**, Davis Dam to Lake Havasu, in **TA-3**, Hydrologic Resources).

TA 15.2.1 Methodology

WAPA's Colorado River Storage Project Python-based model (CRiSPPy) and Reclamation's Colorado River Simulation System (CRSS) model and Decision Making under Deep Uncertainty (DMDU) analysis framework inform the basis for the effects analysis. Refer to **Chapter 3**, **Section 3.2.6**, Decision Making under Deep Uncertainty for additional details on the DMDU framework and **Appendix E**, DMDU Overview and Approach, for an overview of how to interpret the DMDU conditional box plots, robustness of futures, and vulnerability bar plots. The CRSS model models: potential water releases from the dams; reservoir elevations; and power generation for each of the alternatives and the Continued Current Strategies (CCS) Comparative Baseline. Additional information on CRSS model and model assumptions can be found in **Appendix A**, CRSS Model Documentation. The CRiSPPy model was updated to specifically address the scope of this Final EIS. The model covers 34 years of monthly operations (2027–2060) across 400 hydrology conditions with each alternative representing 163,200 model runs. The CRiSPPy model is a hydropower scheduling tool developed by Argonne National Laboratory for WAPA that combines optimization algorithms, data management, and graphical user interface. CRiSPPy model assumptions can be found in the technical report CRiSPPy: An advanced hydropower scheduling tool for the Colorado River Storage Project (Ploussard et al. 2025). The analysis of the impacts of the alternatives on electricity rates (wholesale) and the market value of the electricity for Glen Canyon Dam is based on analysis WAPA and Argonne National Laboratory prepared in the Post-

2026 Environmental Impact Statement Rate Analysis for the Colorado River Storage Project (Yu et al. 2025).

TA 15.2.2 Impact Analysis Area

The analysis area for Issues 1-4 encompasses the four primary dams in the Colorado River corridor from the full pool elevation of Lake Powell to the Southerly International Boundary: Glen Canyon Dam/Lake Powell reservoir, the Hoover Dam/Lake Mead reservoir, Davis Dam/Lake Mohave reservoir, and Parker Dam/Lake Havasu reservoir. The analysis area for Issue 5 consists of the WAPA retail power customers of Glen Canyon Dam power that are in the states of Arizona, Colorado, Nevada, New Mexico, Nebraska, Utah, and Wyoming.

Assumptions

All action alternatives, except for the Basic Coordination Alternative, incorporate mechanisms related to the storage and delivery of conserved water in Lake Powell and/or Lake Mead (refer to **Appendix S**). Unless otherwise specified, impacts reflect modeling assumptions about voluntary conservation behavior.

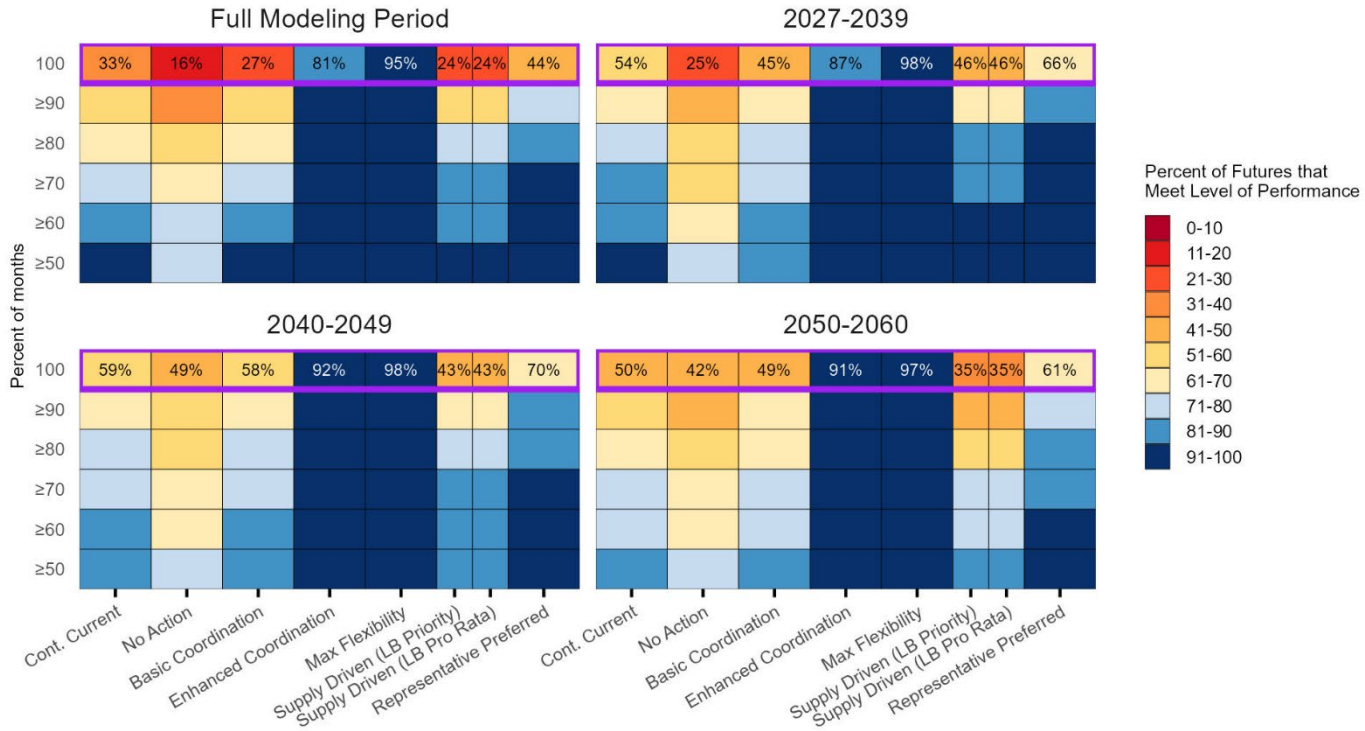
The Lower Basin electrical generation and firm capacity modeling results are direct outputs from the CRSS model. Refer to **Appendix A**, CRSS Model Documentation, for more details related to model assumptions and documentation. The Glen Canyon Dam electrical generation and firm capacity modeling results are direct outputs from the CRiSPPy model. The modeled firm capacity in a given month is calculated as the largest, or peak, value of the power output modeled by CRiSPPy in that month. For additional information and modeling assumptions, please refer to CRiSPPy: An advanced hydropower scheduling tool for the Colorado River Storage Project (Ploussard et al. 2025). The Glen Canyon Dam rates analysis data was developed by Argonne National Laboratory. Information and modeling assumptions for the rates analysis can be found in the Post-2026 Environmental Impact Statement Rate Analysis for the Colorado River Storage Project (Yu et al. 2025)

Impact Indicators

- Lake Powell and Lake Mead Reservoir elevations – Reservoir elevations were evaluated in relation to the minimum power pool elevations for Lake Powell and Lake Mead and in relation to Glen Canyon Dam and Hoover Dam infrastructure and safety.
- Firm capacity (MW) – Firm capacity is the reliable, guaranteed amount of power output from a powerplant that accounts for operational constraints such as water releases and ramp rates. Firm capacity is measured in MW. This analysis utilizes firm capacity as an indicator rather than physical capacity because it more accurately reflects the actual conditions WAPA and Reclamation use for operational decisions.
- Energy generation (MWh) – The amount of energy created over a certain period, measured in MWhs. Energy generation is dependent on reservoir head and water release volume.
- Spillway releases – spillway releases due to operational activities.
- Electricity rates – The minimum average rate increase amount per major rate increase measured in $/MWhs for customers of Glen Canyon Dam power.
- Market value of electricity – The future market value of electricity generated at Glen Canyon Dam measured in millions of dollars per year.

TA 15.2.3 Issue 1: How do the alternatives impact the frequency at which reservoir elevations drop below minimum power pool at Lake Powell and Lake Mead?

Minimum power pool is the lowest reservoir elevation level at which a hydropower plant can produce power. The frequency at which reservoir elevations drop below minimum power pool for Glen Canyon Dam/Lake Powell reservoir and Hoover Dam/Lake Mead reservoir were measured by calculating the percent of futures in which the elevations of the reservoirs achieve the preferred minimum performance of maintaining elevations at or above 3,490 feet and 950 feet, respectively (refer to **Figure TA 15-10** and **Figure TA 15-12**); and by using vulnerability figures that display conditions that could cause Lake Powell and Lake Mead to drop below these thresholds (3,490 feet and 950 feet respectively), representing undesirable performance when elevations fall below minimum power pool in one or more months (refer to **Figure TA 15-11** and **Figure TA 15-13**).



In addition to the importance of elevation 3,490 to hydropower at Lake Powell, there are also infrastructure concerns associated with the uncertainty of extended operations through the river outlet works as the sole means of sustained water releases from Glen Canyon Dam that could compromise the reliability and operational flexibility of Glen Canyon Dam and affect the ability to meet critical downstream water supply needs, as described in **Section 1.8.4.1**.

Figure TA 15-10 below shows the percentage of futures for each alternative (columns) in which Lake Powell elevation is 3,490 feet or above in the percent of months specified by each row. The highlighted row represents the preferred minimum level of performance, which is for elevations to be at least 3,490 feet in all months (i.e., 100 percent of the time). Results are shown for the Full Modeling Period and three subperiods: 2027–2039, 2040–2049, and 2050–2060.

In the Full Modeling Period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 81 percent and 95 percent of modeled futures, respectively, which is considerably more robust than the other alternatives. The Representative Preferred Alternative meets the preferred minimum performance level in 44 percent of futures, with the third highest robustness score. The No Action, Supply Driven (both Lower Basin Priority [LB Priority] and Lower Basin Pro Rata [LB Pro Rata] approaches), Basic Coordination Alternatives, and CCS Comparative Baseline are only able to meet the preferred minimum performance at or below 33 percent of futures. Across all subperiods modeled, both Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in greater percentages of futures than the others, never falling below 87 percent of futures. The next best performing is the Representative Preferred Alternative, ranging between 61 to 70 percent of futures across all subperiods.

Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. Maximum Operational Flexibility (98 percent) and Enhanced Coordination (87 percent) are the most robust alternatives, followed by the Representative Preferred Alternative (66 percent). The No Action Alternative is the least robust (25 percent), and the Basic Coordination Alternative (45 percent), Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative (46 percent), and the CCS Comparative Baseline (54 percent) perform in the middle.

Figure TA 15-10
Lake Powell Power Pool: Robustness.
Percent of futures in which Lake Powell elevation is at least 3,490 feet in the percent of months specified in each row

Note: Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water). This remains true for the following models in this technical appendix.

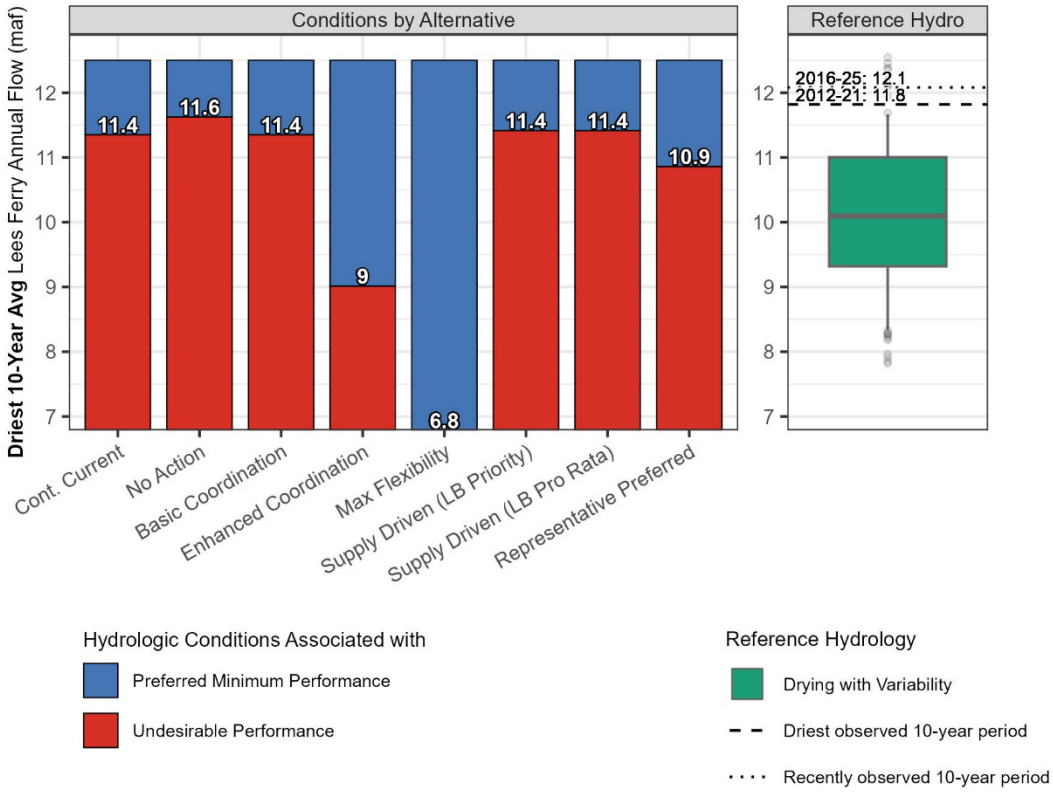


Figure TA 15-11 below shows what flow conditions are likely to cause Lake Powell's elevation to fall below 3,490 feet in any month. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-10** above, which defined a future as successful when an alternative stayed above minimum power pool in 100 percent of months.

For this vulnerability analysis, the driest 10-year average Lees Ferry natural flow was determined to be a skillful predictor of undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

The CCS Comparative Baseline, Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would likely be vulnerable to Lake Powell elevation falling below 3,490 feet under a 10-year average Lees Ferry natural flow of 11.4 maf or drier, which is slightly less

vulnerable than the No Action Alternative which is likely to be vulnerable if the 10-year average is 11.6 maf or drier. These conditions are similar to the driest observed 10-year average of 11.8 maf and occur in more than 75 percent of traces in the Drying with Variability Ensemble. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are not likely to be vulnerable to undesirable performance unless the 10-year average flow is much drier than any observed conditions; fewer than 25 percent of traces in the Drying with Variability Ensemble include conditions that would be likely to cause vulnerability in the Enhanced Coordination Alternative, while the Maximum Operational Flexibility Alternative is not vulnerable to any traces in the Drying with Variability Ensemble.

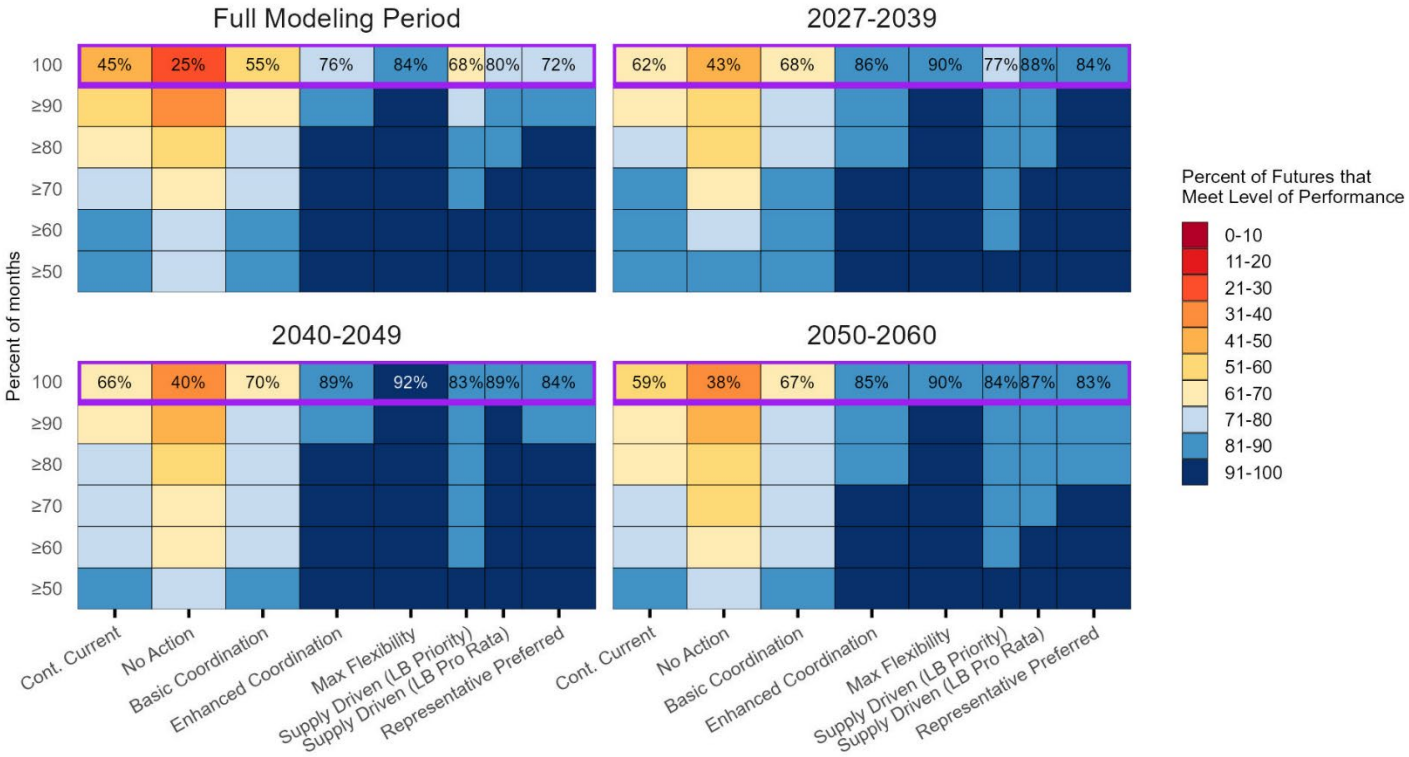

Figure TA 15-11
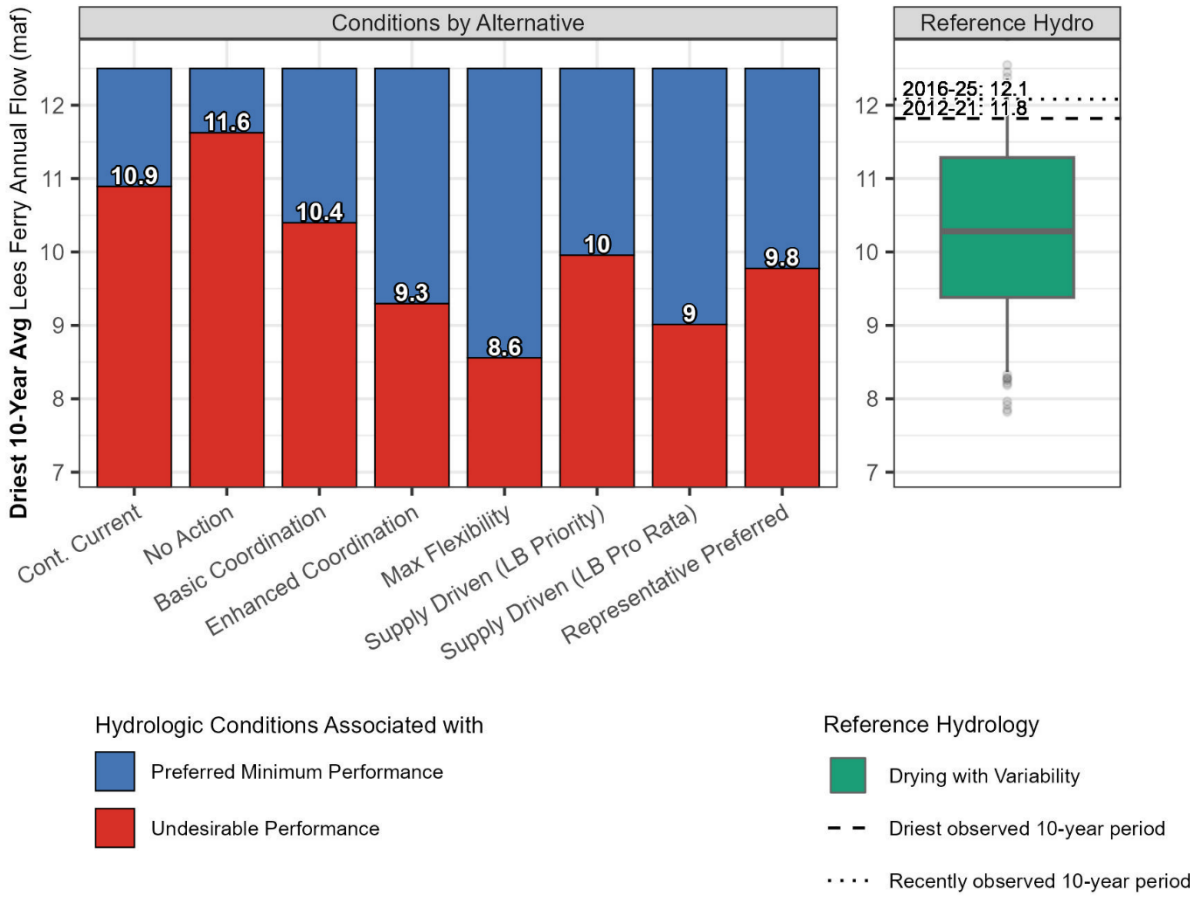
Lake Powell Power Pool: Vulnerability.
Conditions that Could Cause Lake Powell Elevation Below 3,490 Feet in any Month

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to at least one occurrence of Lake Powell elevation falling below 3,490 feet under a 10-year average flow of 10.9 maf. While these conditions have not yet been observed, absent additional action, this alternative is reasonably likely to be vulnerable in the next 10 years because these conditions occur in nearly 75 percent of traces in the Drying with Variability Ensemble, which represents a drier future.

Figure TA 15-12 below shows the percentage of modeled futures in which Lake Mead elevations are maintained at or above 950 feet under each alternative. Results are presented for four modeling periods: the Full Modeling Period, and 2027-2039, 2040-2049, and 2050-2060. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative maintains elevations of 950 feet or above 100 percent of the time.

Figure TA 15-12
Lake Mead Power Pool: Robustness.
Percent of futures in which Lake Mead elevation is at least 950 feet in the percent of months specified in each row



In the Full Modeling Period, the Maximum Operational Flexibility (84 percent), Supply Driven (LB Pro Rata approach) (80 percent), Enhanced Coordination (76 percent), and Representative Preferred (72 percent) Alternatives were fairly robust. The Supply Driven Alternative (LB Priority approach) performed moderately well, meeting the preferred minimum performance in 68 percent of modeled futures. The CCS Comparative Baseline (45 percent), and Basic Coordination (55 percent) and No Action (25 percent) Alternatives did not perform as well as the other alternatives.

Across the subperiods, the Maximum Operational Flexibility, Supply Driven (LB Pro Rata approach), Enhanced Coordination, and Representative Preferred Alternatives meet the preferred minimum performance in 80 to 92 percent of all futures and are considerably more robust than the other alternatives. The CCS Comparative Baseline, Basic Coordination, and No Action Alternatives met the preferred minimum performance in fewer futures.

Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Maximum Operational Flexibility, Supply Driven (LB Pro Rata approach), Enhanced Coordination, and Representative Preferred Alternatives meet the preferred minimum performance in 84 percent or more of futures, followed closely by the Supply Driven Alternative (LB Priority approach) (77 percent). The Basic Coordination Alternative (68 percent), CCS Comparative Baseline (62 percent), and No Action Alternative (43 percent) are less robust.

Figure TA 15-13 below shows what flow conditions are likely to cause the Lake Mead elevation to fall below 950 feet in any month, resulting in reduced or lost hydropower generation. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-12** above, which defined a future as successful when an alternative maintained Lake Mead elevation above 950 feet 100 percent of the time.

Figure TA 15-13
Lake Mead Power Pool: Vulnerability.
Conditions that Could Cause Lake Mead Elevation Below 950 Feet in any Month

For this vulnerability analysis, the driest 10-year average Lees Ferry annual flow was determined to be a skillful predictor of undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 maf) and the average flow

from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison. The Drying with Variability median value is 10.3 maf.

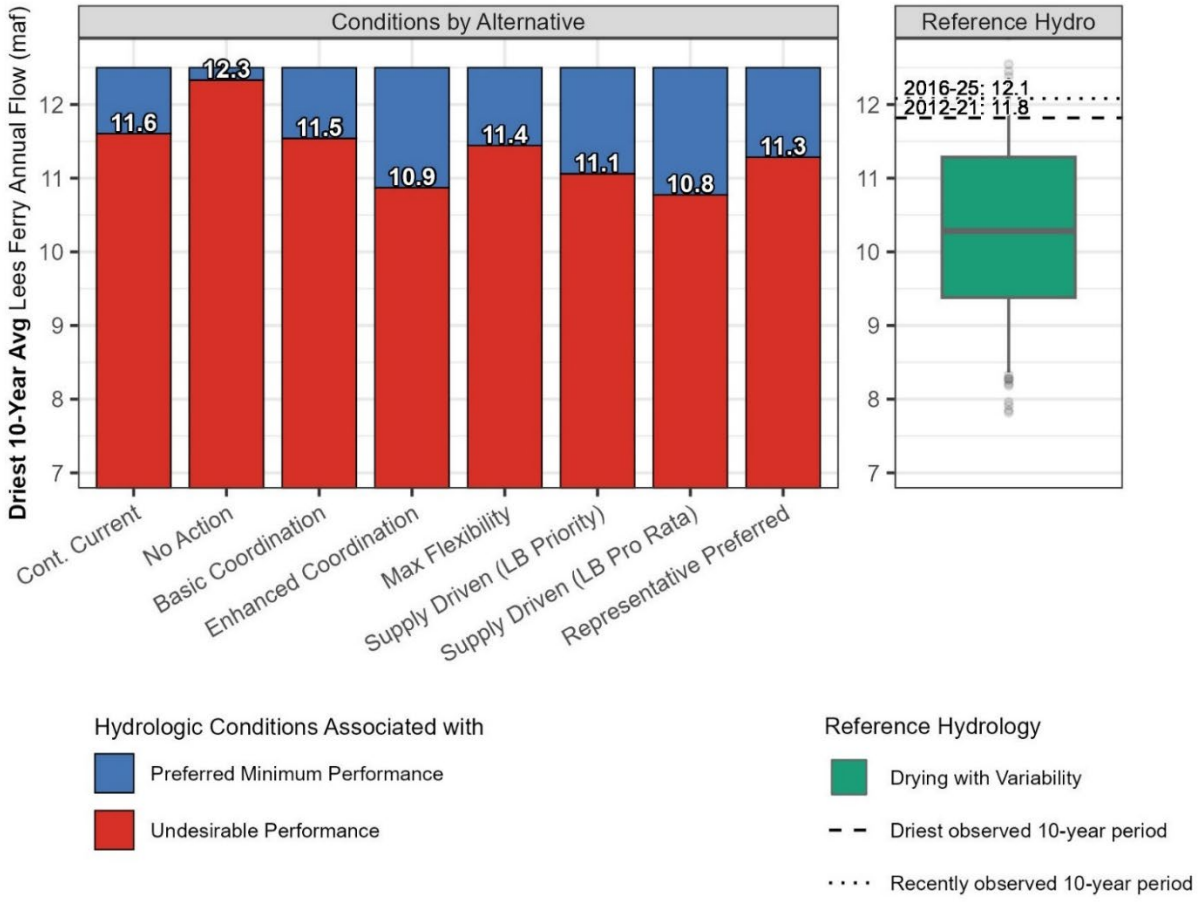
The No Action Alternative (11.6 maf) and CCS Comparative Baseline (10.9 maf) are most vulnerable to undesirable performance (nearly 75 percent or more traces in the Drying with Variability ensemble included these conditions or worse). In contrast, the Maximum Operational Flexibility (8.6 maf), Supply Driven (LB Pro Rata approach) (9 maf), and Enhanced Coordination (9.3 maf) Alternatives reach undesirable performance as hydrologic conditions become drier (around 25 percent or less of the Drying with Variability traces included these conditions or worse) indicating lower vulnerability. The Representative Preferred (9.8 maf) and Supply Driven (LB Priority approach) (10 maf) Alternatives are in the middle, being vulnerable in 25 to 50 percent of traces in the Drying with Variability Ensemble. The driest observed 10-year average Lees Ferry flow in the historical record is 11.8 maf; therefore, vulnerability thresholds for all alternatives are below what has already occurred.

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to at least one occurrence of Lake Mead elevation falling below 950 feet under a 10-year average flow of 9.8 maf. This alternative may or may not be vulnerable in the next 10 years because these conditions have not yet been observed but occur in more than 25 percent and fewer than 50 percent of traces in the Drying with Variability Ensemble, which represents a drier future.

Figure TA 15-14 below reports the percent of modeled futures in which each alternative maintains Lake Mead elevations at or above 1,035 feet in the percentage of time specified in each row. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative maintains elevations at or above 1,035 feet at least 90 percent or more of the time. At an elevation of 1,035 feet, Hoover's high-head units can operate, marking the minimum elevation for viable high-head turbine operation. Total plant capacity at 1,035 feet is substantially reduced (approximately 382 MW), and additional capacity increases with higher elevations as head improves and more units become usable. Four modeling periods are shown: the Full Modeling Period, 2027-2039, 2040-2049, and 2050-2060.

In the Full Modeling Period, the percentage of futures that meets the preferred minimum performance level is highest under the Supply Driven Alternative (LB Pro Rata approach) at 55 percent, followed by the Enhanced Coordination Alternative at 46 percent. The Supply Driven (LB Priority approach) (43 percent), Maximum Operational Flexibility (36 percent), and the Representative Preferred (32 percent) Alternatives outperform the CCS Comparative Baseline (19 percent), and Basic Coordination (26 percent) and No Action (9 percent) Alternatives. The CCS Comparative Baseline, Basic Coordination and No Action Alternatives are the least robust with respect to maintaining the Lake Mead elevation required for high-head turbine performance.

Figure TA 15-14
Lake Mead High-Head Turbines: Robustness.
Percent of futures in which Lake Mead elevation is at least 1,035 feet in the percent of months specified in each row



For the first sub-period (2027-2039), all alternatives achieved the preferred minimum performance in 18 to 36 percent of futures. No Action Alternative was the least robust, meeting the preferred performance in 7 percent of futures. In the second subperiod (2040-2049), the Supply Driven (LB Pro Rata approach) (80 percent), Supply Driven (LB Priority approach) (73 percent), Enhanced Coordination (73 percent), and Maximum Operational Flexibility (72 percent) Alternatives performed significantly better than the previous decade. In the final subperiod (2050-2060), the Supply Driven Alternative (LB Pro Rata approach) meets the preferred minimum performance in 82 percent of futures. The lowest performing alternative across all subperiods was the No Action Alternative, followed by the CCS Comparative Baseline.

Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Supply Driven Alternative (LB Pro Rata approach) is the most robust (36 percent), followed by the Supply Driven (LB Priority approach) (26 percent) and Representative Preferred (25 percent) Alternatives. The remaining action alternatives and CCS Comparative Baseline range from 18 to 23 percent. The No Action Alternative is the least robust at 7 percent.

Figure TA 15-15 below shows the flow conditions associated with Lake Mead elevation falling below 1,035 feet in one or more months. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-14** above, which defined a future as successful when an alternative maintains Lake Mead elevations at or above 1,035 feet at least 90 percent of the time.

Figure TA 15-15
Lake Mead Power Pool: Vulnerability.
Conditions that could cause Lake Mead elevation to fall below 1,035 feet in more than 10 percent of months

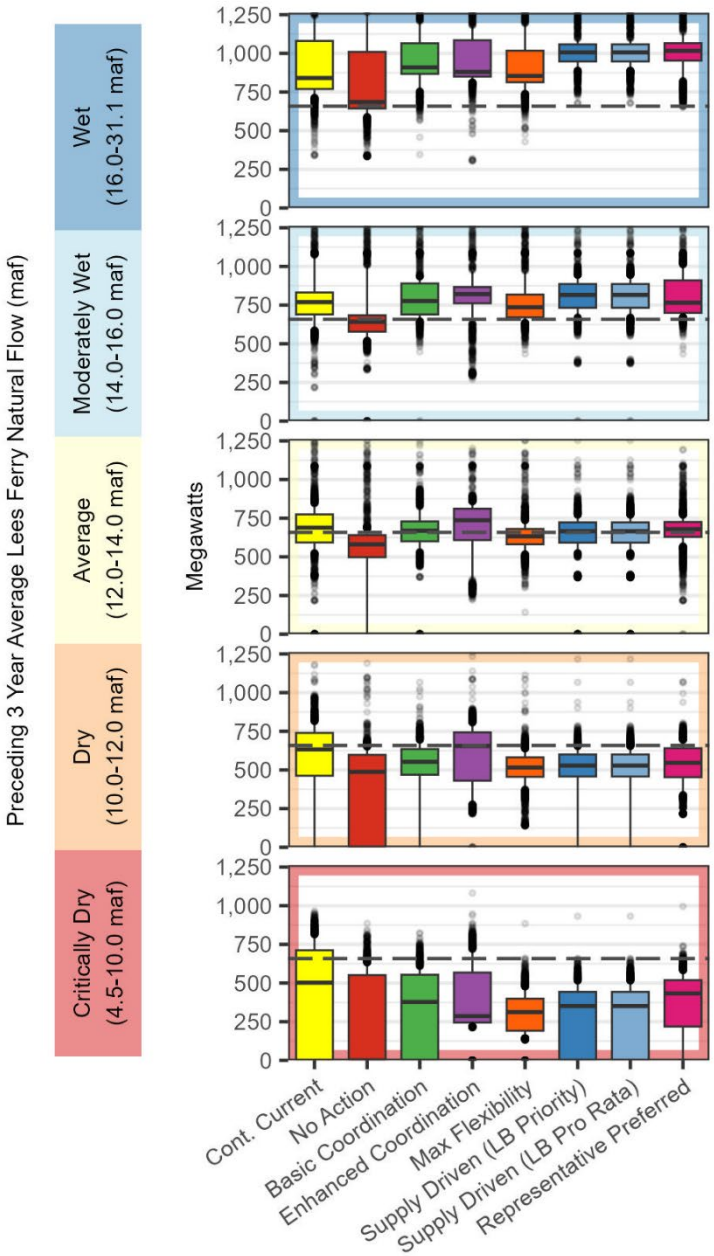
For this vulnerability analysis, the driest 10-year average Lees Ferry annual flow was determined to be a skillful predictor of undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison. The Drying with Variability median value is 10.3 maf.

The No Action Alternative (12.3 maf) is vulnerable to conditions wetter than the recent 10-year average of 12.1 maf, making it the most vulnerable alternative. Following are the CCS Comparative Baseline (11.6 maf), and Basic Coordination (11.5 maf), Maximum Operational Flexibility (11.4 maf), and Representative Preferred (11.3 maf) Alternatives which are vulnerable to hydrological conditions that occur in 75 percent or more of the Drying with Variability traces. Enhanced Coordination (10.9 maf), Supply Driven (LB Priority approach) (11.1 maf), and Supply Driven (LB Pro Rata approach) (10.8 maf) Alternatives were vulnerable to hydrological conditions that occur in 50 to 75 percent of the Drying with Variability traces.

The driest observed 10-year average Lees Ferry flow in the historical record is approximately 11.8 maf; except for the No Action Alternative, vulnerability thresholds are below what has already occurred.

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to Lake Mead elevation falling below 1,035 feet in more than 10 percent of months under a 10-year average flow of 11.3 maf. Absent additional action, this alternative is reasonably likely to be vulnerable in the next 10 years because these conditions are close to what has already occurred and they occur in about 75 percent of traces in the Drying with Variability Ensemble.

Summary of Issue 1 Impacts



Across both Lake Powell and Lake Mead, the Maximum Operational Flexibility and Enhanced Coordination Alternatives consistently show higher robustness, maintaining elevations above minimum power pool in the greatest percentages of modeled futures, and are less vulnerable to undesirable performance under drier hydrological conditions. In contrast, the CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (LB Priority approach) Alternatives exhibit greater vulnerability, with higher frequencies of dropping below minimum power pool and broader exposure to low-elevation conditions, especially under drier hydrology. At Lake Powell, Maximum Operational Flexibility and Enhanced Coordination Alternatives perform best, maintaining preferred conditions in 81 to 95 percent of futures over the full modeling period and showing lower vulnerability (between 6.8–9 maf), while other alternatives reach undesirable performances. The Representative Preferred Alternative is less protective of elevation 3,490 feet than the Enhanced Coordination and Maximum Operational Flexibility Alternatives, but more protective than the other alternatives and CCS Comparative Baseline. Similarly, at Lake Mead, Maximum Operational Flexibility, Enhanced Coordination, Supply Driven (LB Pro Rata approach), and Representative Preferred Alternatives demonstrate stronger performance (72 to 84 percent robustness), whereas the No Action Alternative and CCS Comparative Baseline are the least robust and most vulnerable, indicating a higher likelihood of dropping below minimum power pool under a wider range of hydrologic conditions.

TA 15.2.4 Issue 2: How would the alternatives impact the firm capacity of the Glen Canyon and Hoover Powerplants?

Firm capacity is the reliable, guaranteed amount of power output from a powerplant that accounts for operational constraints such as water releases and ramp rates. Firm capacity is measured in MW. This section will consider how the different alternatives impact the firm capacities of the hydropower plants at the Glen Canyon Dam and Hoover Dam.

Figure TA 15-16 below shows the firm capacity of Glen Canyon Dam across five different potential flow categories (Wet [16.0-31.1 maf], Moderately Wet [14.0-16.0 maf], Average [12.0-14.0 maf], Dry [10.0-12.0 maf], and Critically Dry [4.5-10.0 maf]) defined by the preceding 3-year average of Lees Ferry natural flow using August as the flow month. Reclamation used the estimated capacity for the month of August as it corresponds to peak energy demand and typically reflects the maximum available generating capacity. The dashed horizontal line represents the historical average firm capacity (658.3 MW, based on August 2016–2025 conditions). The bold center line of each box represents the median value, the box bounds represent the 25th to 75th percentile of the modeled results, the lines extend to the 10th and 90th percentiles, and the outliers are represented as dots beyond these lines.

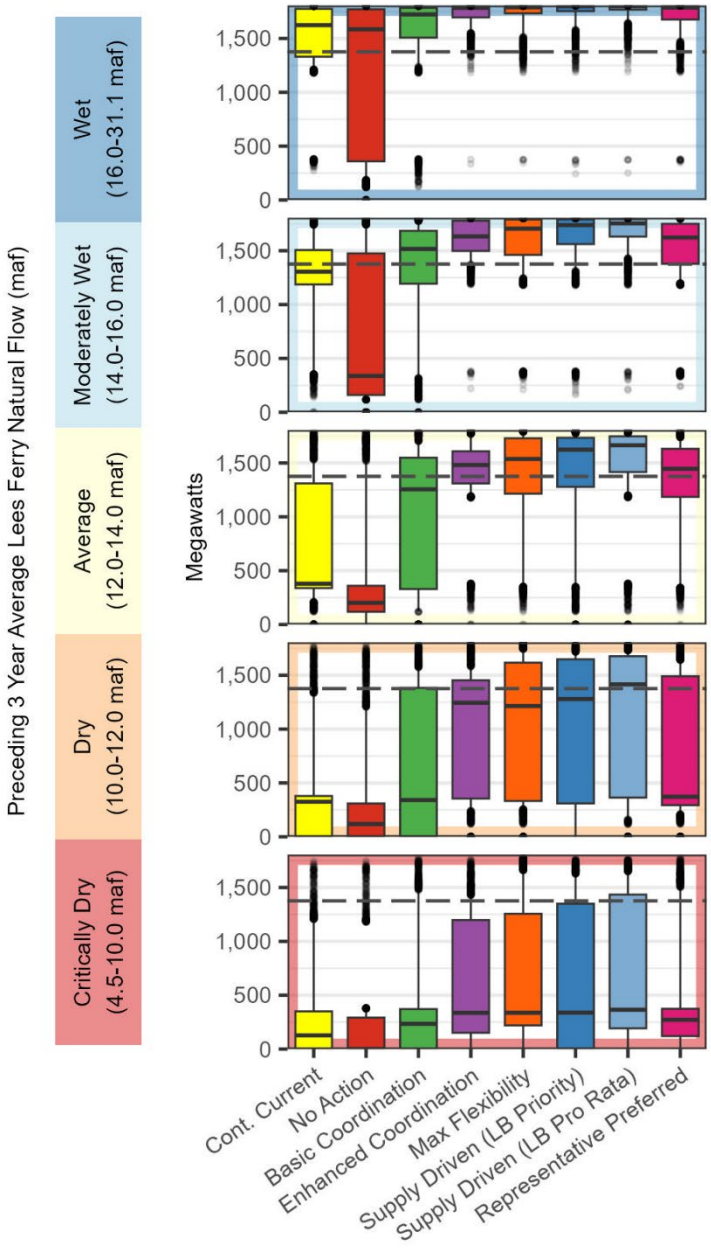
Figure TA 15-16
Glen Canyon August Power Capacity: Box Plots

Across most alternatives, firm capacity is highest under the Wet Flow Category, with higher median values and relatively narrower interquartile ranges, indicating strong and consistent performance under wetter hydrologic conditions. The Representative Preferred Alternative performs best with a median of 1,016 MW. The Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative had a median 1,006 MW and similar variability to the Representative Preferred Alternative. The Enhanced Coordination, Maximum Operational Flexibility, and Basic Coordination Alternatives, and the CCS Comparative Baseline had median firm capacities ranging from 841 to 909

MW. The No Action Alternative had the lowest median at 685 MW, just above the historical average firm capacity from August 2016–2025 of 658.3 MW.

In the Moderately Wet Flow Category, the Enhanced Coordination, Basic Coordination, Representative Preferred, Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, and the CCS Comparative Baseline generally exhibit higher median firm capacity and more favorable distributions than the Maximum Operational Flexibility and No Action Alternatives, which have lower medians.

Under the Average Flow Category, the Enhanced Coordination Alternative has the highest median value, followed closely by the CCS Comparative Baseline while the No Action Alternative has the lowest median indicating reduced performance. The remaining action alternatives cluster around the historical average firm capacity with similar median values and comparable interquartile ranges, suggesting similar levels of firm capacity under average hydrological conditions.



In the Dry Flow Category, median value declines across all alternatives and variability increases, reflecting heightened sensitivity to hydrologic stress. The Enhanced Coordination Alternative exhibits the highest median value in this category, followed by the CCS Comparative Baseline. While the other alternatives have lower medians, their interquartile ranges are narrower, indicating less variable firm capacities. Under dry conditions the No Action Alternative has the lowest median and a firm capacity of 0 MW in at least 25 percent of years.

Under the Critically Dry Flow Category, the CCS Comparative Baseline, and No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives have at least 25 percents of years with 0 MW of firm capacity, indicating a high likelihood of undesirable performance under the driest conditions. These results highlight that alternatives emphasizing coordination and flexibility generally maintain higher medians and reduced variability, while less coordinated approaches are more susceptible to firm capacity loss as hydrologic conditions deteriorate.

In the Dry Flow Category, the Representative Preferred Alternative has a median August power capacity of 546 MW and an interquartile range (187 MW) that is near the middle of all alternatives. In the Critically Dry Flow Category, the Representative Preferred Alternative has a median capacity of 433 MW. With an interquartile range of 300 MW, the Representative Preferred Alternative is less variable than all alternatives, except the Maximum Operational Flexibility Alternative.

Figure TA 15-17 below shows the August firm capacity of Hoover Dam across five different potential flow categories (Wet [16.0-31.1 maf], Moderately Wet [14.0-16.0 maf], Average [12.0-14.0 maf], Dry [10.0-12.0 maf], and Critically Dry [4.5-10.0 maf]) defined by the preceding 3-year average of Lees Ferry natural flow. Reclamation used the estimated capacity for the month of August as it corresponds to peak energy demand and typically reflects the maximum available generating capacity. The dashed horizontal line represents the historical average firm capacity (1,376 MW, the average firm capacity between August 2016 to August 2025 based on historical data). The bold center line of each box represents the median value, the top and bottom of each box captures the 25th to 75th percentile of the modeled results, the lines extend to the 10th and 90th percentiles, and the outliers are represented as dots beyond these lines.

Figure TA 15-17
Hoover August Power Capacity: Box Plots

Under the Wet Flow Category, most alternatives show relatively high firm capacity with narrow interquartile ranges and similar medians, indicating stable capacity under wetter conditions. The exception in this category is the No Action Alternative which has a similar median to other alternatives (1585 MW) but much higher variability than the other alternatives with an interquartile range of 1412 MW.

In the Moderately Wet Flow Category, the Supply Driven (both LB Priority and LB Pro Rata approaches), Basic Coordination, Enhanced Coordination, Representative Preferred, and Maximum Operational Flexibility Alternatives generally have median power capacities higher than the historical

average value and relatively narrow interquartile ranges. The CCS Comparative Baseline median (1,305 MW) fell slightly below the historical average firm power capacity. The No Action Alternative had the widest range of variability and the median firm capacity (337 MW) was well below the other alternatives.

Under the Average Flow Category, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative had the highest median firm capacities (1,624 and 1,664 MW respectively). The Maximum Operational Flexibility and Enhanced Coordination Alternatives had similar medians but the Enhanced Coordination Alternative was less variable than Supply Driven or Maximum Operational Flexibility. The Representative Preferred Alternative has a median firm capacity (1,446 MW) slightly above the historical average and similar variability to preceding alternatives. The Basic Coordination, and No Action Alternatives, and the CCS Comparative Baseline performed considerably worse than the other alternatives with lower median firm capacities and greater variability.

Under the Dry Flow Category, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative had the highest median firm capacities, followed by the Enhanced Coordination and Maximum Operational Flexibility Alternatives. The Representative Preferred Alternative had a much lower median firm capacity (372 MW) but similar variability to the preceding alternatives. The CCS Comparative Baseline and No Action and Basic Coordination Alternatives performed the worst with power capacity reaching zero in more than 25 percent of years.

In the Critically Dry Flow Category, the Supply Driven (both LB Priority and LB Pro Rata approaches), Maximum Operational Flexibility, and Enhanced Coordination Alternatives experienced wide variability for firm capacity but had median firm capacities around 350 MW. The CCS Comparative Baseline, and No Action, and Basic Coordination Alternatives show the lowest medians and the potential for zero capacity in more than 25 percent of years under the Critically Dry Flow Category.

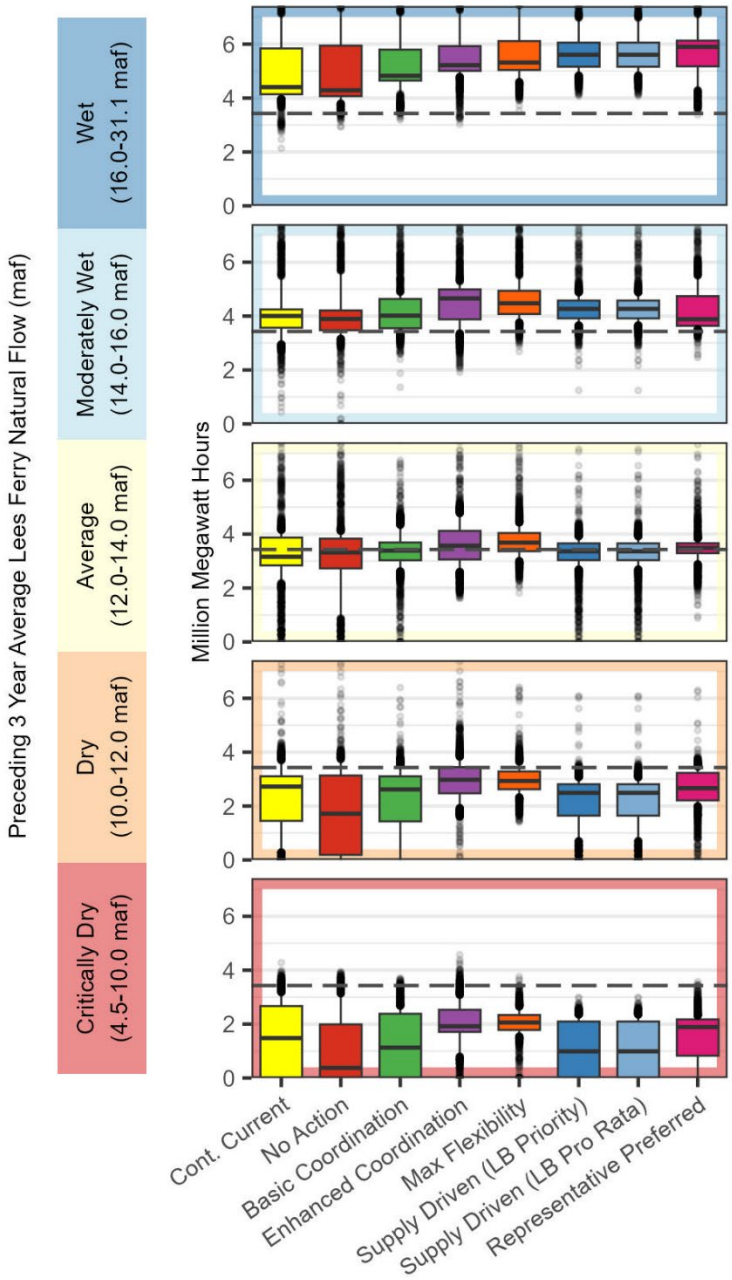
In the Dry Flow Category, the Representative Preferred Alternative has a median firm capacity of 372 MW with an interquartile range of 1,197 MW. The median of the Representative Preferred Alternative is lower than the other action alternatives but the variability is similar. In the Critically Dry Flow Category, the Representative Preferred Alternative has a median firm capacity (271 MW) that is similar to the other action alternatives. With an interquartile range of 253 MW, the Representative Preferred Alternative is the least variable of all action alternatives.

Summary of Issue 2 Impacts

The firm capacity at Glen Canyon Dam under the Wet Flow Category is the highest under the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative. In the Moderately Wet Flow Category, the Supply Driven (both LB Priority and LB Pro Rata approaches) and Enhanced Coordination Alternatives performed with the highest firm capacity. Under Average and Dry Flow Category, the Enhanced Coordination Alternative had the highest median firm capacity. In the Critically Dry Flow Category, the CCS Comparative Baseline had a wide range of variability, with the highest 75th percentile exceeding the historical average firm capacity, and the 25th percentile falling

to 0 MW. Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives 25th percentiles did not fall to 0 MW like that of the other alternatives.

For the Hoover Powerplant, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative provided the highest firm capacities across all flow categories. Considered collectively, the Maximum Operational Flexibility Alternative leads to relatively high firm capacity for both the Glen Canyon Powerplant and the Hoover Powerplant. Although the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative provides high firm capacity, they have a wide interquartile variability indicating less reliable performance under drier conditions. The CCS Comparative Baseline, Basic Coordination and No Action Alternatives performed the worst across all flow categories, with lower median values and 25th percentiles falling to 0 MW in the Dry and Critically Dry Categories. The Representative Preferred Alternative outperforms the CCS Comparative Baseline, No Action Alternative, and Basic Coordination Alternative, but has a lower median capacity than the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, across all flow categories.



TA 15.2.5 Issue 3: How would the alternatives impact the energy generation of the Glen Canyon, Hoover, Davis, and Parker Powerplants?

Energy generation is the amount of energy created over a certain period, measured in MWhs. Energy generation is dependent on reservoir head and water release volume. The model inputs used to develop the figures in the energy generations analysis simulated releases and lake reservoir elevations to calculate estimated energy generation. **Figure TA 15-18**, **Figure TA 15-19**, **Figure TA 15-20**, and **Figure TA 15-21** illustrate the power generation response of Glen Canyon, Hoover, Davis, and Parker Powerplants, respectively. The box plots illustrate how the alternatives respond during different hydrologic conditions that are based on the preceding 3-year average of Lees Ferry natural flow. The bold center line of each box represents the median value, the top and bottom of each box captures the 25th to 75th percentile of the modeled results, the lines extend to the 10th and 90th percentiles, and the outliers are represented as dots beyond these lines.

Figure TA 15-18 below shows that under the Wet and Moderately Wet Flow Categories at Glen Canyon Dam, the Supply Driven (both LB Priority [5.6 and 4.3 million MWhs] and LB Pro Rata [5.6 and 4.3 million MWhs] approaches), Maximum Operational Flexibility (5.3 and 4.8 million MWhs), and Enhanced Coordination (5.2 and 4.7 million MWhs) Alternatives, resulted in slightly higher median energy generation values than the other alternatives. The Representative Preferred Alternative performs best under the Wet Flow Category at 5.9 million MWhs but worst under the Moderately Wet Category at 3.9 million MWhs. All alternatives performed above the historical average energy generation of 3.4 million MWhs (2016-2025) in both categories.

Under the Average Flow Category, the Maximum Operational Flexibility (3.7 million MWhs) and Enhanced Coordination (3.6 million MWhs) Alternatives performed slightly above the historical average energy generation value. The median energy generation for the other alternatives remain near the historical average energy generation of approximately 3.4 million MWhs.

Figure TA 15-18
Water Year Glen Canyon Energy Generation: Box Plots

Under the Dry Flow Category, the Maximum Operational Flexibility (2.9 million MWhs) and Enhanced Coordination (2.9 million MWhs) Alternatives have the highest median energy generation and lowest variability of all alternatives. CCS Comparative Baseline, and the No Action, and Basic Coordination Alternatives have greater variability in energy generation than the other alternatives. Under the No Action Alternative energy generation falls to 0 million MWhs in almost 25 percent of years. The No Action Alternative had the lowest median energy generation value of 1.7 million MWhs.

Under the Critically Dry Flow Category, the Maximum Operational Flexibility (2.1 million MWhs), Enhanced Coordination (1.9 million MWhs), and Representative Preferred (1.9 million MWhs) Alternatives continue to show the highest median energy generation values. Energy generation under the CCS Comparative Baseline (1.5 million MWhs), No Action (0.4 million MWhs), Basic Coordination (1.1 million MWhs), and Supply Driven (LB Priority [0.9 million MWhs] and LB Pro Rata [0.9 million MWhs] approaches) Alternatives fall to 0 million MWhs in at least 25 percent of years and have median values never exceeding 1.7 million MWhs.

The Representative Preferred Alternative in the Dry (2.7 million MWhs) and Critically Dry (1.9 million MWhs) Categories experienced higher median values.

Figure TA 15-19 below shows for the Hoover Powerplant, under the Wet and Moderately Wet Flow Categories, the Maximum Operational Flexibility Alternative (4.6 and 3.6 million MWhs), the Supply Driven (both LB Priority [4.9 and 3.6 million MWhs] and LB Pro Rata [5.0 and 3.9 million MWhs] approaches), Representative Preferred (4.6 and 3.5 million MWhs), and the Enhanced Coordination (4.5 and 3.7 million MWhs) Alternatives generally produce the highest median energy generation. The other alternatives perform similarly, except that energy generation under the No Action Alternative falls below the historical average of 3.3 million MWhs (2016-2025) in over 25 percent of years in the Wet Flow Category.

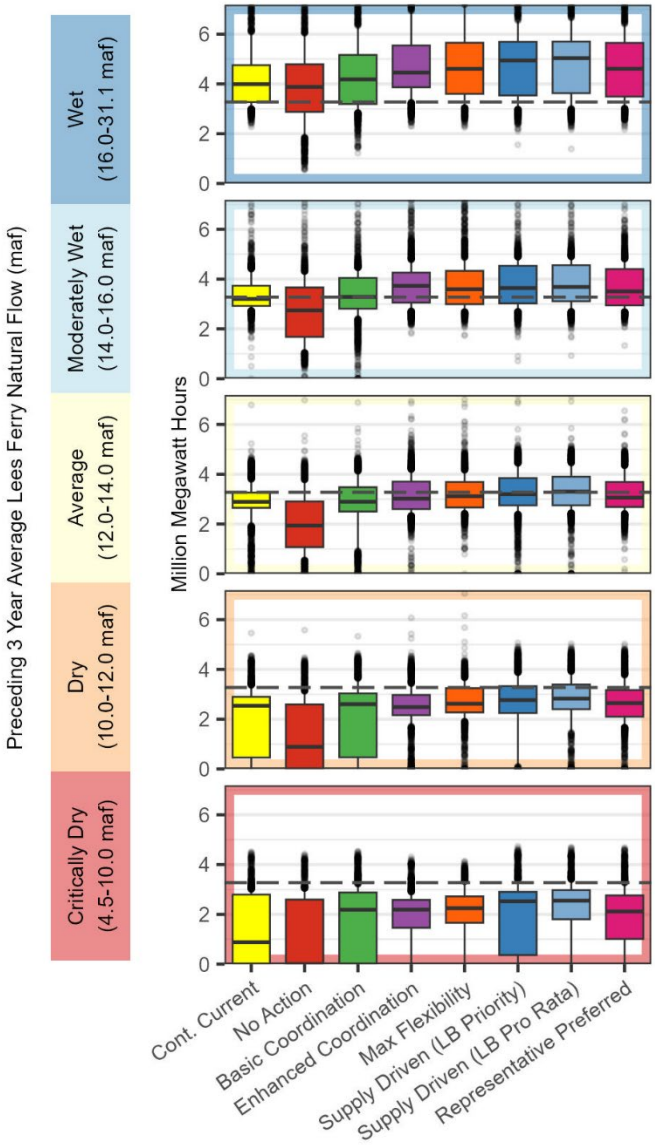
Under the Average Flow Category, the Supply Driven (both LB Priority [3.2 million MWhs] and LB Pro Rata [3.3 million MWhs] approaches) Alternative had the overall highest median energy generation, like the historical average of 3.3 million MWhs (2016-2025). All other action alternatives and the CCS Comparative Baseline had similar median values and are characterized by relatively small interquartile ranges. The No Action Alternative has the greatest interquartile variability and produces the lowest level of median energy generation at 1.9 million MWhs.

In the Dry Flow Category, median energy generation falls below the historical average energy generation for all alternatives. Variability increases markedly over the Dry Flow Category for the CCS Comparative Baseline (2.5 million MWhs), No Action (0.9 million MWhs), and Basic Coordination (2.6 million MWhs) Alternatives. Energy generation reaches 0 million MWhs in more than 25 percent of years under the No Action Alternative.

Under the Critically Dry Flow Category, median energy generation decreased considerably for the CCS Comparative Baseline (0.9 million MWhs) and No Action Alternative. Energy generation fell to 0 million MWhs in more than 50 percent of the time for the No Action Alternative. The median energy generation for the other alternatives was similar to the Dry Flow Category; however, performance was more variable (wider interquartile range) for the Enhanced Coordination, Supply Driven (LB Priority approach), and Representative Preferred Alternatives.

The Representative Preferred Alternative under Dry (2.6 million MWhs) and Critically Dry (1.0 million MWhs) Categories had relatively high median values. 25 percent of years fall to 1 million MWhs or less under the Critically Dry Flow Category.

Figure TA 15-19
Water Year Hoover Energy Generation: Box Plots



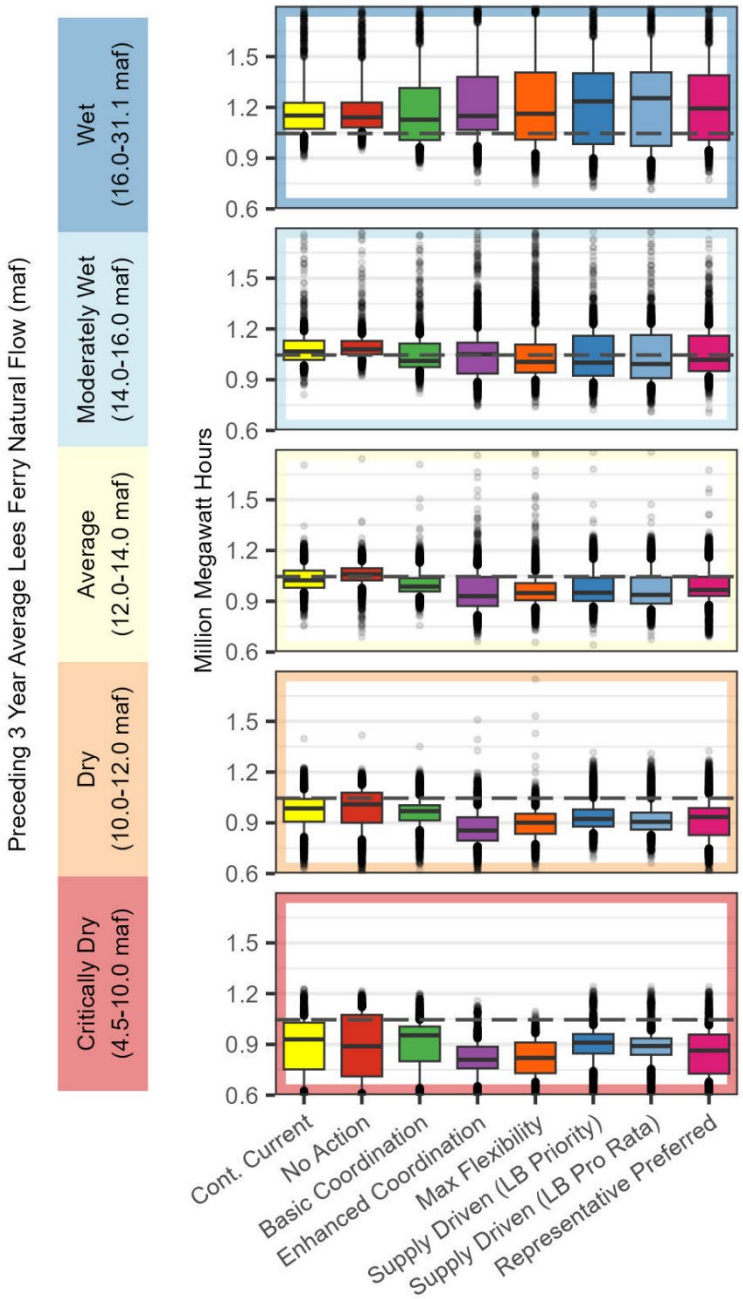


Figure TA 15-20 below shows that for the Davis Powerplant under the Wet Flow Category, the Supply Driven (both LB Priority [1.3 million MWhs] and LB Pro Rata [1.3 million MWhs] approaches) Alternative produces the highest median value, with the 25th percentile falling below the historical average value of 1.0 million MWhs and the 75th percentile at 1.4 million MWhs. All other alternatives performed similarly, with median energy generation near 1.1 million MWhs, but CCS Comparative Baseline and No Action exhibiting the narrowest interquartile ranges, indicating the lowest variability in annual generation value compared to the other alternatives.

Under the Moderately Wet and Average Flow Categories, variability decreases and all alternatives result in median energy generation values near or below the Davis Dam historical average of 1.0 million MWhs. The No Action Alternative (1.1 million MWhs) and CCS Comparative Baseline (1.0

million MWhs) median values perform best in these flow categories and, similar to the Wet Flow Category, have some of the lowest variability in annual generation values.

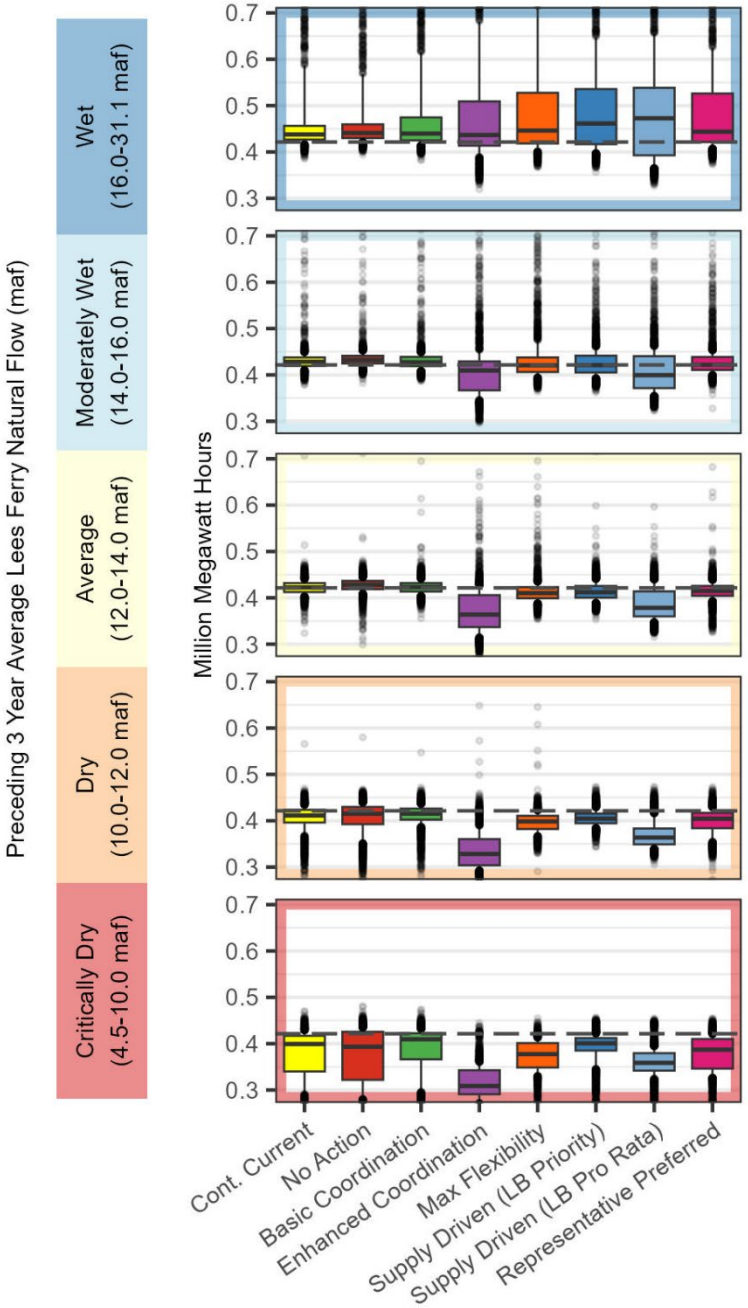
Figure TA 15-20
Water Year Davis Energy Generation: Box Plots

Under the Dry Flow Category, the CCS Comparative Baseline (0.9 million MWhs) and No Action Alternative (1.0 million MWhs) have slightly higher median energy generation values than the other alternatives. These alternatives begin to show greater interquartile variability in drier flow conditions. The Enhanced Coordination Alternative (0.8 million MWhs) yields the lowest median energy

generation value among all alternatives. In the Critically Dry Flow Category, all alternatives perform similarly to the Dry Flow Category. Interquartile variability of energy generation increases for all alternatives, and all but the No Action Alternative falls below the historical average of 1.0 million MWhs in 75 percent or more of years.

The Representative Preferred Alternative under Dry (0.9 million MWhs) and Critically Dry (0.8 million MWhs) Categories had relatively high median values.

Figure TA 15-21 shows that for the Parker Powerplant, under the Wet Flow Category, the Supply Driven (both LB Priority [0.46 million MWhs] and LB Pro Rata [0.47 million MWhs] approaches) Alternative have the highest levels of median energy generation value and above the 2016-2025 historical average (0.42 million MWhs). The Supply Driven Alternative (LB Pro Rata approach) displays a lower 25th percentile of 0.39 million MWhs. The other alternatives have similar median energy generation values, just above the historical average with the CCS Comparative Baseline and No Action Alternative exhibiting the narrowest interquartile variability.



Under the Moderately Wet Flow Category, most alternatives produce energy generation at or near the historical average level. The Supply Driven (LB Pro Rata approach) and Enhanced Coordination Alternatives show relatively wider interquartile ranges indicating more variable energy generation and result in median energy generation valued at just below the historical average.

Under the Average and Dry Flow Categories, all alternatives, other than the Supply Driven (LB Pro Rata approach) and Enhanced Coordination Alternatives generally exhibit narrow interquartile variability and similar median energy generation values, ranging between 0.40 to 0.42 MWhs. The Supply Driven (LB Pro Rata approach) (0.36 million MWhs) and Enhanced Coordination (0.33 million MWhs) Alternatives resulted in a much wider interquartile ranges and a lower median value, indicating these alternatives are more sensitive to drier flow conditions than the others.

Median energy generation continues to decrease in the Critically Dry Flow Category with about 75th percent or more years for all alternatives falling below the historical average. The relative performance between Alternatives is similar to the Average and Dry Flow Categories. The most notable difference is the wider interquartile ranges for all alternatives indicating increased vulnerability to low generation outcomes under the driest conditions.

The Representative Preferred Alternative under Dry (0.4 million MWhs) and Critically Dry (0.39 million MWhs) Categories had relatively high median values.

Figure TA 15-21
Water Year Parker Energy Generation: Box Plots

Summary of Issue 3 Impacts

Energy generation at each of the powerplants responds differently under each of the alternatives. Under wetter conditions, the Glen Canyon Powerplant would have the highest energy generation under the Supply Driven (both LB Priority and LB Pro Rata approaches), Enhanced Coordination, and Maximum Operational Flexibility Alternatives. As conditions become drier, the Representative Preferred and Maximum Operational Flexibility Alternatives remain the most robust, while other

alternatives exhibit greater variability and increased risk of decreased energy generation under critically dry conditions. The Hoover Powerplant would produce the highest amounts of energy under the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative in all five flow categories. The Davis Powerplant would have the highest power production under the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative under the Wet Flow Category. Under the Moderately Wet to Critically Dry Flow Categories, the No Action Alternative, followed by the CCS Comparative Baseline, generally produced the most energy generation. The Parker Powerplant would produce the most power under the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative under the Wet Flow Category. As conditions become drier, the alternatives (with the exceptions of Enhanced Coordination and Supply Driven [LB Pro Rata approach] Alternatives) have similar median values.

TA 15.2.6 Issue 4: How would the alternatives impact spillway use?

Spillway infrastructure is affected by reservoir elevation, particularly high elevations, which vary greatly between alternatives. High reservoir elevations, for extended durations, pose a risk to spillway infrastructure. Keeping the reservoir water level below the spillway crest minimizes spillway drum gate use and spillway use, preserves the water supply, maintains flood storage capacity, and reduces wear and tear on spillway infrastructure. This analysis compares the various action alternatives to the No Action Alternative and the CCS Comparative Baseline for the following metrics:

- Lake Powell pool elevations
- Lake Mead pool elevations

Lake Powell

Critical high elevations at Lake Powell are listed in **Table TA 15-1** below. Reclamation minimizes controlled discharge over the spillway, as these discharges are not intended for frequent or extended operation. One way to reduce these controlled discharges is to maintain a vacant space requirement in the reservoir, which serves as a buffer of unused storage capacity to absorb large runoff inflows without causing controlled discharge.

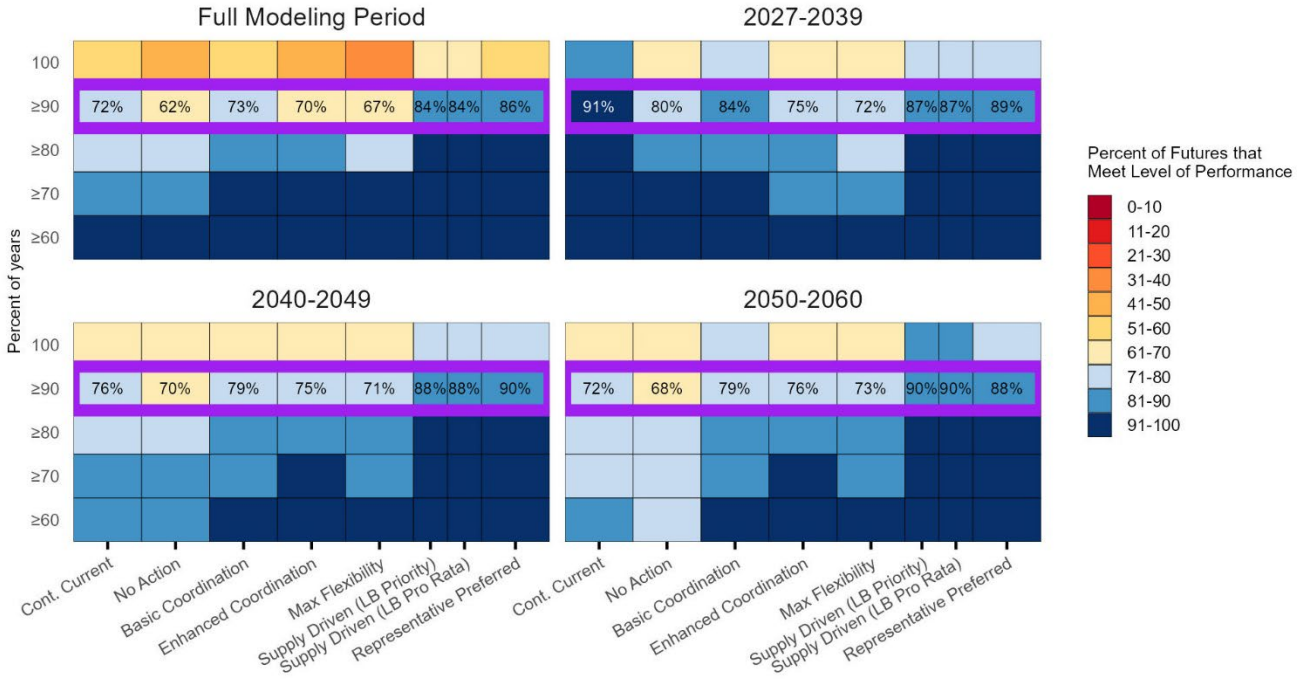


Table TA 15-1
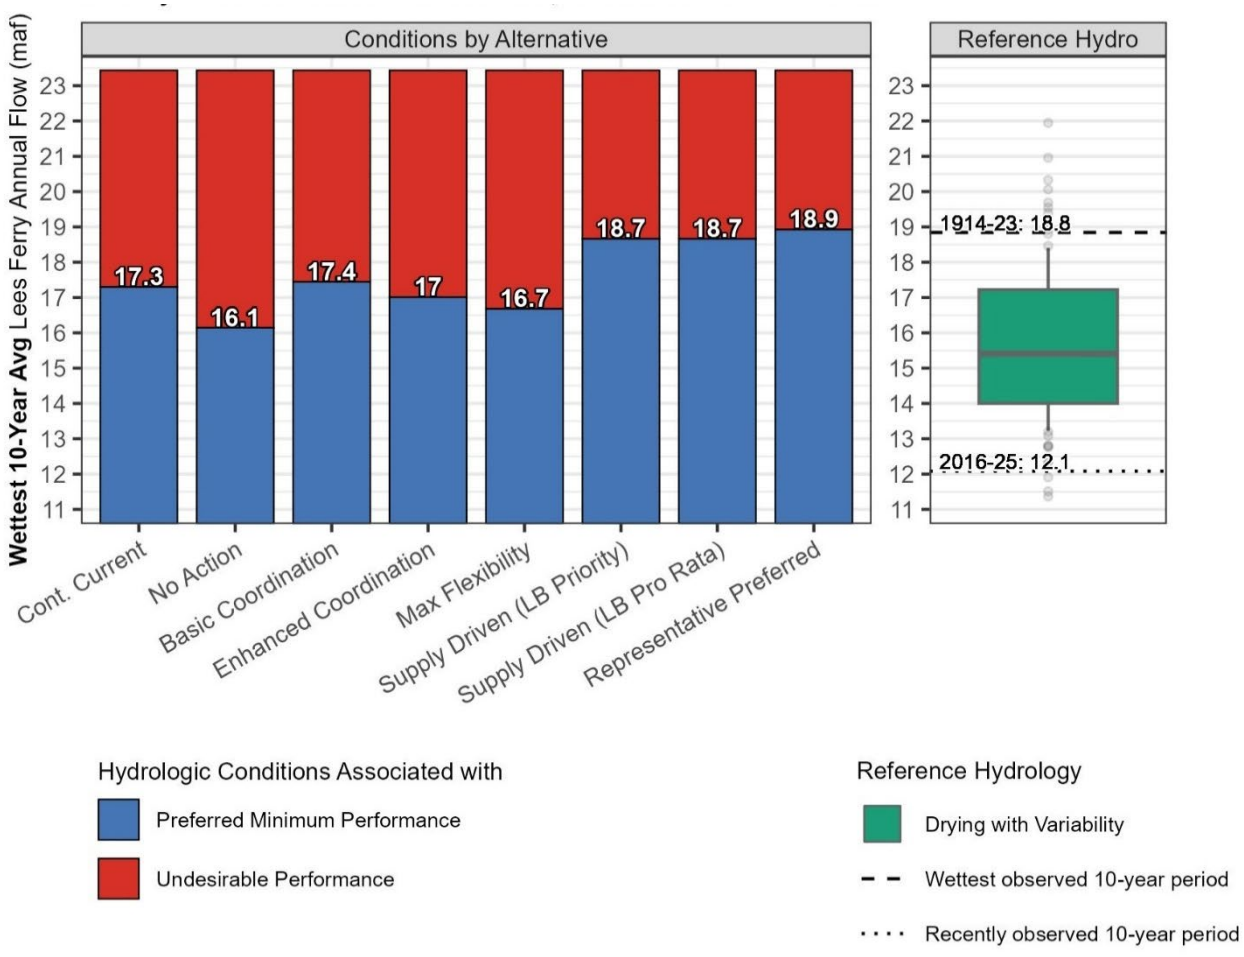
Critical Elevations at Lake Powell

Critical Condition	Associated Elevation	Description of Critical Elevation
Spillway	3,700 feet	Glen Canyon Dam spillway
Vacant Space Requirement	3,684 feet	Target reservoir elevation on January 1. Allows for 1.9 maf of flood control storage up to the top of the spillway

Figure TA 15-22 below reports the percentage of futures in which Lake Powell elevation does not exceed 3,684 feet on January 1 in the percent of years specified by each row. Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative maintains January 1 elevations below 3,684 feet in at least 90 percent of

years. Higher rows represent stricter performance requirements that are more difficult to achieve. Keeping Lake Powell below 3,684 feet ensures that sufficient reservoir volume is reserved to accommodate spring runoff.

Figure TA 15-22
Lake Powell Elevation 3,684 Feet: Robustness.
Percent of futures in which the January 1 Lake Powell elevation does not exceed 3,684 feet in the specified percent of years



In the Full Modeling Period, the Representative Preferred Alternative is the most robust, meeting the preferred minimum level of performance in 86 percent of futures. The Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative is the second most robust, meeting the preferred minimum level of performance in 84 percent of futures. The Basic Coordination, Maximum Operational Flexibility, Enhanced Coordination Alternatives, and the CCS Comparative Baseline perform similarly, meeting the preferred minimum performance in 67-73 percent of futures. The No Action Alternative has the worst performance at 62 percent of futures.

For the subperiod 2027-2039, the CCS Comparative Baseline was the most robust with 91 percent of futures meeting the preferred minimum performance. The Supply Driven (both LB Priority and LB Pro Rata approaches) and Representative Preferred Alternatives met the preferred minimum performance in 87 and 89 percent of futures, respectively. The No Action, Basic Coordination, Enhanced Coordination, and Maximum Operational Flexibility Alternatives experienced similarly high robustness, performing between 72-84 percent of years meeting the preferred minimum performance.

In the subperiods 2040-2049 and 2050-2060, the Supply Driven (both LB Priority and LB Pro Rata approaches) and Representative Preferred Alternatives were the most robust, meeting the preferred minimum performance in 88-90 percent of futures. The No Action Alternative was the least robust meeting the preferred minimum performance in 68-70 percent of futures.

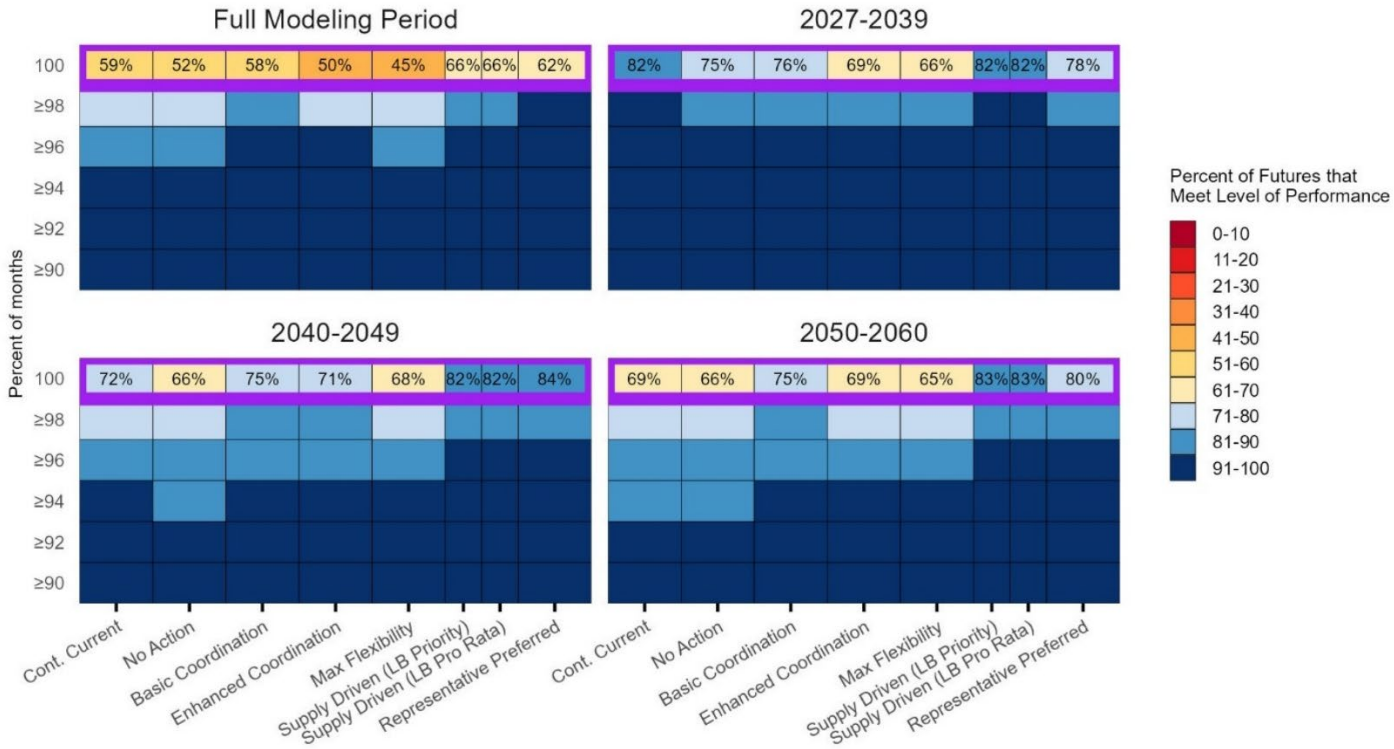
Figure TA 15-23 below looks at conditions that could cause the January 1 Lake Powell elevation to exceed 3,684 feet in 10 percent or more years. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-22**, which determined a future as successful when an alternative kept Lake Powell below this buffer elevation in at least 90 percent of years.

Figure TA 15-23
Lake Powell Preservation of Spring Runoff Space: Vulnerability.
January One Conditions that Could Cause Lake Powell Elevation Above 3,684 in 10 percent or More Years

For this vulnerability analysis, the wettest 10-year average of Lees Ferry Annual Flow was identified as a skillful predictor of undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The wettest observed 10-year average flow from 1914-1923 (18.8 maf) and the average flow

from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison. The reference Drying with Variability median value is 15.4 maf.

The Supply Driven (both LB Priority and LB Pro Rata approaches) (18.7 maf) and Representative Preferred (18.9 maf) Alternatives are the least vulnerable; less than 10 percent of traces in the Drying with Variability Ensemble include conditions this wet. The CCS Comparative Baseline (17.3 maf) and Basic Coordination Alternative (17.4 maf) are vulnerable to about 25 percent of traces in the Drying with Variability Ensemble. The No Action (16.1 maf), Maximum Operational Flexibility (16.7 maf), and Enhanced Coordination (17.0 maf) Alternatives become vulnerable under less extreme wet conditions; between 25 and 50 percent of traces in the Drying with Variability Ensemble include conditions this wet. All alternatives are expected to satisfy the preferred minimum performance under the driest 50 percent of traces in the Drying with Variability Ensemble, which includes the recent 10-year average from 2016–2025 (12.1 maf).



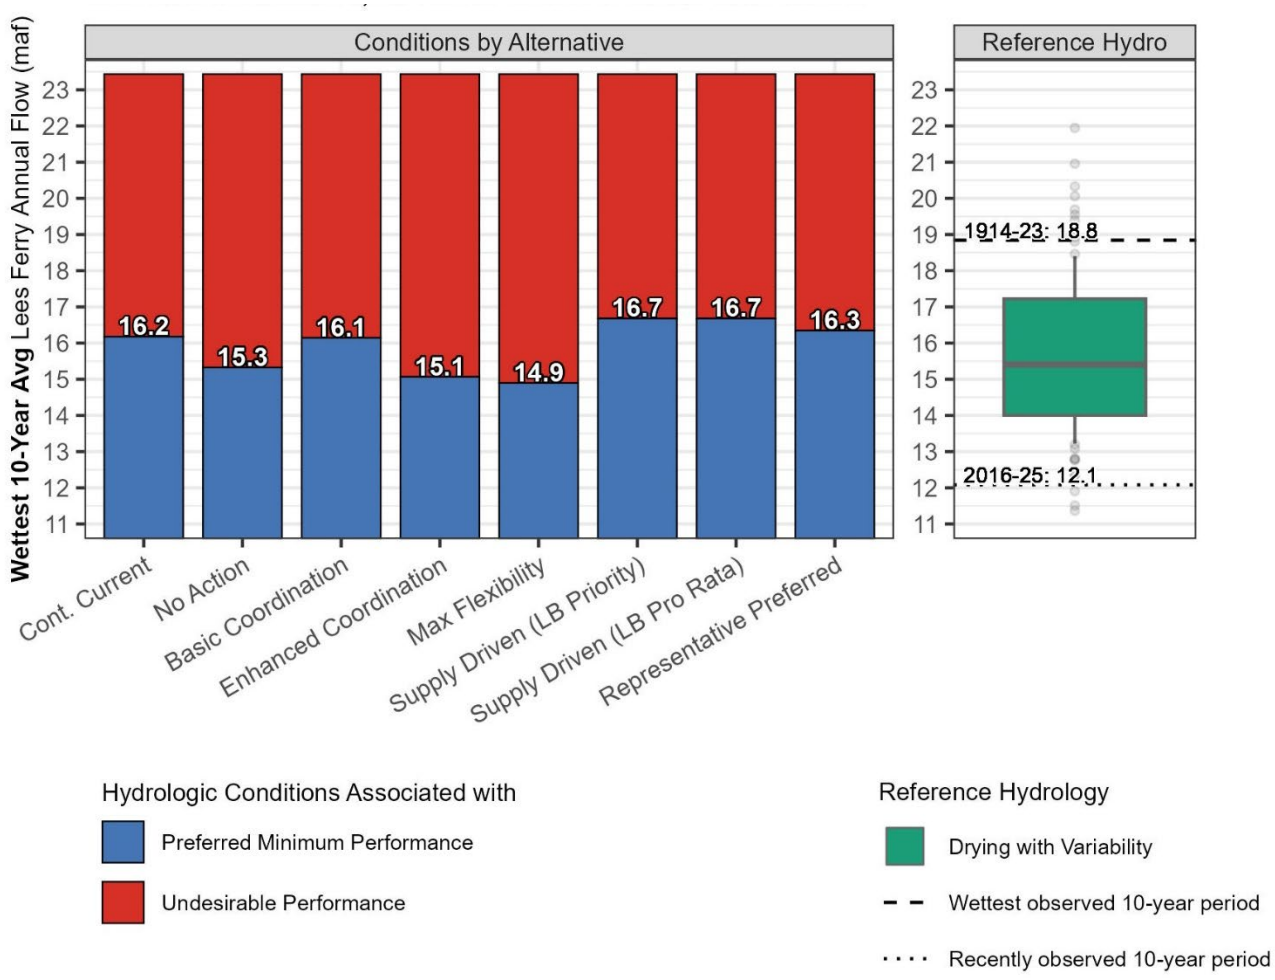
Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to January 1 Lake Powell elevation above 3,684 feet in more than 10 percent of years if the wettest 10-year average Lees Ferry annual flow is greater than 18.9 maf. This alternative is reasonably unlikely to be vulnerable in the next 10 years because the recently observed 10-year period is below 18.9 maf and fewer than 10 percent of traces in the Drying with Variability Ensemble include conditions this wet.

Figure TA 15-24 below depicts the ability of each alternative to maintain a Lake Powell pool elevation below 3,700 feet in the percentage of months specified by each row. Pool elevations below this threshold reduce the likelihood of large-magnitude spillway releases and provide an important buffer to protect dam infrastructure. Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative maintains elevations below 3,700 feet in 100 percent of months.

Under the Full Modeling Period, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative is the most robust, keeping Lake Powell below 3,700 feet in 66 percent of futures. The Representative Preferred Alternative was the second most successful at 62 percent of futures. The CCS Comparative Baseline and Basic Coordination Alternative are successful in 59 and 58 percent of futures, respectively. The No Action and Enhanced Coordination Alternatives are successful in 52 and 50 percent of futures. The Maximum Operational Flexibility Alternative was the least robust with 45 percent of futures meeting the preferred minimum performance.

In the three subperiods, the Supply Driven (both LB Priority and LB Pro Rata approaches) and Representative Preferred Alternatives were the most robust, meeting the preferred minimum performance in 82 and 83 percent of futures, respectively. Basic Coordination Alternative performed consistently between 75-76 percent of futures. The CCS Comparative Baseline met the preferred minimum performance in 82 percent of futures during subperiod 2027–2039, with performance declining to 69 percent by subperiod 2050–2060. The No Action, Enhanced Coordination, and Maximum Operational Flexibility Alternatives were consistently the least robust, meeting the preferred minimum performance between 65-75 percent of futures.

Figure TA 15-24
Lake Powell Elevation 3,700 Feet: Robustness.
Percent of futures in which Lake Powell elevation is below 3,700 feet in the specified percent of months



Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Maximum Operational Flexibility (66 percent) and Enhanced Coordination (69 percent) Alternatives are the least robust. All other alternatives and the CCS Comparative Baseline meet the preferred minimum performance level between 75 and 82 percent of futures, including the Representative Preferred Alternative (78 percent).

Figure TA 15-25 below shows what flow conditions are likely to cause the elevation of Lake Powell to exceed 3,700 feet in one or more months. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-24** above, which defined a future as successful when an alternative stayed below 3,700 feet in 100 percent of months. For this vulnerability analysis, the wettest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The wettest observed 10-year average flow from 1914-1923 (18.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison. The reference Drying with Variability median value is 15.4 maf.

The No Action (15.3 maf), Enhanced Coordination (15.1 maf), and Maximum Operational Flexibility (14.9 maf) Alternatives show the most vulnerability being vulnerable in about 50 percent of traces in the Drying with Variability Ensemble. The CCS Comparative Baseline (16.2 maf), as well as Basic Coordination (16.1 maf) and Representative Preferred (16.3 maf) Alternatives are slightly less vulnerable. The Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative is least vulnerable, reaching undesirable performance when the wettest 10-year average flow exceeds 16.7 maf. About 25 percent of traces in the Drying with Variability Ensemble exceed this value. The wettest observed 10-year average Lees Ferry annual flow in the historical record is approximately 18.8 maf; therefore, the vulnerability thresholds for all alternatives are below what has already occurred. However, the most recent 10-year average is 12.1 maf, which is significantly drier than the conditions expected to cause vulnerability.

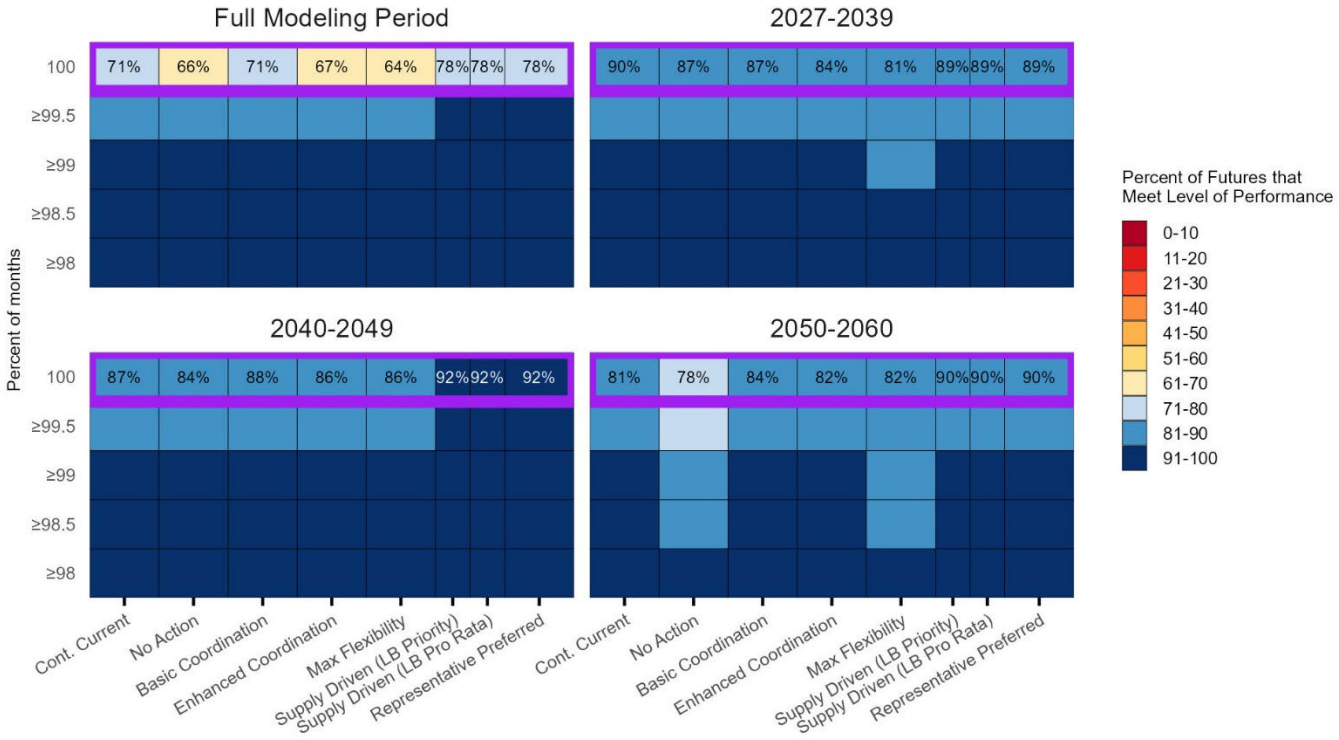


Figure TA 15-25
Lake Powell Preservation of Spring Runoff Space: Vulnerability.
Conditions that Could Cause Lake Powell Elevation Above 3,700 Feet or Greater in 10 percent or More Months

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to at least one occurrence of Lake Powell elevation above 3,700 feet if the wettest 10-year average Lees Ferry annual flow is greater than 16.3 maf. This alternative may or may not be vulnerable in the next 10 years because different aspects of the Reference Hydrology panel conflict. Considering the Drying with Variability Ensemble, between 25-50 percent of traces are greater than 16.3 maf, suggesting this alternative may or may not be vulnerable. However, the recently observed 10-year period is below 16.3 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.

Figure TA 15-26 below shows the ability of each alternative to avoid Glen Canyon Dam spillway releases in the specified percent of months. Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative avoids spillway releases in 100 percent of months. Minimizing spillway releases maximizes water supply and power generation while reducing wear and tear to the spillway structure.

Figure TA 15-26
Glen Canyon Dam Spillway Releases: Robustness.
Percent of futures in which spillway releases are avoided in the specified percent of months

Under the Full Modeling Period, the Supply Driven (both LB Priority and LB Pro Rata approaches) and Representative Preferred Alternatives are most robust with 78 percent of futures meeting the preferred minimum performance, followed by Basic Coordination and CCS Comparative Baseline,

both at 71 percent, respectively. The No Action, Enhanced Coordination, and Maximum Operational Flexibility Alternatives were the least robust in 64-67 percent of futures.

Under the three subperiods, all alternatives maintained a high level of robustness, with no alternative falling below 81 percent of futures meeting the preferred minimum performance. The only exception to this is in subperiod 2050-2060, where the No Action Alternative is less robust with 78 percent of futures meeting the preferred minimum performance.

Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. All alternatives and the CCS Comparative Baseline perform well, meeting the preferred minimum performance between 81 and 90 percent of futures. The Representative Preferred Alternative avoids using the Glen Canyon Dam spillway in 890 percent of futures.

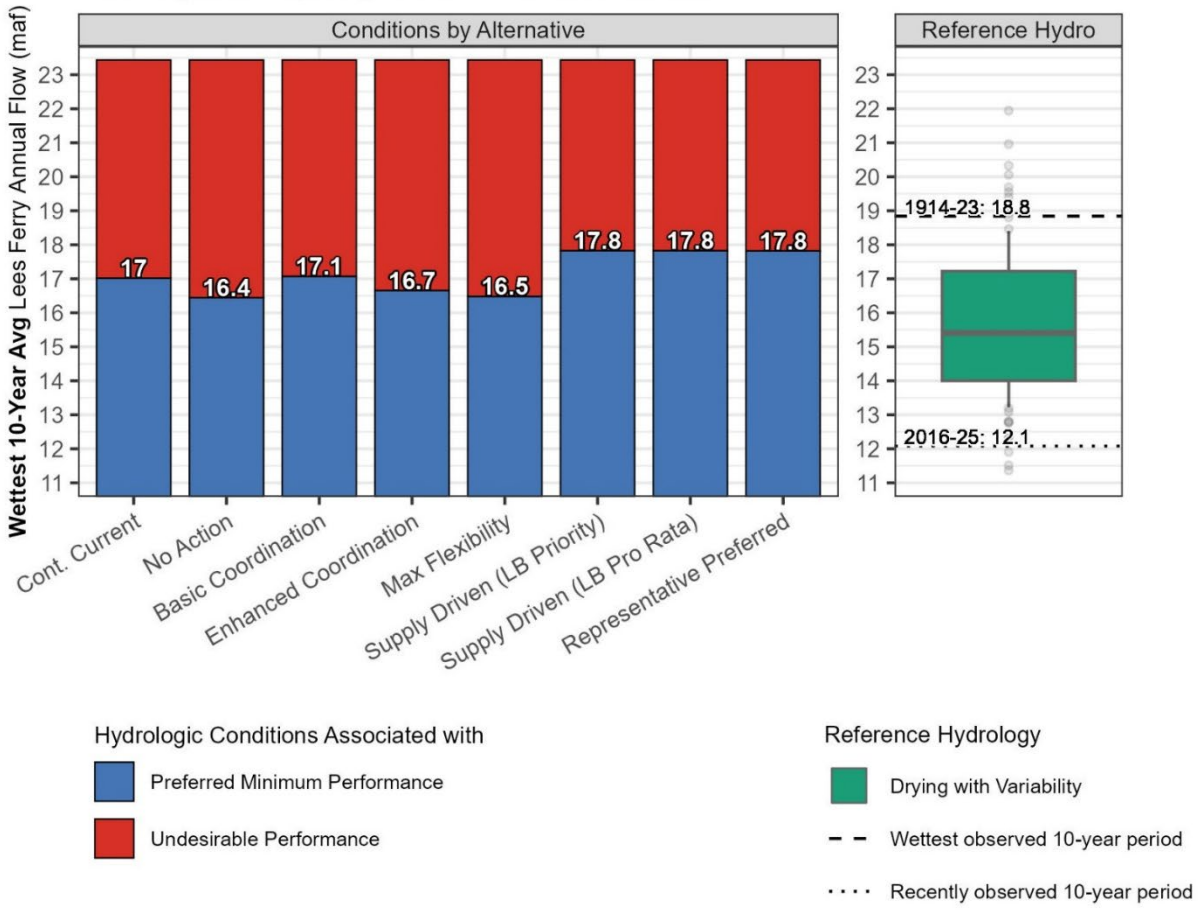

Figure TA 15-27 below shows what flow conditions are likely to cause Glen Canyon Dam spillway releases in one or more months. Spillway releases may result in reduced operational flexibility and increased flood control risk. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-26** which determined a future as successful when an alternative avoided spillway releases in 100 percent of months.

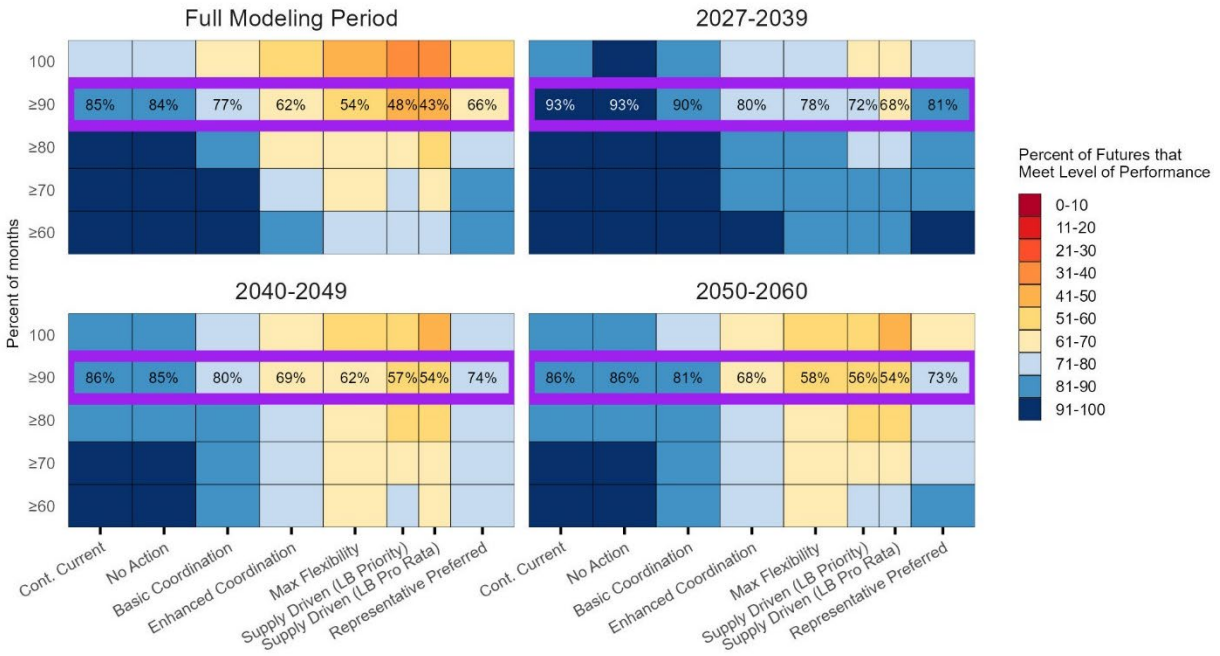
For this vulnerability analysis, the wettest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The wettest observed 10-year average flow from 1914-1923 (18.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison. The reference Drying with Variability median value is 15.4 maf.

If the future includes a wettest 10-year average Lees Ferry annual flow of around 15.4 maf (i.e., the Drying with Variability median value), each alternative is suggested to avoid spillway releases in any month throughout the modeling period. The Supply Driven (both LB Priority and LB Pro Rata approaches at 17.8 maf) and Representative Preferred (17.8 maf) Alternatives require wetter hydrologic conditions before reaching undesirable performance and are less vulnerable compared to the other alternatives. The remaining alternatives reach undesirable performance at flows ranging from 16.4-17.1 maf, indicating greater vulnerability under comparatively lower flow conditions. All alternatives experience vulnerability to spillway releases under the wettest 10-year average in the historical record (18.8 maf).

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to one or more spillway releases if the wettest 10-year average Lees Ferry annual flow is greater than 17.8 maf. However, considering the Drying with Variability Ensemble, less than 25 percent of traces are greater than 17.8 maf, suggesting this alternative is reasonably unlikely to be vulnerable in the next 10 years. Further, the recently observed 10-year period is below 17.8 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.

Figure TA 15-27
Glen Canyon Dam Spillway Releases: Vulnerability.
Conditions that Could Cause Glen Canyon Dam Spillway Release in One or More Months

Lake Mead



Critical high elevations at Lake Mead are listed in **Table TA 15-2** below. Reclamation minimizes uncontrolled discharge over the spillway as they are not intended for frequent or extended operation. One way to reduce these uncontrolled discharges is to maintain a vacant space requirement in the reservoir to absorb large runoff inflows without causing uncontrolled discharge.

Table TA 15-2
Critical Elevations at Lake Mead

Critical Condition	Associated Elevation	Description of Critical Elevation
Spillway	1,205.4 feet	Hoover Dam spillway crest
Maximum Operating Elevation	1,219.6 feet	Allows for 1.5 maf of flood control storage up to the top of the spillway
Maximum Spillway Discharge	1,226.9 feet	Spillway discharge at this elevation is 40,000 cfs, which triggers a "Imminent Life-Threatening Emergency" response

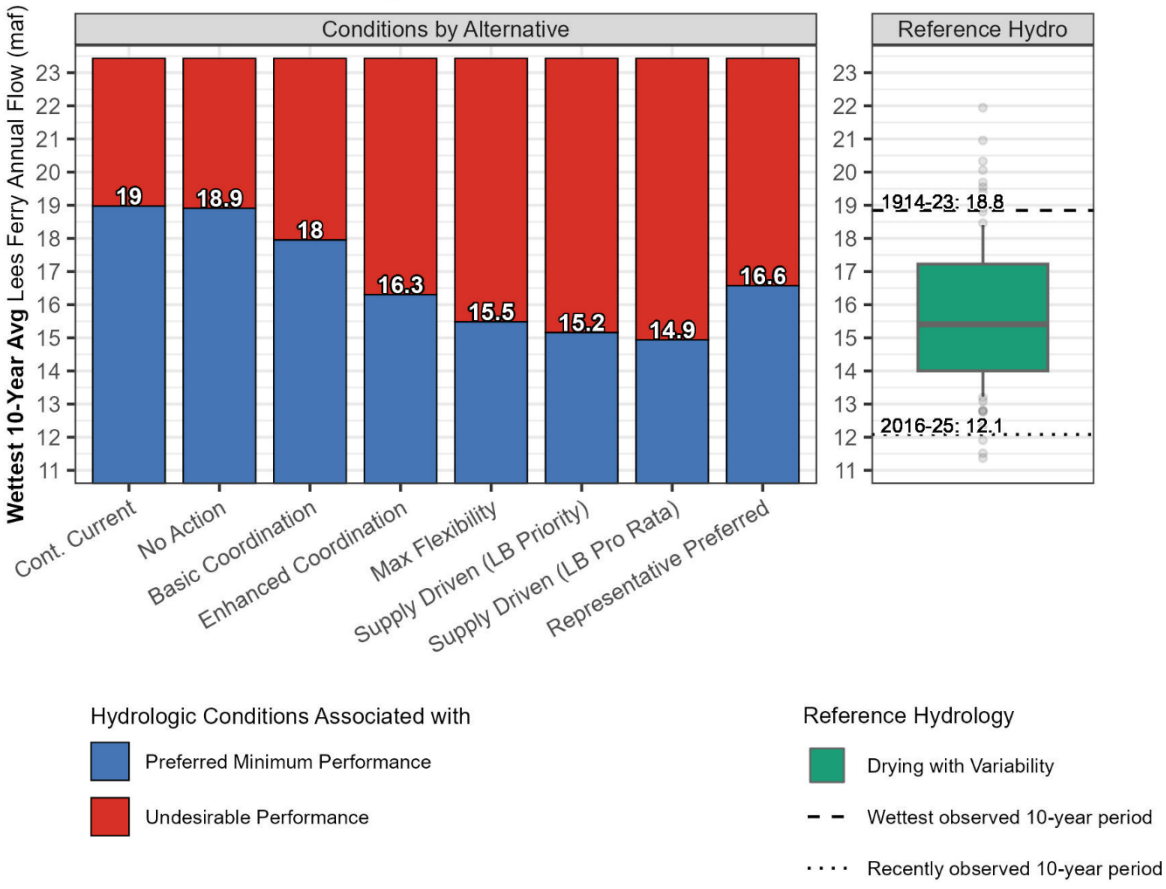
Figure TA 15-28 below reports the percentage of futures in which each alternative keeps Lake Mead below elevation 1,205.4 feet in the percent of months specified by each row. This elevation is the invert of the spillway drum gates for Hoover Dam, and operating above the spillway drum gates level increases the likelihood for mechanical failure. Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative maintains elevations below 1,205.4 feet in at least 90 percent of months. 90 percent of the months was chosen as the preferred minimum performance level because it provides a reasonable amount of flexibility to infrequently go above 1,205.4 feet in very wet hydrology.

Figure TA 15-28
Hoover Dam Spillway Crest Avoidance: Robustness.
Percent of futures in which Lake Mead elevation does not exceed 1,205.4 feet in the specified percent of months

In the Full Modeling Period, the CCS Comparative Baseline and the No Action Alternative are most robust at staying below elevation 1,205.4 feet in 85 and 84 percent of futures, respectively. The Basic

Coordination (77 percent), the Representative Preferred (66 percent), and Enhanced Coordination (62 percent) Alternatives futures follow. The Maximum Operational Flexibility (54 percent) and the Supply Driven (both LB Priority at 48 percent and LB Pro Rata at 43 percent) Alternatives are the least robust.

Across the three subperiods, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative is the least robust, while the CCS Comparative Baseline and No Action Alternative were the most robust with 85-93 percent of futures meeting the preferred minimum.



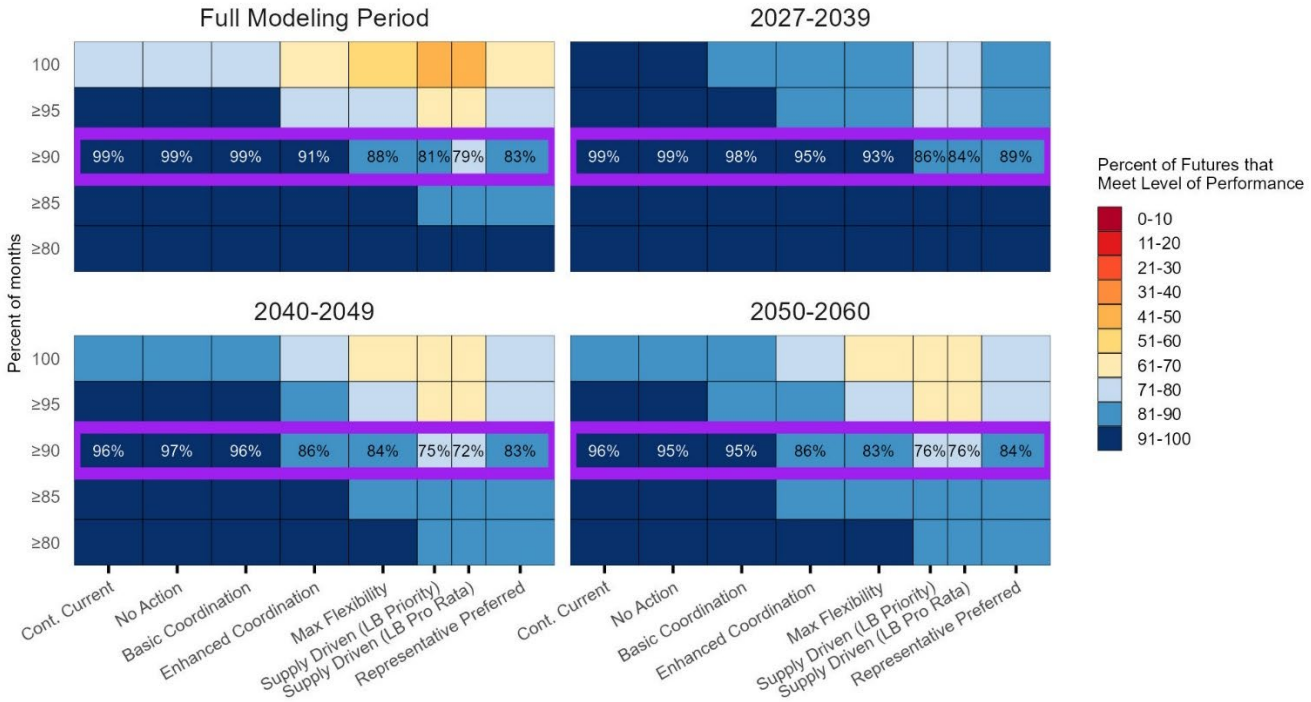
Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The CCS Comparative Baseline and No Action Alternative are the most robust (both 93 percent), followed closely by the Basic Coordination Alternative (90 percent). The Representative Preferred (81 percent), Enhanced Coordination (80 percent), and Maximum Operational Flexibility (78 percent) Alternatives are similar. The Supply Driven (LB Priority approach) Alternative (72 percent) and Supply Driven (LB Pro Rata approach) Alternative (68 percent) are the least robust.

Figure TA 15-29 below shows what flow conditions are likely to cause the elevation of Lake Mead to exceed 1,205.4 feet in at least 10 percent of months. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-28** above, which defined a future as successful when an alternative stayed below 1,205.4 feet in at least 90 percent of months.

For this vulnerability analysis, the wettest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The wettest observed 10-year average flow from 1914-1923 (18.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

If the future includes a wettest 10-year average Lees Ferry annual flow of around 15.4 maf (i.e., the Drying with Variability median value), modeling results indicate undesirable performance for the Supply Driven (both LB Priority [15.2 maf] and LB Pro Rata [14.9 maf] approaches) Alternative. This alternative, along with the Maximum Operational Flexibility (15.5 maf) Alternative, reach undesirable performance at comparatively lower flow thresholds, indicating higher vulnerability. The Representative Preferred (16.6 maf) and Enhanced Coordination (16.3 maf) display less vulnerability by performing above the median 10-year average Lees Ferry annual flow of 15.4 maf. The Basic Coordination (18 maf) and No Action (18.9 maf) Alternatives, as well as the CCS Comparative Baseline (19 maf), require wetter hydrologic conditions to reach undesirable performance and are therefore the least vulnerable alternatives. Under the No Action Alternative and CCS Comparative Baseline, Lake Mead elevations above 1,205.4 feet in more than 10 percent of months appear unlikely under most Drying with Variability traces, as the vulnerability thresholds of 18.9 maf and 19 maf, respectively, exceed the 90 percentile of the Drying with Variability Ensemble. From 1914 to 1923, the wettest 10-year average was 18.8 maf. All alternatives, with exception of the CCS Comparative Baseline and No Action Alternative, are vulnerable to conditions that have already occurred.

Figure TA 15-29
Hoover Dam Spillway Crest Avoidance: Vulnerability.
Conditions that could cause Lake Mead elevation above 1,205.4 feet in 10 percent or more months



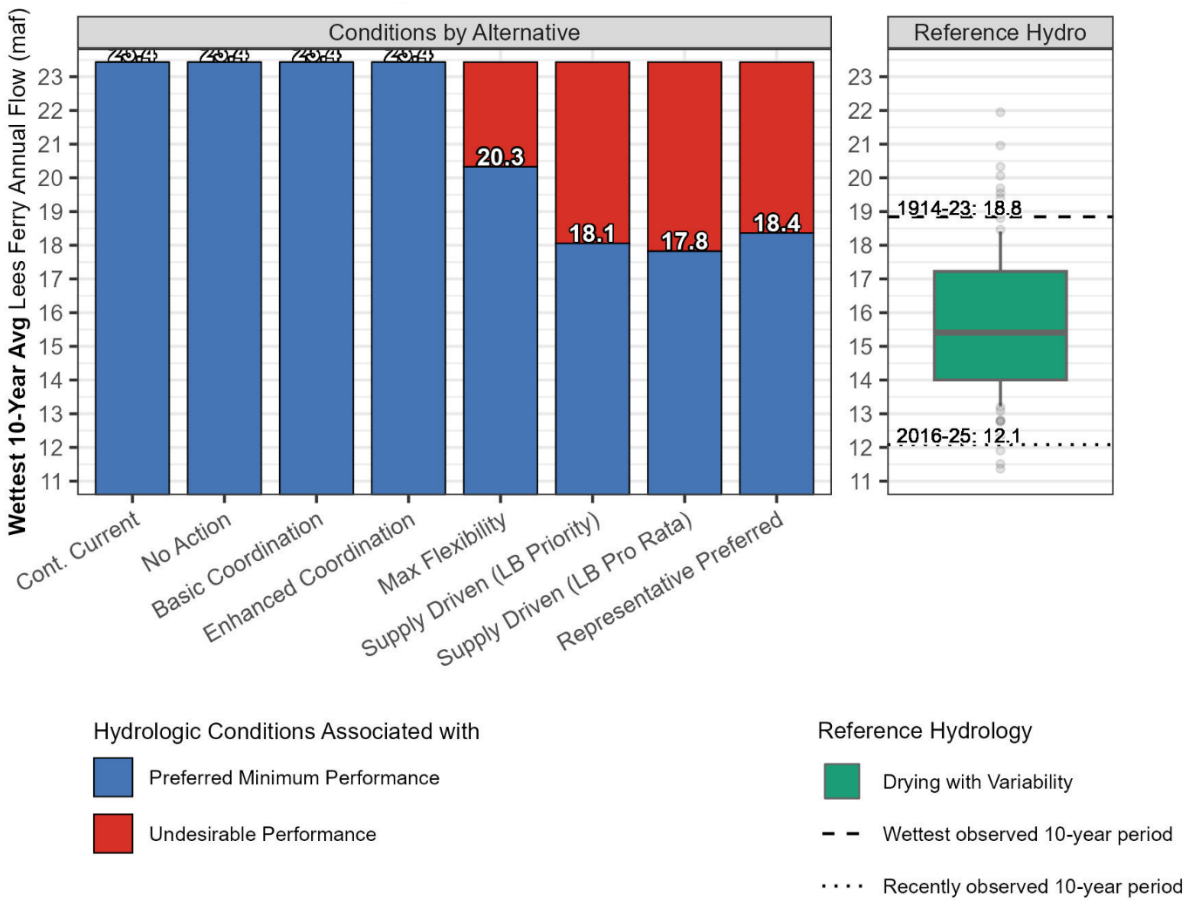
Modeling indicates that the Representative Preferred Alternative would likely be vulnerable if the wettest 10-year average annual flow at Lees Ferry exceeds 16.6 maf, resulting in Lake Mead elevations above 1,205.4 feet in at least 10 percent of months. However, considering the Drying with Variability Ensemble, about 25 percent of traces are greater than 16.6 maf, suggesting this alternative is reasonably unlikely to be vulnerable in the next 10 years. Further, the recently observed 10-year period is below 16.6 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.

Figure TA 15-30 below depicts the ability of each alternative to maintain a Lake Mead pool elevation below 1,219.6 feet in the specified percent of months, which is an important flood buffer elevation for protecting dam infrastructure. The model evaluates multiple future simulation periods, including three subperiods: 2027–2039, 2040–2049, and 2050–2060. Results shown for the Full Modeling Period reflect performance across the complete modeled timeframe, rather than any individual subperiod. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative is below 1,219.6 feet in at least 90

percent of months. The greater than or equal to 90 percent row was chosen because it provides a reasonable amount of flexibility to go above 1,219.6 feet occasionally in very wet hydrology.

Figure TA 15-30
Avoidance of Lake Mead Maximum Operating Elevation: Robustness. Percent of futures in which Lake Mead elevation does not exceed 1,219.6 feet in the percent of months specified in each row

Over the Full Modeling Period, the CCS Comparative Baseline, as well as Basic Coordination and No Action Alternatives are successful at keeping Lake Mead below 1,219.6 feet in 99 percent of futures. The Maximum Operational Flexibility and Representative Preferred Alternatives meets this threshold in 88 percent and 83 percent of futures, respectively. The Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative is least robust, with the preferred minimum performance met in 81 and 79 percent of futures, respectively.



The subperiod 2027-2039 experiences high robustness across all alternatives, with the Supply Driven (both LB Priority [86 percent] and LB Pro Rata [84 percent]) Alternative being least robust. The subperiods 2040-2049 and 2050-2060 have slightly reduced robustness in respect to the subperiod 2027-2039, as the Enhanced Coordination (86 percent), Maximum Operational Flexibility (83-84 percent), Representative Preferred (83-84 percent), and Supply Driven (both LB Priority and LB Pro Rata approaches) (72-76 percent) Alternatives fall slightly.

Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. All alternatives perform well, meeting the preferred minimum performance between 84 percent (Supply Driven [LB Pro Rata approach]) and 99 percent (No Action) of futures.

The Representative Preferred Alternative meets the preferred minimum performance level in 89 percent of futures.

Figure TA 15-31 below shows what flow conditions are likely to cause the elevation of Lake Mead to exceed 1,219.6 feet in more than 10 percent of months, as elevations above this level may reduce available flood control capacity and operational flexibility. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-30** above, which defined a future as successful when an alternative stayed below 1,219.6 feet in at least 90 percent of months.

Figure TA 15-31
Avoidance of Lake Mead Maximum Operating Elevation: Vulnerability. Conditions that could cause Lake Mead elevation to exceed 1,219.6 feet in 10 percent or more months

For this vulnerability analysis, the wettest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The wettest observed 10-year average flow from 1914-1923 (18.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

The CCS Comparative Baseline (23.4 maf), as well as No Action (23.4 maf), Basic Coordination (23.4 maf), and Enhanced Coordination (23.4 maf) Alternatives require wetter hydrologic conditions to reach undesirable performance and are therefore less vulnerable. These alternatives demonstrated no vulnerability for the full range of reference hydrology Drying with Variability traces, indicating a low likelihood that Lake Mead elevation would rise above 1,219.6 feet in more than 10 percent of months. The wettest 10-year average Lees Ferry annual flows for the Maximum Operational Flexibility (20.3 maf), Representative Preferred (18.4 maf), and Supply Driven (both LB Priority [18.1 maf] and LB Pro Rata [17.8 maf] approaches) Alternatives are comparatively lower; though, above the Drying with Variability median wettest 10-year average Lees Ferry annual flow of 15.4 maf.

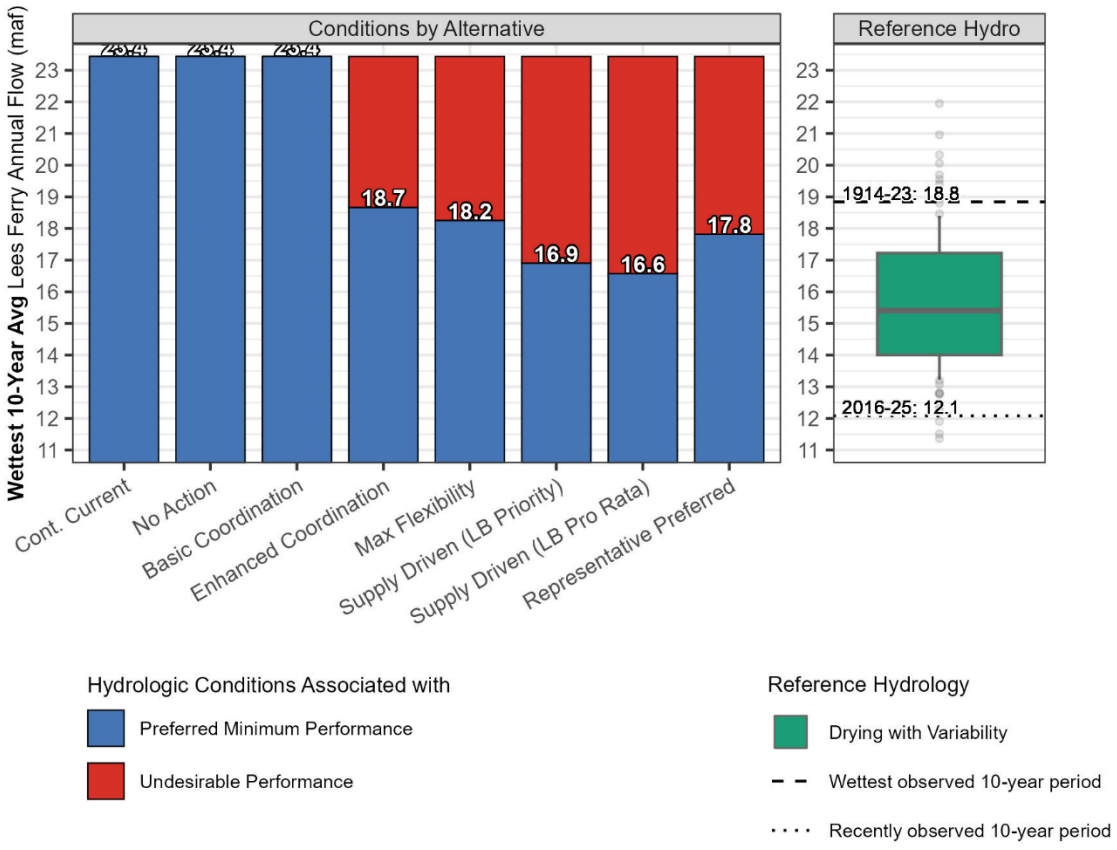
Modeling indicates that the Representative Preferred Alternative would likely be vulnerable if the wettest 10-year average annual flow at Lees Ferry exceeds 18.4 maf, resulting in Lake Mead elevations above 1,219.6 feet in at least 10 percent of months. However, considering the Drying with Variability Ensemble, only about 10 percent of traces are greater 18.4 maf, suggesting this alternative is reasonably unlikely to be vulnerable in the next 10 years. The recently observed 10-year period is well below 18.4 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.

Figure TA 15-32 below depicts the ability of each alternative to maintain a Lake Mead pool elevation below 1,226.9 feet in the specified percent of months. The analysis evaluates multiple future simulation periods, including three modeled subperiods: 2027–2039, 2040–2049, and 2050–2060. In addition to these subperiods, the Full Modeling Period refers to the entire future simulation horizon evaluated for each modeled future, encompassing all years in the analysis. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative is below 1,226.9 feet in 100 percent of months. At this elevation, spillway releases exceed 40,000 cfs, which is considered a life-threatening emergency downstream.

Under the Full Modeling Period, the Supply Driven (both LB Priority [73 percent] and LB Pro Rata [70 percent] approaches) Alternative is the least robust. The Maximum Operational Flexibility (82 percent) performs similarly to Enhanced Coordination (83 percent) and Representative Preferred (78 percent) Alternatives. The No Action (92 percent) and Basic Coordination (91 percent) Alternatives, as well as CCS Comparative Baseline (92 percent), are the most robust with Lake Mead remaining below the critical level of 1,226.9 feet in 100 percent of futures. If the requirement relaxes to staying below 1,226.9 feet at Lake Mead in 98 percent of futures, all alternatives increase in robustness. For the subperiods, alternatives range between 84 to 98 percent of futures meeting the preferred minimum performance.

Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. All alternatives perform well, meeting the preferred minimum performance between 88 and 98 percent of futures. The Representative Preferred Alternative meets the preferred minimum performance in 93 percent of futures.

Figure TA 15-32
Avoidance of Lake Mead Maximum Spillway Discharge: Robustness.
Percent of futures in which Lake Mead elevation does not exceed 1,226.9 feet in the specified percent of months



Representative Preferred **Figure TA 15-33** below shows what flow conditions are likely to cause the elevation of Lake Mead to exceed 1,226.9 feet in any month. At this elevation, release flows exceed 40,000 cfs, which is considered an emergency downstream. This definition of undesirable performance is based on the highlighted row in **Figure TA 15-32**, which specified that a future was successful if Lake Mead stayed below 1,226.9 feet in 100 percent of months.

For this vulnerability analysis, the wettest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability Ensemble using this streamflow summary statistic. The wettest observed 10-year average flow from 1914-1923 (18.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

The CCS Comparative Baseline (23.4 maf), as well as No Action (23.4 maf) and Basic Coordination (23.4 maf) Alternatives require wetter hydrologic conditions to reach undesirable performance and are therefore less vulnerable. Zero traces in the Drying with Variability Ensemble exhibit these conditions, indicating a low likelihood that Lake Mead elevation would rise above 1,226.9 feet in any month. The wettest 10-year average Lees Ferry annual flows for the Enhanced Coordination (18.7 maf), Representative Preferred (17.8 maf), Maximum Operational Flexibility (18.2 maf), and Supply Driven (both LB Priority [16.9 maf] and LB Pro Rata [16.6 maf] approaches) Alternatives are

comparatively lower; though, above the Drying with Variability median wettest 10-year average Lees Ferry annual flow of 15.4 maf.

Figure TA 15-33
Avoidance of Lake Mead Maximum Spillway Discharge: Vulnerability. Conditions that could cause Lake Mead elevation to exceed 1,226.9 feet in 1 or more months

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to one or more occurrences of Lake Mead elevation above 1,226.9 feet if the wettest 10-year average Lees Ferry annual flow is greater than 17.8 maf. However, considering the Drying with Variability Ensemble, less than 25 percent of traces are greater than 17.8 maf, suggesting this alternative is reasonably unlikely to be vulnerable in the next 10 years. The recently observed 10-year period is well below 17.8 maf, suggesting that this alternative is unlikely to be vulnerable if the next 10 years are similar to or drier than the most recent 10 years.

Summary of Issue 4 Impacts

From a spillway use perspective, keeping the reservoir water level below the spillway crest minimizes spillway drum gate use and spillway use, preserves the water supply, maintains flood storage capacity, and reduces wear and tear on spillway infrastructure. Maintaining lower reservoir levels allows inflow to be routed through controlled outlets and respond to spring runoff. The alternatives generally perform similarly under wet hydrologic flow conditions, apart from the Supply Driven

Alternative (both LB Priority and LB Pro Rata approaches) generally performing best for Lake Powell and the No Action Alternative and the CCS Comparative Baseline performing best for Lake Mead.

High elevation reservoir infrastructure and critical flood storage buffers for Glen Canyon Dam and Lake Powell are better protected under the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative during wetter hydrological conditions. Conversely, at Hoover Dam and Lake Mead, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative has the least preferred performance in terms of keeping Lake Mead below critical high elevations. For Lake Mead, the duration spent above these high-water thresholds is minimized under the No Action and Basic Coordination Alternatives and the CCS Comparative Baseline. Under the Basic Coordination Alternative, both Glen Canyon Dam and Hoover Dam achieve preferred minimum performance and high-water thresholds are minimized. The Enhanced Coordination and Maximum Operational Flexibility Alternatives provide the second and third most preferred performance when considering Glen Canyon Dam and Hoover Dam collectively. The performance of the Representative Preferred Alternative varied, generally ranking from mid- to upper-performing at Glen Canyon Dam and roughly the middle-performing alternative at Hoover Dam.

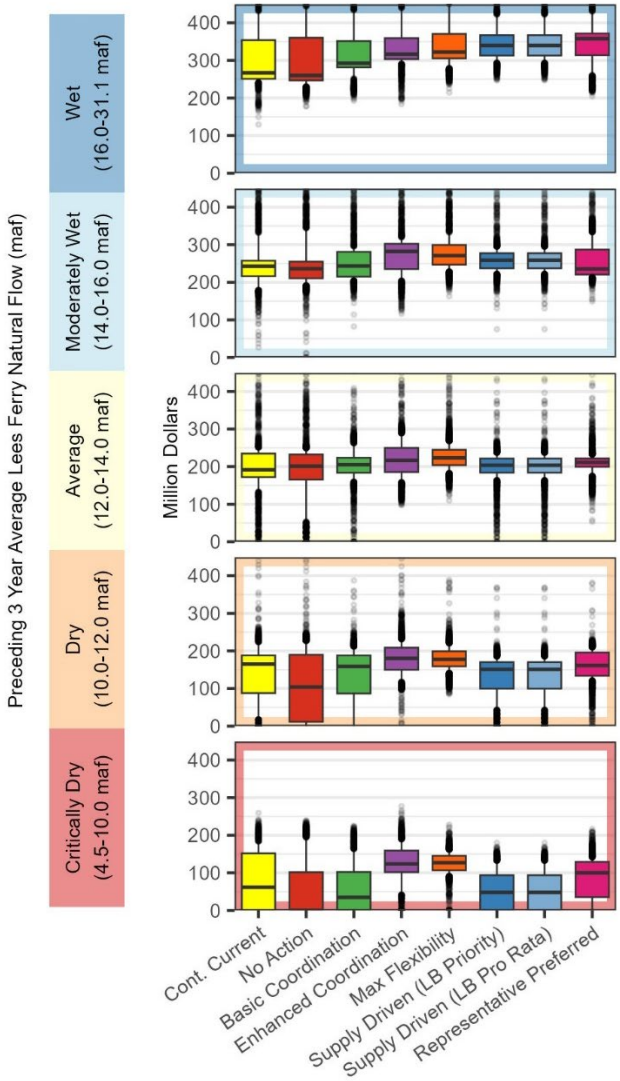
TA 15.2.7 Issue 5: How would changes in energy generation impact electricity rates and the market value of electricity?

Glen Canyon Dam

Argonne National Laboratories and WAPA's report, "Post-2026 Environmental Impact Statement Rate Analysis for the Colorado River Storage Project" (Yu et al. 2025), assessed the relative impacts of various Glen Canyon Dam hydrological scenarios on the CRSP's Firm Electric Service rates. This analysis utilized an advanced simulation tool to estimate future generation production along with a stepwise rate adjustment framework. This framework is consistent with CRSP's obligation to remain financially self-sustaining and deliver cost-based power services (DOE 2025) and was used to evaluate the rate implications of simulated Glen Canyon Dam-only generation outcomes. It is important to note that CRSP's Firm Electric Service rates encompass hydropower generation resources beyond Glen Canyon Dam; therefore, the identified rate impacts are theoretical, representing uncertainty associated with future Glen Canyon Dam hydrological conditions. The report found that the Enhanced Coordination and Maximum Operational Flexibility Alternatives consistently yielded more favorable hydropower generation outcomes, associated with higher electricity production. These alternatives also indicated fewer rate adjustments, smaller average increases per adjustment, and substantially lower maximum rate increases when an increase was identified. Specifically, under wet or average hydrologic conditions, these alternatives led to results similar to or slightly better than other alternatives. Under dry hydrologic conditions, they resulted in substantially smaller rate increases and less frequent rate adjustments. Overall, Enhanced Coordination and Maximum Operational Flexibility are identified as entailing less adverse economic impact on U.S. electricity consumers and providing greater protection against extreme adverse outcomes compared to the other five alternatives. The modeling framework and key methodological choices supporting these findings, as documented in Yu et al. (2025), included comprehensive data on CRSP's plant characteristics, hydrological conditions, Argus forward prices, and CRSP's power purchase and sales transactions. Another important point to note is that the rate adjustment

framework used in the study is a simplified version of actual rate-changing processes, as it is based solely on assumed revenue requirements and simulated electricity production. Consequently, it provides a directional analysis for comparing policy scenarios rather than forecasting actual consumer rates, requiring careful contextualization to avoid misinterpretation. Extreme hydrological conditions, potentially leading to very low or even zero simulated electricity production, can result in a non-trivial subset of degenerate results, projecting unrealistic rate increases or decreases. These extreme events, particularly zero electricity production from Glen Canyon Dam, are unprecedented and fall outside the scope of the current analysis framework, as they cannot be resolved through standard rate adjustments.

Figure TA 15-34 shows the estimated annual market value of hydropower generation by combining modeled annual energy production with an illustrative wholesale electricity price. A fixed 2028 fiscal year value per MWhs was developed using Argonne National Laboratory available data and multiplies it by the annual generation from WAPA's CRiSPPy model. Results were then applied uniformly across all alternatives and five potential flow categories (Wet Flow Category, Moderately Wet Flow Category, Average Flow Category, Dry Flow Category, and Critically Dry Flow Category). The box plots show variability in annual generation value (in millions of dollars) across futures within each flow category, highlighting how both hydrologic conditions and alternative operations influence potential energy value.



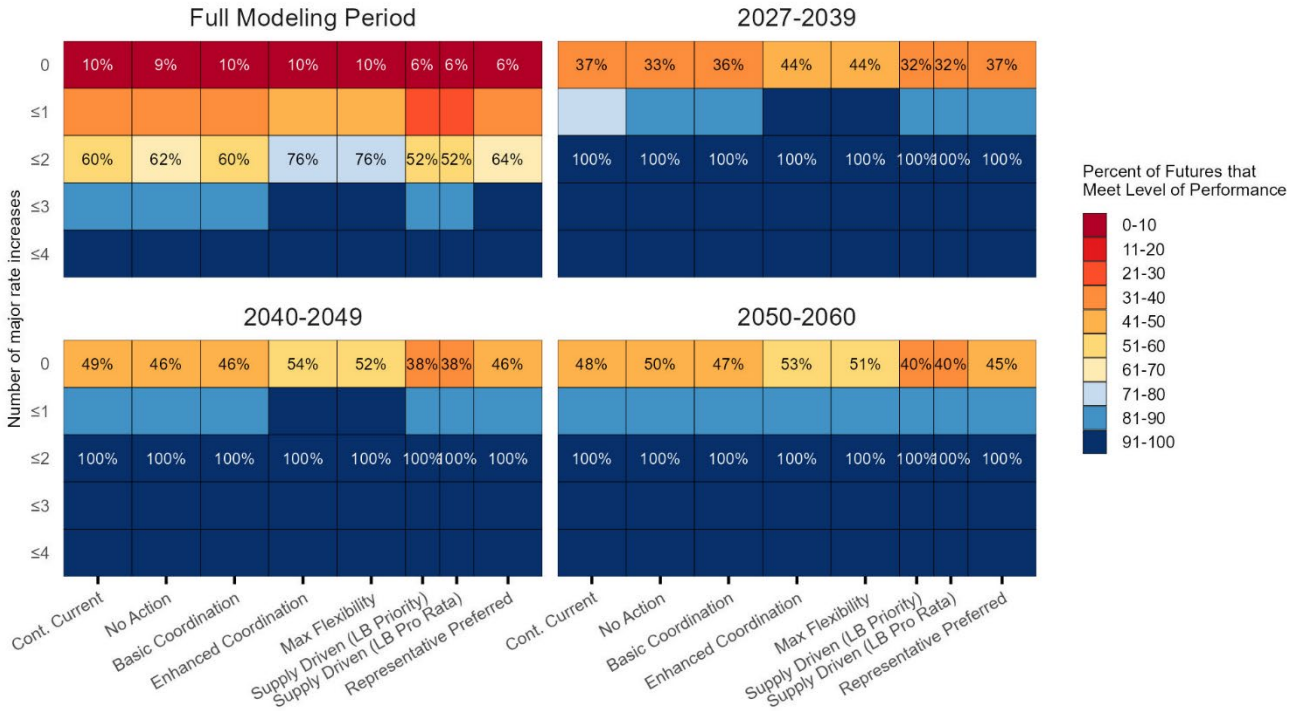
In the Wet Flow Category, the Representative Preferred Alternative resulted in the highest overall annual generation with a median value of $358 million. The Supply Driven (both LB Pro Rata and LB Priority approaches) Alternative experienced high median value of $340 million annually. The CCS Comparative Baseline ($267 million) and No Action Alternative ($260 million) had the lowest median values.

Within the Moderately Wet Flow Category, all alternatives retain similar metrics with relatively narrower interquartile ranges, indicating strong and consistent performance. However, Enhanced Coordination and Maximum Operational Flexibility experienced slightly higher median values than the others, with median values of $282 million and $271 million, respectively.

The Average Flow Category had similar performance across all alternatives and with relatively narrow interquartile ranges. The CCS Comparative Baseline had the lowest median value of $190 million, while the Maximum Operational Flexibility Alternative experienced the highest median value of $223 million.

Under the Dry Flow Category, Enhanced Coordination and Maximum Operation Flexibility had higher median values of $180 and $178 million, respectively. The No Action Alternative had the lowest value among the other alternatives, at $104 million. Both the CCS Comparative Baseline and No Action Alternative showed the widest interquartile ranges, with 25th percentiles of $12 million for the No Action Alternative and $88 million for the CCS Comparative Baseline. These larger interquartile ranges suggest greater variability in annual generation value compared to the other alternatives.

Figure TA 15-34
Annual Market Value of Glen Canyon Dam Generation: Box Plots



The Critically Dry Flow Category resulted in the lowest overall annual values for all alternatives. The Enhanced Coordination and Maximum Operational Flexibility Alternatives showed the narrowest interquartile ranges and highest median annual value, with median values of $124 million and $127 million. The Representative Preferred Alternative resulted in a median value of $100 million annually but with much larger interquartile ranges than the Enhanced Coordination and Maximum Operation Flexibility Alternatives. All other alternatives and CCS Comparative Baseline exhibited similarly larger interquartile ranges, but with at least 25 percent of years having values reach $0.

The Representative Preferred Alternative maintained relatively high median annual values under dry ($161 million) and critically dry ($100 million) flow conditions, outperforming the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives.

Figure TA 15-35 below shows the number of futures where CRSP customers could potentially see major rate increases under each alternative across the modeled futures at Glen Canyon Dam. The rows of the heat map represent the number of times in which there is major rate increases at or below a given threshold.

Figure TA 15-35 shows results for the Full Modeling Period and three subperiods: 2027-2039, 2040-2049, and 2050-2060. Consistent with WAPA's rate-setting procedures, cost-based rates are reviewed and adjusted on a five-year cycle. Therefore, the maximum number of rate changes that can occur in any of the three subperiods is 2.

Figure TA 15-35
Glen Canyon Dam CRSP Major Rate Increases: Robustness.
Percent of futures with the specified number of major rate increases

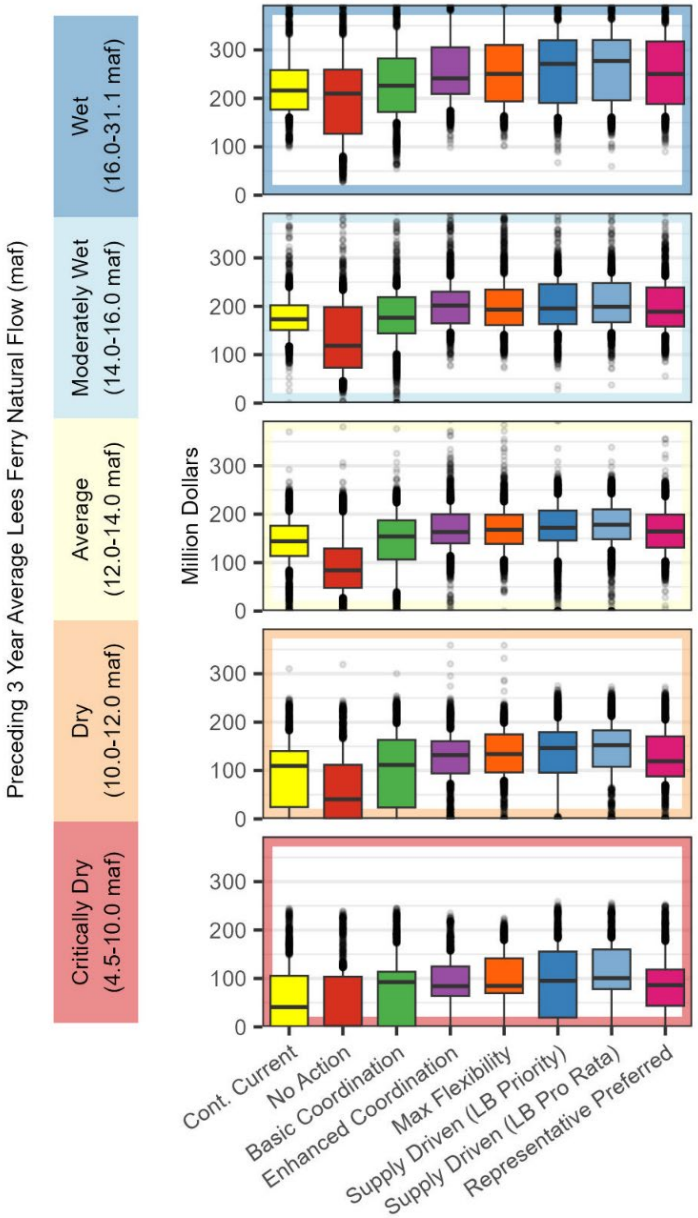
Note: Robustness modeling for the anticipated number of major rate increases was performed only for Glen Canyon Dam, based on historical rate information provided by WAPA. Each subperiod reflects the average of two rate evaluations, consistent with WAPA's rate-setting practices, which generally involve reviewing and adjusting rates on a five-year cycle but may occur more frequently in response to changing operational or hydrologic conditions.

For the Full Modeling Period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust with respect to limiting major rate increases to two or fewer times, doing so in 76 percent of futures. By comparison, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative is the least robust. Only 52 percent of futures under these alternatives remain at or below two major rate increases, and a larger share of futures exceed this threshold, indicating greater exposure to repeated or sustained rate adjustments. The CCS Comparison Baseline, as well as the No Action, Representative Preferred, and Basic Coordination Alternatives,

perform intermediately, with 60 to 64 percent of futures remaining at or below two major rate increases, and declining robustness for all alternatives at more stringent performance thresholds.

Based on the planned length of this decision, it is important to compare robustness in the 2027-2039 modeling period. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust at having 0 rate increases, doing so in 44 percent of modeled futures. The Representative Preferred Alternative and CCS Comparative Baseline are the next most robust, both having 0 rate increases in 37 percent of futures. All alternatives have 1 or less rate increases in 81 percent or more of futures. As noted above, WAPA's rates are reviewed and adjusted on a five-year cycle. Since the subperiods range from 9 – 12 years, it is not possible to trigger 3 or more rate increases in a subperiod, so all alternatives have a score of 100 percent in the rows for 2, 3, and 4 rate increases.

Hoover Dam



Hoover Dam provides federally marketed hydropower to Arizona, California, and Nevada through the BCP, managed by WAPA. Funding for the project's operation, maintenance, and capital costs is entirely self-supported by these hydropower sales to contracted entities, requiring no taxpayer funding. Historically, cost-based rates kept Hoover power lower than regional wholesale market alternatives. Under this framework, customers pay a fixed annual base charge to cover these costs, allocated by contract share rather than actual generation. However, as declining water levels reduce generation output, the unit cost of the remaining power rises. This creates a financial swing: when generation drops sufficiently, Hoover Dam's unit cost surpasses market rates, making power uneconomical and potentially forcing contracted entities to abandon their long-term contracts.

Figure TA 15-36 below shows the annual market value of hydropower at Hoover Powerplant. The economic analysis is based on a dollar-per-MWhs value provided by the Lower Basin Dams Office using WY 2027 data. The dollar-per-MWhs rate was then multiplied by the modeled energy generation from CRSS to compute market value. The market value depends on water surface elevation, with values being greater if elevation is above 1,035 feet and lower if below 1,035 feet. To show how market value can change due to different hydrology, results are grouped into five flow categories: (Wet Flow Category, Moderately Wet Flow Category, Average Flow Category, Dry Flow Category, and Critically Dry Flow Category).

Under the Wet Flow Category, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative result in the highest median market values of approximately $271-277 million annually. All other alternatives had a median market value that exceeded $200 million. The No Action Alternative had a value of $127 million or less in 25 percent of years, much lower than all other alternatives.

Within the Moderately Wet Category, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative experienced the highest 75th percentiles ($246-248 million) and 25th percentiles ($163-167 million). Similar to the Wet Flow Category, the No Action Alternative had the lowest median market value and the largest interquartile range, with a 25th percentile of $73 million and 75th percentile of $198 million.

Figure TA 15-36
Annual Market Value of Hoover Dam Generation: Box Plots

Under the Average Flow Category, most alternatives see a median market value decline to below $200 million. The Enhanced Coordination ($163 million), Maximum Operational Flexibility ($168 million), Supply Driven (both LB Priority and LB Pro Rata approaches) ($172 million and $178 million, respectively), and Representative Preferred ($165 million) Alternatives generally maintain higher medians and moderate interquartile ranges, while the No Action ($84 million) and Basic Coordination ($154 million) Alternatives tend to show lower medians and greater variability.

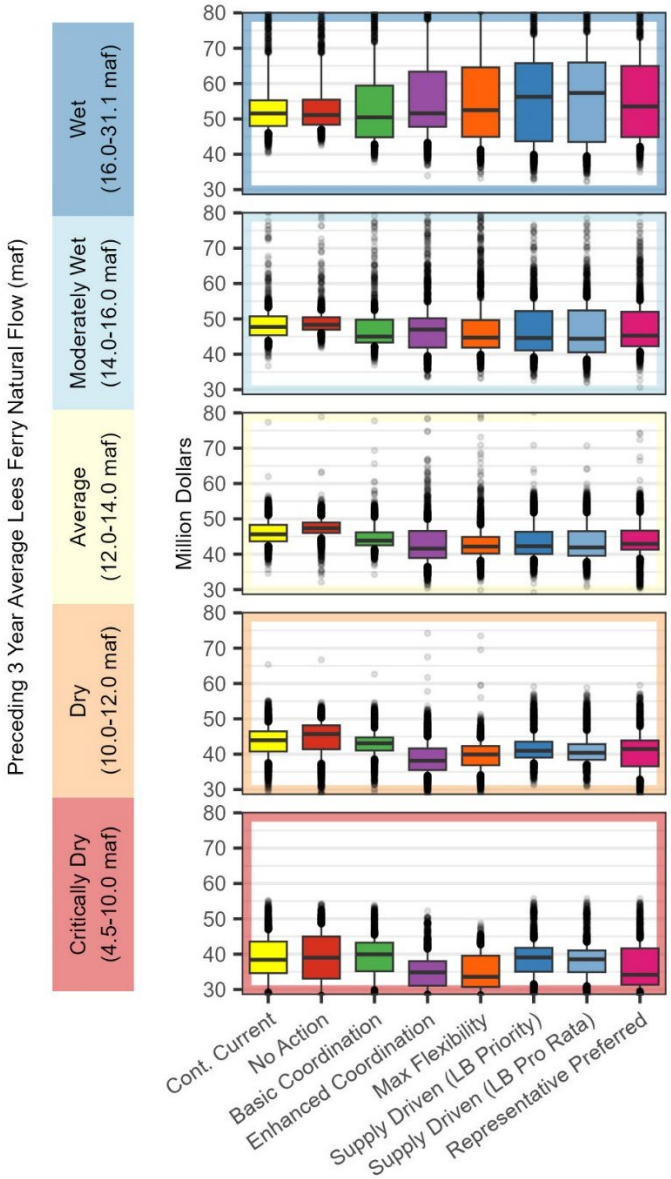
Dry and Critically Dry Flow Categories resulted in the lowest overall annual values. Maximum Operational Flexibility ($142-$175 million), Basic Coordination ($93-$112 million), Representative

Preferred ($86-119 million), and Supply Driven (LB Pro Rata approach) ($160-$183 million) Alternatives showed the highest median annual values. Basic Coordination Alternative resulted in a higher median value but with much larger interquartile ranges than the other alternatives. The CCS Comparative Baseline, No Action and Basic Coordination Alternatives all fall to $0 in 25 percent or more years.

Modeling indicates that the Representative Preferred Alternative maintained a median value of $119 million annually under the Dry Flow Category and $86 million under the Critically Dry Flow Category. In the Critically Dry Flow Category, the 25th percentile is $44 million.

Davis and Parker Dam

The PDP is a federally operated system combining the Parker and Davis Dam hydroelectric facilities and transmission infrastructure on the Colorado River. Reclamation operates and maintains the dams and powerplants, while WAPA markets and transmits the generated electricity to customers under long term contracts.



WAPA sets rates using a cost-recovery framework designed to recover annual project costs including operations, maintenance, replacements, and federal investment repayment. WAPA currently markets the project as a firm, fixed monthly delivery obligation, purchasing supplemental wholesale power to meet this commitment. Declining generation from the powerplants has increased the need for supplemental power, driving significant rate increases due to market price volatility. Starting in October 2028, a new marketing plan will align WAPA's delivery obligations with hydropower availability. This change will potentially create a financial swing. If generation drops sufficiently, PDP rates could surpass market rates, making the power uneconomical and potentially forcing contracted entities to abandon their long-term contracts.

Figure TA 15-37 below shows the annual market value of hydropower at Davis Dam based on CRSS modeling of generation and an assumed dollar-per-MWhs rate to determine the financial value (in millions of dollars). The results are grouped by preceding 3-year average Lees Ferry natural flow to show how fiscal value is influenced by hydrology for each alternative. Differences in fiscal value are driven by differences in releases across the alternatives (see **Figure TA 3-26** in **TA 3**, Hydrologic Resources for calendar year releases from Davis Dam).

Under the Wet Flow Category, all action alternatives exhibit relatively large interquartile ranges, indicating that hydropower value at Davis Dam is sensitive to operational differences during favorable hydrologic conditions. The Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative experienced the highest median value of $56-57 million annually, followed by Representative Preferred Alternative at $54 million. The Basic Coordination Alternative produced the lowest median market value, at $50 million annually.

In the Moderately Wet Flow Category, the No Action Alternative and CCS Comparative Baseline show similarly high median values of $47.7-$48 million annually. The Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative has the lowest median value at $44.3-45 million.

Figure TA 15-37
Annual Market Value of Davis Dam Generation: Box Plots

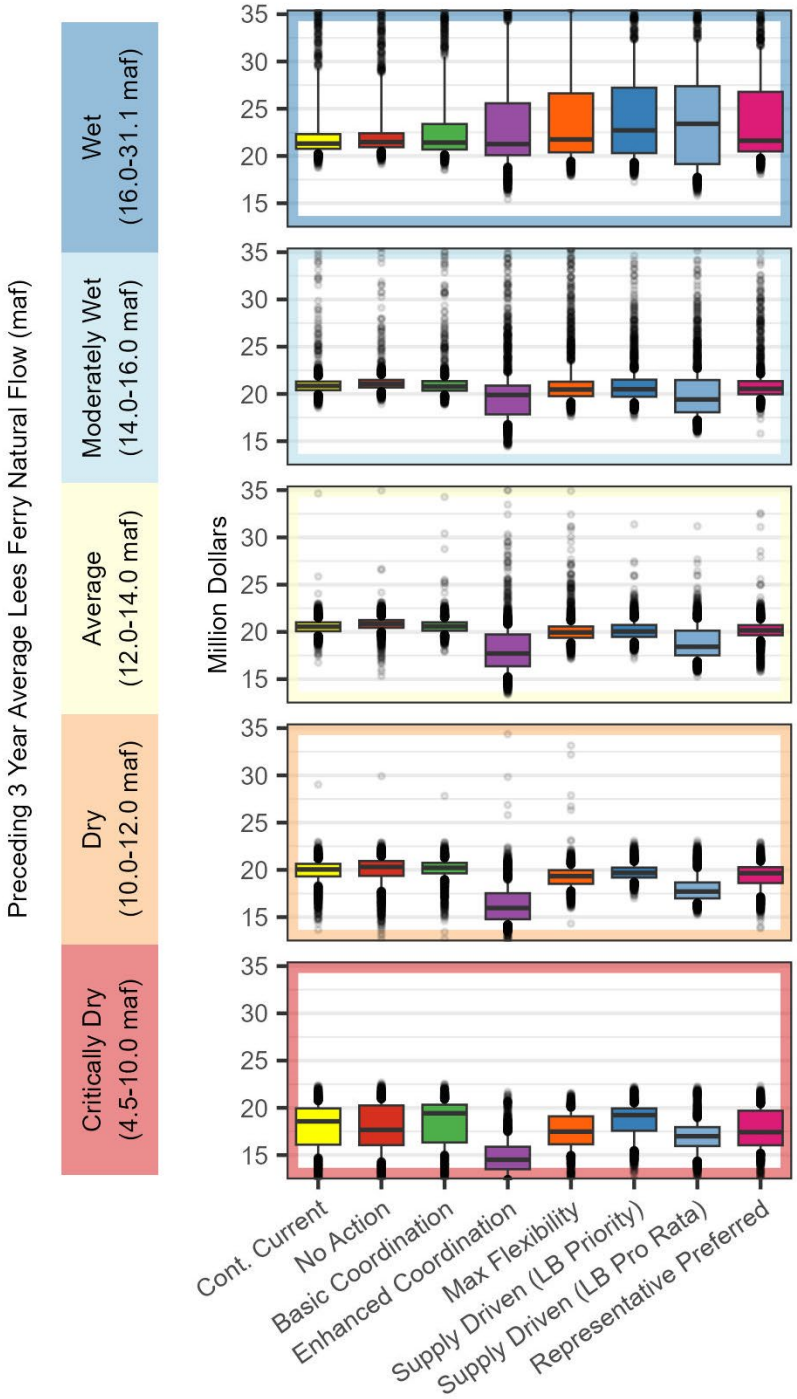
Under the Average Flow Category, the No Action Alternative and CCS Comparative Baseline show similarly high median values of $46-$47 million annually. The Supply Driven (both LB Priority and LB Pro Rata approaches) and Enhanced Coordination Alternatives have the lowest median values, both at $42 million annually.

Under the Dry and Critically Dry Flow Categories, all alternatives display substantially lower median values and vulnerability to low-generation outcomes. Under the Dry Flow Category, the No Action Alternative had the highest median values at $46 million and $44 million, respectively. The action alternatives have similar median values ranging between $38-$42 million.

Under the Critically Dry Flow Category, Maximum Operational Flexibility ($34 million), Representative Preferred ($34 million), and Enhanced Coordination ($35 million) Alternatives had the lowest median values, while the Basic Coordination Alternative had the highest median value of $40 million annually.

Modeling indicates that the Representative Preferred Alternative maintained a median value of $41 million annually in the Dry Flow Category. Under the Critically Dry Flow Category, the Representative Preferred Alternative median value dropped to $34 million annually.

Figure TA 15-38 below shows the annual market value of hydropower generation at Parker Dam, which was calculated by combining modeled annual energy production with an illustrative wholesale electricity price. Annual energy generation is simulated using CRSS, and a fixed fiscal year value per MWhs is applied to determine the dollar values anticipated for each alternative. Results are grouped into five categories by preceding three-year average Lees Ferry natural flow as shown in the figure. Differences in market value between alternatives is due primarily to differences in releases (see **Figure TA 3-27** in **TA 3,** Hydrologic Resources for calendar year releases from Parker Dam).



Under the Wet Flow Category, the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative exhibits the largest interquartile range, indicating larger sensitivity to operational differences when hydrologic conditions are favorable, although the median value is $22.7-$23 million annually. The median market values vary little between all alternatives with none falling less than $20 million annually.

Under the Moderately Wet and Average Flow Categories, median market values decline slightly across all alternatives and interquartile ranges narrow, reflecting less variability and sensitivity to hydrologic conditions. Median values across all alternatives range from $18-$21 million annually. Enhanced Coordination and Supply Driven (LB Pro Rata) Alternatives both experience larger interquartile ranges, with 25th percentiles dropping to $16 million and $18 million, respectively.

Under the Dry and Critically Dry Flow Categories, Enhanced Coordination and Supply Driven (LB Pro Rata) Alternatives have noticeably lower median values than the other alternatives, with values of $15 million and $16.9 million, respectively. CCS Comparative Baseline ($18.6-$20 million), as well as No Action ($17.7-$20 million), Basic Coordination ($19.4-$20 million), Supply Driven (LB Priority) ($19.2-$19.7 million), and Representative Preferred ($17.4-$19.6 million) Alternatives generally showed higher median market values across these categories.

Modeling indicates that the Representative Preferred Alternative maintained a median market value of $19.6 million annually across the Dry Flow Category. Under the Critically Dry Flow Category, the Representative Preferred Alternative had a median value of $17.4 million annually.

Figure TA 15-38
Annual Market Value of Parker Dam Generation: Box Plots

Summary of Issue 5 Impacts

Market value generally declined as hydrologic conditions became drier, reflecting lower energy generation across all facilities. The differences among alternatives was greatest at Glen Canyon Dam and Hoover Dam, while Davis Dam and Parker Dam exhibited smaller variations in market value.

For Glen Canyon Dam, the Representative Preferred Alternative achieved the highest market values under wet conditions ($358 million annually), while the Enhanced Coordination ($180-$216 million annually) and Maximum Operational Flexibility ($127-$178 million annually) Alternatives performed best under dry and critically dry conditions, maintaining the highest median values and lowest variability. The No Action Alternative and CCS Comparative Baseline generally produced lower market values and experienced greater variability.

For Hoover Dam the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative generally produced the highest market values under wet and moderately wet conditions ($195-$277 million annually). Under average, dry, and critically dry conditions, the Enhanced Coordination, Maximum Operational Flexibility, Representative Preferred, and Supply Driven (LB Pro Rata) Alternatives maintained higher median market values and narrower interquartile ranges than the CCS Comparative Baseline and No Action Alternative consistently exhibited lower values with greater variability.

For Davis Dam, under wetter flow conditions, wider interquartile ranges were present in Basic Coordination, Enhanced Coordination, Maximum Operation Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and the Representative Preferred Alternatives. Median values were between $50-$57 million annually. Under moderately wet and average conditions, median values generally range between $41-$489 million annually across all alternatives. Under dry and critically dry conditions, market values declined across all alternatives; however, the Enhanced Coordination Alternative had the lowest value with 25 percent of years falling to $28 million or less, annually.

For Parker Dam, market values exhibited the least variation among alternatives, with most median values ranging between approximately $15-$23 million annually, across all flow categories. Under Dry and Critically Dry Categories, the Enhanced Coordination ($15.5-$16 million) and Supply Driven (LB Pro Rata approach) ($16.9-$17.7 million) Alternatives tended to produce lower median market values than the other alternatives.

Overall, the Representative Preferred and Maximum Operational Flexibility Alternatives generally maintained higher market values and reduced variability under increasingly dry hydrologic conditions, whereas the No Action Alternative and CCS Comparative Baseline were more likely to exhibit lower market values and greater variability, particularly at Glen Canyon and Hoover Dams.

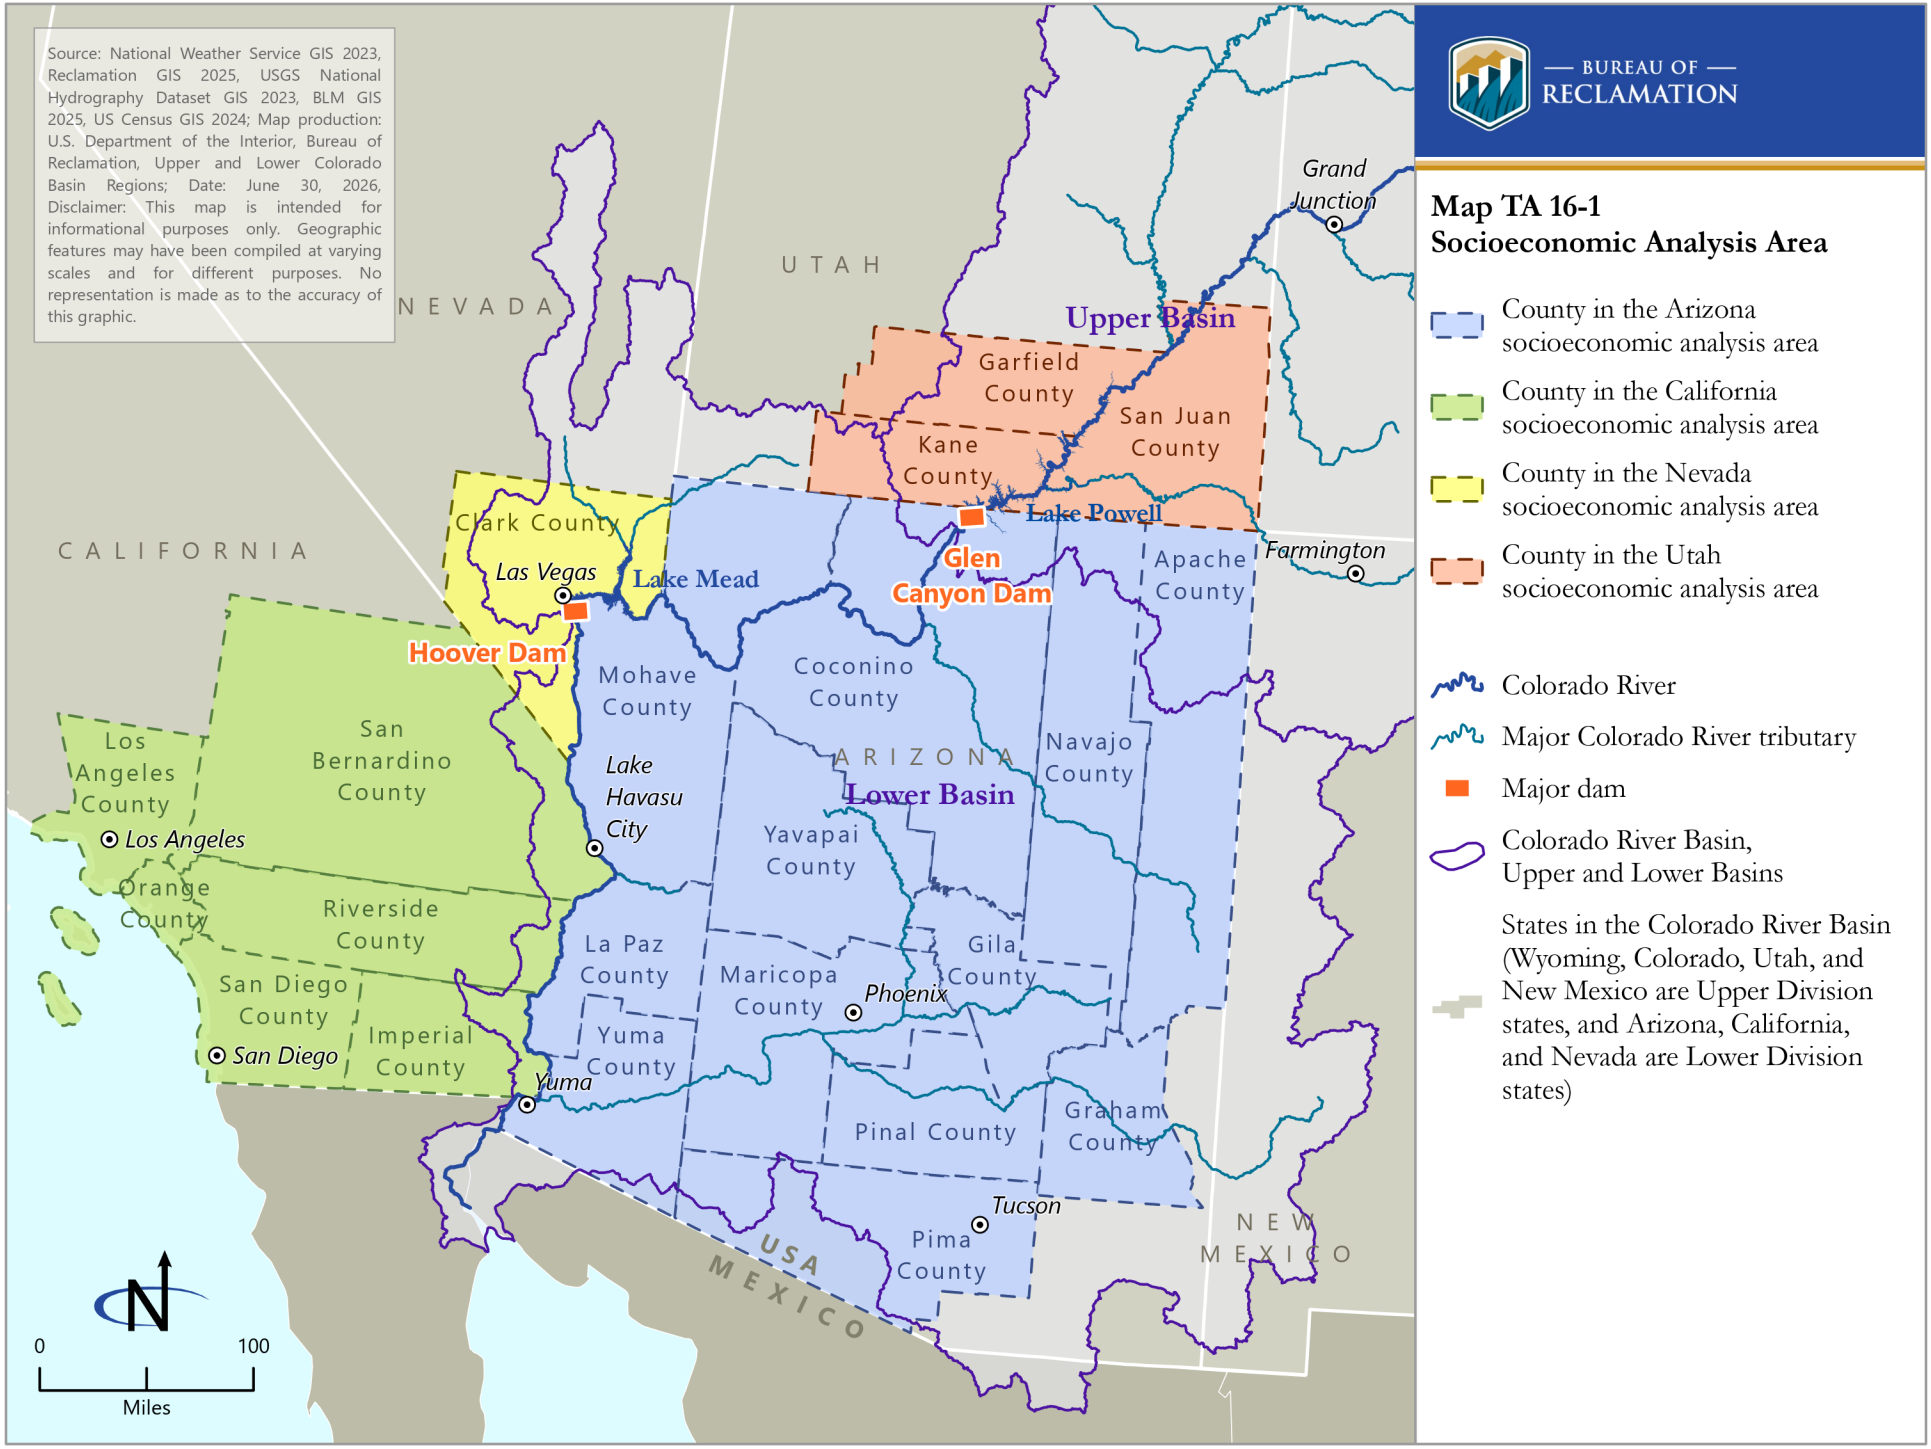
TA 16. Socioeconomics

TA 16.1 Affected Environment



TA 16.1.1 Socioeconomic Analysis Area

The analysis area for the socioeconomic analysis includes counties in Arizona, California, Nevada, and Utah (see **Map TA 16-1** for a map of the socioeconomic analysis area). In **Section TA 16.2.1**, Methodology, in the Impact Analysis Area subsection under the Agriculture, Recreation, and Ecosystem Services and Nonmarket Values subsections, the socioeconomic analysis area is further described as it relates to each issue statement that was analyzed in this technical appendix. The analysis of impacts on economic and social conditions due to changes in agricultural production included Arizona, California, and Nevada. The analysis on economic impacts from changes in recreational use included Arizona, California, Nevada, and Utah. The impact analysis on ecosystem services and nonmarket values included Arizona, California, Nevada, and Utah. The counties and communities that are included in the socioeconomic analysis area are described further below, by state.

The Arizona analysis area consists of Apache, Coconino, Gila, Graham, La Paz, Maricopa, Mohave, Navajo, Pima, Pinal, Yavapai, and Yuma Counties. These include counties that are directly adjacent to Lake Powell, Lake Mead, or the mainstream Colorado River; counties in which impacts from Colorado River shortages would likely occur; and counties where tribal reservations affected by Colorado River or Central Arizona Project (CAP) shortages are located.[1] The counties in which measurable mainstream Colorado River or CAP shortages could potentially occur to tribal and non-tribal irrigation entitlement holders, resulting in reductions in agricultural production, are La Paz, Maricopa, Mohave, Pinal, Pima, and Yuma Counties.

Apache, Coconino, Gila, Graham, Navajo, and Yavapai Counties would not experience a water shortage to irrigation entitlement holders attributable to the alternatives; however, they are included in the analysis area because of the ties these counties have to recreation-related economic activity on the Colorado River as well as ties to Indian water rights settlements involving CAP water and non-CAP Colorado River water delivered through the CAP. Please refer to **Table 18-3**, CAP Water Entitlements, in **Section TA 18.1.2**, Water Entitlements, Water Deliveries, and Storage and Conservation Options, in **TA 18**, Indian Trust Assets, for details on tribes with CAP contracts.

[1] See **Section 1.5.1**, Geographic Scope of Scope of the Proposed Federal Action and Affected Regions and Interests, of the Final EIS, for more information on the geographic scope that would be affected by the alternatives analyzed.

Miles

The California analysis area consists of Imperial, Los Angeles, Orange, Riverside, San Bernardino, and San Diego Counties. These counties were selected because they are either directly adjacent to the Colorado River, or they are within the Metropolitan Water District of Southern California service area. Although Ventura County is also in the Metropolitan Water District of Southern California service area, it does not receive any water from the Colorado River; therefore, it is not included in the analysis area.

The Nevada analysis area consists of Clark County. The analysis area was limited to Clark County because Clark County is adjacent to Lake Mead and encompasses the Southern Nevada Water Authority's service area and other individual water providers. Shortages in Nevada would be limited to Southern Nevada Water Authority's service area.

The Utah analysis area consists of Garfield, Kane, and San Juan Counties. Utah will not experience shortages under any alternative, so Utah was not included in the analysis area for the agriculture economic impact analysis in this technical appendix. However, changes in storage at Lake Powell could result in changes in recreation-related expenditures made in these Utah analysis area counties; therefore, the following sections include baseline data for Utah because they relate to economic and social conditions due to changes in recreation.

TA 16.1.2 Baseline Economic Conditions

This section provides an overview of baseline economic conditions related to Colorado River water use with the potential to be affected by water shortages. Baseline data used to inform this section were collected from the United States (U.S.) Bureau of Economic Analysis, the U.S. Bureau of Labor Statistics, the U.S. Census Bureau, and current, relevant literature. These data are county-level data on employment, labor income, unemployment rates, poverty, and the market value of agricultural production in the analysis areas. The county-level data do not distinguish between water sources that were used in support of the economic conditions presented, which may include a combination of the mainstream Colorado River, CAP, and other water sources.

Arizona

Employment and Personal Income

Table TA 16-1 and **Table TA 16-2**, below, provide an overview for employment by sector for the counties in the analysis area in Arizona in 2010 and 2022, respectively. Full- and part-time employment in Arizona totaled almost 4.3 million jobs in 2022, an increase of approximately 1.1 million jobs from 2010 levels. Farm employment totaled almost 28,000 jobs in 2022 and accounted for 0.6 percent of the total employment in the state; this is a small reduction from the number of jobs and the percentage of the total employment in 2010, at almost 29,000 jobs and 0.9 percent of the total employment.

Table TA 16-1
Arizona Employment by Industry (2010)

D = not shown to avoid disclosure of confidential information; estimates are included in higher-level totals.

Employment in the analysis area counties represents approximately 98.1 percent of the total employment in Arizona. Farm employment in the 12 counties totaled about 26,000 jobs in 2022 and represented about 0.6 percent of the total employment in the analysis area counties.[2] Farm employment made up a larger percentage of the total employment in Apache and Navajo Counties than in the rest of the counties in the analysis area, with 19.2 percent and 8.7 percent of the total employment, respectively (BEA 2024a). In 2022, employment in the arts, entertainment, and recreation sector totaled approximately 84,000 jobs (or 2.0 percent of the total employment in the analysis area), which was an increase from 2010 jobs by about 27 percent.

Total personal income in Arizona was almost $430.1 billion in 2022, compared with $293.8 billion in 2010 (adjusted to 2022 dollars). Likewise, per capita income increased from approximately $46,000 in 2010 (adjusted to 2022 dollars) to approximately $58,000 in 2022; this is a 27.3 percent increase (see **Table TA 16-3**; BEA 2024b). Arizona farm earnings per farm worker, in 2022, were about $35,000 ($965.1 million in farm earnings divided by 27,735 farm jobs), which was an increase of about $3,000 from 2010 earnings (adjusted to 2022 dollars; BEA 2024a, 2024b).

The total personal income generated in the 12 counties represented 97.9 percent of the state total in 2022. Among the 12 counties, average per capita income ranged from a low of approximately $42,000 per year in Graham County and Navajo County to a high of $63,000 per year in Maricopa County. Only Maricopa and Coconino Counties had per capita income above that of the state of Arizona (about $58,000). In 2022, farm earnings per farm worker, including proprietor's income, in the analysis area ranged from an accounting loss[3] of about $3,000 in Apache County to earnings per worker of about $112,000 in Yuma County (BEA 2024a, 2024b).

Table TA 16-4, Arizona Employment by Industry (2010), displays the annual unemployment rate and the population below poverty. The unemployment rate is a key economic indicator, which can indicate the financial health of an economy; a low rate generally indicates a functioning economy, while a high rate is a concern for the general economy and likely indicates that some individuals in the labor force are in economic distress due to the lack of work and associated income. In 2023, eight of the study area counties in Arizona had annual unemployment rates that were higher than the state unemployment rate of 3.9 percent. Unemployment was notably high in Yuma County, with an unemployment rate of 13.2 percent, which is over three times greater than that of the state of Arizona.

[2] Farm employment does not include employment in other industries that are supported by the farming industry, such as employment in the transportation and warehousing, manufacturing (including food manufacturing), and retail trade (including food and beverage and grocery stores) industries. Changes in water availability that affect the farming industry would also indirectly affect these industries. More information on indirect impacts on employment, labor income, and economic output is discussed in **Section TA 16.2**, Environmental Consequences.

[3] Accounting losses occur when proprietors incur more expenses than the revenues they receive.

Source: BEA 2024b

[1] Personal income is calculated at the place of residence and includes labor income as well as non-labor income, such as dividends, interest, and rent.

[2] Earnings is calculated at the place of work based on labor income, such as wages and salaries, supplements, and proprietors' income.

[3] Accounting losses in farm earnings occur when proprietors incur more expenses than the revenues they receive.

Across the Arizona analysis area, nine out of the 12 counties had a higher percentage of people living below the poverty level than the state (12.8 percent), with the largest percentage of people below poverty in Apache County (31.2 percent) and Navajo County (24.7 percent). This suggests that economic considerations are important factors for many individuals throughout the analysis area, and management actions that impact economic opportunities and economic conditions could greatly affect the surrounding communities.

Table TA 16-4
Arizona Analysis Area Unemployment and Poverty (2023)

Geographic Area	Unemployment (%)	% Below Poverty
Apache County	7.9	31.2
Coconino County	4.2	17.7

Agriculture

Agriculture is an important part of the economy in Arizona. Approximately 35 percent of Arizona's land area in 2022 was used for agricultural purposes (on cropland, pastureland, woodland, or other; USDA 2024). In 2022, the market value of agricultural products sold in Arizona contributed $5.2 billion to Arizona's economy. Additional contributions to the economy from agriculture come from the manufacture of crop inputs, crop processing, marketing, and distribution, and agricultural income (Lahmers and Edan 2018). The key crops produced and sold in Arizona include corn, wheat, vegetables, and melons (USDA 2024). The types of crops, amount of water used for agriculture, and the role of agriculture in county economies vary across the state and analysis area. Additional information on irrigated agricultural acreage within the analysis area is provided in **TA 17**, Population and Land Use.

Central and southwestern Arizona farms contribute the largest share of agricultural production in terms of sales values. In 2022, the total market value of agricultural products sold in the Arizona analysis area contributed $4.8 billion to Arizona's economy, which was about 91 percent of the market value of agricultural products sold in the state and about one percent of the Arizona total gross domestic product (GDP). The market value of crops sold in the analysis area (excluding values for La Paz and Yuma Counties to avoid disclosure of confidential information) was about $1.3 billion. Across Maricopa, Pima, and Pinal Counties, the market value of crops sold in 2022 ranged

from about $87.1 million in Pima County to about $742.6 million in Maricopa County (USDA 2024). In 2024, compared with the other analysis area counties, Yuma County and La Paz County had the highest farming output as a percentage of the counties' total economic output, with about 9.2 percent and 7.4 percent of total output coming from the farming industry in La Paz and Yuma Counties, respectively (IMPLAN 2025).

Table TA 16-5 presents a summary of the market value of on-farm agricultural production with respect to county and state GDP. **Table TA 16-6** presents the county-level economic output from the farming industry and the percentage of farming economic output to total county-level output.

Table TA 16-5
Market Value of Agricultural Production in Arizona Analysis Area (2022)

Area	Market Value of Crops Sold ($1,000)	Percentage of Market Value of Crops Sold to County GDP	Percentage of Market Value of Crops Sold to Arizona GDP	Market Value of Agricultural Products Sold ($1,000)
Maricopa County	742,596	0.21	0.16	1,558,021
Pima County	87,130	0.16	0.02	97,973
Pinal County	365,172	3.06	0.08	1,169,581
Total within CAP counties[1]	1,194,898	0.29	0.25	2,825,575
Apache County	3,411	0.12	0.00	16,985
Coconino County	1,437	0.02	0.00	22,593
Gila County	412	0.02	0.00	9,351
La Paz County[2]	(D)	(D)	(D)	270,641
Mohave County	48,846	0.63	0.01	56,558
Navajo County	4,898	0.14	0.00	47,996
Yuma County[2]	(D)	(D)	(D)	1,507,066
Total Arizona analysis area[3]	1,253,902	0.28	0.26	4,756,765

Sources: BEA 2024c; USDA 2024

[1] CAP values are aggregated values for Maricopa, Pima, and Pinal Counties.

[2] D = not shown to avoid disclosure of confidential information.

[3] The totals for the Arizona analysis area do not include data for La Paz and Yuma Counties because the U.S. Department of Agriculture determined the data were too sensitive to disclose.

Table TA 16-6
Farming Economic Output in Arizona Analysis Area (2024)

Area	Total Farming Output (thousand 2025$)	Percentage of County Output
Maricopa County	845,776	0.11
Pima County	56,129	0.05
Pinal County	371,328	1.18
Total within CAP counties[1]	1,273,233	0.14
Apache County	3,719	0.08

Area	Total Farming Output (thousand 2025$)	Percentage of County Output
Coconino County	2,483	0.01
Gila County	1,839	0.03
La Paz County	185,877	9.23
Mohave County	65,350	0.39
Navajo County	6,645	0.09
Yuma County	1,429,958	7.43
Total Arizona analysis area	2,969,103	0.30

Source: IMPLAN 2025

[1] CAP values are aggregated values for Maricopa, Pima, and Pinal Counties.

In 2022, the CAP counties—Maricopa, Pima, and Pinal Counties—accounted for approximately 55 percent of Arizona's harvested acres of hay and haylage crops, 65 percent of the state's harvested acreage of cotton, and 44 percent of the harvested wheat acreage. In 2022, the three western Arizona counties that are located along the Colorado River—Mohave, La Paz, and Yuma Counties—accounted for approximately 33 percent of the statewide harvested hay and haylage acreage, 78 percent of the harvested acres of vegetable crops, and 53 percent of the harvested wheat acres. Yuma County alone accounted for 77 percent of the state's total harvested acres of vegetable crops (USDA 2024).

California

Employment and Personal Income

Table TA 16-7 and **Table TA 16-8**, below, provide an overview for employment by sector for the counties in the analysis area in California in 2010 and 2022, respectively.[4] Full- and part-time employment in California totaled 25.3 million jobs in 2022, an increase of approximately 5.7 million jobs from 2010 levels.

Full- and part-time employment in the six-county analysis area totaled 13.9 million jobs in 2022, representing 55 percent of total California employment. Farm employment in the six counties totaled about 31,000 jobs in 2022 and represented about 0.2 percent of the total employment in the analysis area counties.[5] Farm employment made up a larger percentage of the total employment in Imperial County than in the rest of the counties in the analysis area, with 4.7 percent of the total employment coming from the farm sector in Imperial County (BEA 2024a). In 2022, employment in the arts, entertainment, and recreation sector totaled approximately 395,000 jobs (or 2.8 percent of the total employment in the analysis area), which was an increase from 2010 jobs by about 19 percent.

[4] The analysis does not distinguish between the water source(s) that may support such employment, which may include sources other than, or blended with, mainstream Colorado River water.

[5] Farm employment does not include employment in other industries that are supported by the farming industry, such as employment in the transportation and warehousing, manufacturing (including food manufacturing), and retail trade (including food and beverage and grocery stores) industries. Changes in water availability that affect the farming industry would also indirectly affect these industries. More information on indirect impacts on employment, labor income, and economic output is discussed in **Section TA 16.2**, Environmental Consequences.

Source: BEA 2024a

Total personal income in California was approximately $3.0 trillion in 2022, compared with about $2.2 trillion in 2010 (adjusted for inflation to 2022 dollars). Statewide per capita income also increased from approximately $59,000 in 2010 (adjusted to 2022 dollars) to approximately $77,000 in 2022 (BEA 2024b; see **Table TA 16-9**). In 2022, California farm earnings per farm worker were about $70,000 ($16.0 billion in farm earnings divided by about 228,000 farm jobs), which was a decrease of about $7,000 from 2010 earnings (adjusted to 2022 dollars; BEA 2024a, 2024b).

The total personal income generated in the six analysis area counties represented 48.9 percent of the state total in 2022. Among the six counties, average per capita income ranged from a low of approximately $45,000 per year in Imperial County to a high of $84,000 per year in Orange County. Only Orange County had per capita income above that of the state of California (about $77,000 in 2022). In 2022, farm earnings per farm worker in the analysis area ranged from about $42,000 in San Diego County to about $147,000 in Imperial County (BEA 2024a, 2024b).

Table TA 16-10, Unemployment and Poverty, displays the annual unemployment rate and the percentage of the population living below poverty. In California, all counties excluding Imperial and Los Angeles Counties had 2023 annual unemployment rates below the state annual unemployment rate of 4.8 percent. Unemployment was notably high in Imperial County, with an unemployment rate of 17.3 percent, which is over 3 times greater than that of the state of California.

Across the California analysis area, half of the counties—Imperial, Los Angeles, and San Bernardino Counties—had a higher percentage of people living below the poverty level than the state (12.0 percent). The largest percentage of people below poverty was in Imperial County (19.6 percent). This suggests that economic considerations are important factors, especially in these counties with high percentages of people living below poverty. Management actions that impact economic opportunities and economic conditions could affect the surrounding communities in these counties.

Agriculture

Approximately 24 percent of California's land area in 2022 was used for agricultural purposes (on cropland, pastureland, woodland, or other; USDA 2024). In 2022, the market value of agricultural products sold in California contributed approximately $59 billion to the statewide economy (USDA 2024). The types of crops, amount of water used for agriculture, and the role of agriculture in county economics vary across the state and analysis area. Additional information on irrigated agricultural acreage within the analysis area is provided in **TA 17**, Population and Land Use.

In 2022, the total market value of agricultural products sold in the California analysis area contributed $6.1 billion to California's economy. The market value of crops sold in the analysis area was about $4.7 billion, ranging from about $69.5 million in Orange County to about $2.2 billion in Imperial County (USDA 2024). In 2024, compared with other counties in the analysis area, Imperial County had the highest farming output as a percentage of the county's total economic output, with 15.5 percent of total economic output coming from the farming industry (IMPLAN 2025). **Table TA 16-11** presents a summary of the market value of on-farm agricultural production with respect to county and state GDP. **Table TA 16-12** presents the county-level economic output from the farming industry and the percentage of farming economic output to total county-level output.

The key crops in the California analysis area include hay, vegetables, and wheat. In 2022, the California analysis area counties accounted for approximately 30 percent of California's harvested acres of hay and haylage crops, 16 percent of the state's harvested acreage of vegetables, and 35 percent of the harvested wheat acreage (USDA 2024).

Nevada

Employment and Personal Income

Table TA 16-13, below, provides an overview for employment by sector for Clark County and the state of Nevada in 2010 and 2022. Full- and part-time employment in Nevada totaled almost 2.1 million jobs in 2022, an increase of approximately 584,000 jobs from 2010 levels. In 2022, employment in the arts, entertainment, and recreation sector totaled almost 62,000 jobs, or approximately 3 percent of the state's total employment. Farm employment represented only 0.3 percent of the total employment, with a little more than 5,000 jobs.

Full- and part-time employment in Clark County totaled about 1.5 million jobs in 2022; this is an increase of approximately 466,000 jobs from 2010. Total employment in Clark County represented almost 74 percent of the total employment in Nevada. In 2022, employment in the arts, entertainment, and recreation sector totaled almost 47,000 jobs, or 3.1 percent of the total employment in the county. Farm employment represented less than 0.1 percent of the total employment, with a little more than 400 jobs (see **Table TA 16-13**).[6]

Table TA 16-13
Nevada Employment by Industry (2010 and 2022)

[6] Farm employment does not include employment in other industries that are supported by the farming industry, such as employment in the transportation and warehousing, manufacturing (including food manufacturing), and retail trade (including food and beverage and grocery stores) industries. Changes in water availability that affect the farming industry would also indirectly affect these industries. More information on indirect impacts on employment, labor income, and economic output is discussed in **Section TA 16.2**, Environmental Consequences.

Source: BEA 2024a

Total personal income in Nevada was approximately $197.3 billion in 2022, compared with about $136.9 billion in 2010 (adjusted for inflation to 2022 dollars). Statewide per capita income increased from approximately $51,000 in 2010 (adjusted to 2022 dollars) to approximately $62,000 in 2022 (BEA 2024b; see **Table TA 16-14**). In 2022, Nevada farm earnings per farm worker were about $34,000 ($177.9 million in farm earnings divided by 5,208 farm jobs), which was a decrease of about $3,000 from 2010 earnings (adjusted to 2022 dollars; BEA 2024a, 2024b).

The total personal income in Clark County represented 69.6 percent of the state total in 2022. In 2022, the per capita income in Clark County was approximately $59,000, which was slightly lower than the per capita income for the state. Farm earnings were not a major portion of total earnings in Clark County, with less than 0.1 percent of earnings coming from the farm industry (BEA 2024b; see **Table TA 16-14**).

Table TA 16-14
2010 and 2022 Nevada Personal Income and Earnings (2022$)

[1] Personal income is calculated at the place of residence and includes labor income as well as non-labor income, such as dividends, interest, and rent.

[2] Earnings is calculated at the place of work based on labor income, such as wages and salaries, supplements, and proprietors' income.

Table TA 16-15, below, displays the annual unemployment rate and the percentage of the population below poverty. In 2023, the Nevada analysis area—Clark County—had an annual unemployment rate (5.4 percent) that was slightly higher than the state annual unemployment rate (5.1 percent). Similarly, the percentage of people living below poverty in Clark County (13.2 percent) was slightly higher than the percentage for Nevada (12.6 percent).

Table TA 16-15
Nevada Analysis Area Unemployment and Poverty (2023)

Geographic Area	Unemployment (%)	% Below Poverty
Clark County	5.4	13.2
Nevada	5.1	12.6

Agriculture

Approximately 8.4 percent of Nevada's land area in 2022 was used for agricultural purposes (on cropland, pastureland, woodland, or other; USDA 2024). In 2022, the market value of agricultural

products sold in Nevada contributed nearly $1 billion to the statewide economy. Additional information on irrigated agricultural acreage within the analysis area is provided in **TA 17**, Population and Land Use.

Utah

Employment and Personal Income

Table TA 16-16, below, provides an overview for employment by sector for the Utah analysis area in 2010 and 2022. Full- and part-time employment in Utah totaled almost 2.4 jobs in 2022, an increase of approximately 747,000 jobs from 2010 levels. In 2022, employment in the arts, entertainment, and recreation sector totaled almost 51,000 jobs, or approximately 2.2 percent of the total employment in the state.

Full- and part-time employment in the Utah analysis area totaled about 17,000 jobs in 2022, an increase of approximately 3,000 jobs from 2010. Total employment in the analysis area represented approximately 1.0 percent of the total employment in Utah. In 2022, employment in the arts, entertainment, and recreation sector totaled approximately 400 jobs (or 2.6 percent of the total employment in the analysis area) and represented 6.0 percent of employment in Kane County (see **Table TA 16-16**).

Total personal income in Utah was approximately $205.5 billion in 2022, compared with about $120.9 billion in 2010 (adjusted for inflation to 2022 dollars). Statewide per capita income increased from approximately $44,000 in 2010 (adjusted to 2022 dollars) to approximately $61,000 in 2022 (BEA 2024b; see **Table TA 16-17**).

The total personal income in the analysis area represented 0.6 percent of the state total in 2022. Among the counties in the analysis area, average per capita income ranged from a low of approximately $37,000 per year in San Juan County to a high of $52,000 per year in Garfield County. All counties in the analysis area had per capita income below that of the state of Utah (about $61,000 in 2022; BEA 2024b; see **Table TA 16-17**).

Table TA 16-18, below, displays the annual unemployment rate and the percentage of the population below poverty. In 2023 in the Utah analysis area, all the counties had a higher annual unemployment rate and percentage of population living below poverty than the state of Utah. This suggests that economic considerations are important factors for many individuals throughout the analysis area, and management actions that impact economic opportunities and economic conditions could greatly affect the surrounding communities.

TA 16.1.3 Economic Contributions from Recreational Use

As discussed in **TA 14**, Recreation, recreational activities with the potential to be affected by proposed management include recreation such as boating, camping, and hiking on and adjacent to reservoirs at Lake Powell and Lake Mead, as well as river-based recreation downstream in Glen Canyon and Grand Canyon. Information is also included on wildlife refuges on the Colorado River because the alternatives may affect these refuges.

When visitors recreate on lakes or rivers, the dollars they spend on purchases, such as lodging, gas, food, and outdoor equipment, support local and regional economic contributions, including direct, indirect, and induced jobs; labor income; and economic output.[7] Direct economic contributions occur when businesses sell goods and services to area visitors, such as outfitter services. Indirect economic contributions are additional jobs and economic activity supported when businesses purchase supplies and services from other local businesses, such as supplies used by outfitter businesses. Induced economic contributions occur when employees use their income to purchase goods and services in the local economy, resulting in further induced effects from visitor spending. Economic output is a measure of the total estimated value of the production of goods and services supported by visitor spending, including the direct, indirect, and induced effects.

Table TA 16-19, below, displays the total economic contributions from lake-based recreation occurring in the Glen Canyon National Recreation Area (NRA), which includes Lake Powell, and in the Lake Mead NRA, which includes Lake Mohave. **Table TA 16-20** displays economic contributions associated with Grand Canyon National Park (GCNP).

[7] Direct, indirect, and induced impacts—as used in this context—are economic terms used to describe the impacts from changes in economic activity. For more information on the types of economic activity that are included in each type of impact, please refer to **Section TA 16.2.1**, Methodology.

Table TA 16-19
Summary of Economic Contributions for National Park Service (NPS) Lake-Based Recreation (2023)

NPS Unit	Total Recreational Visits	Visitor Spending (1,000s of 2023$)	Jobs[1]	Labor Income (1,000s of 2023$)[2]	Value Added (1,000s of 2023$)[3]	Economic Output (1,000s of 2023$)[4]	% of Spending from Nonlocals
Glen Canyon NRA	5,206,934	$539,912	6,298	$226,266	$384,281	$670,369	96.3
Lake Mead NRA	5,798,541	$292,463	3,131	$130,744	$219,232	$357,760	88.3

Source: Flyr and Koontz 2024

[1] Jobs measure annualized full- and part-time jobs that are supported by NPS visitor spending.

[2] Labor income includes employee wages, salaries, and payroll benefits, as well as proprietors' incomes, that are supported by NPS visitor spending.

[3] Value added measures the contribution of NPS visitor spending to the GDP of a regional economy. Value added is equal to the difference between the amount an industry sells a product for and the product's production cost.

[4] Economic output is a measure of the total estimated value of the production of goods and services supported by NPS visitor spending. Economic output is the sum of all intermediate sales (business to business) and final demand (sales to consumers and exports).

Table TA 16-20
Summary of Economic Contributions for NPS River-Based Recreation (2023)

NPS Unit	Total Recreational Visits	Visitor Spending (1,000s of 2023$)	Jobs[1]	Labor Income (1,000s of 2023$)[2]	Value Added (1,000s of 2023$)[3]	Economic Output (1,000s of 2023$)[4]	% of Spending from Nonlocals
GCNP	4,733,705	$768,411	10,060	$350,177	$582,513	$1,022,191	98.8

Source: Flyr and Koontz 2024

[1] Jobs measure annualized full- and part-time jobs that are supported by NPS visitor spending.

[2] Labor income includes employee wages, salaries, and payroll benefits, as well as proprietors' incomes, that are supported by NPS visitor spending.

[3] Value added measures the contribution of NPS visitor spending to the GDP of a regional economy. Value added is equal to the difference between the amount an industry sells a product for and the product's production cost.

[4] Economic output is a measure of the total estimated value of the production of goods and services supported by NPS visitor spending. Economic output is the sum of all intermediate sales (business to business) and final demand (sales to consumers and exports).

Total economic output for lake-based recreation was $358 million from Lake Mead NRA and $670 million from Glen Canyon NRA. These amounts reflect total economic output from visitor spending, including spending by local visitors who live in gateway regions and nonlocal visitors who travel to National Park Service (NPS) sites from outside gateway regions. Spending by nonlocal visitors represents an influx of dollars from outside the local economy. In addition, nonlocal visitors typically have higher levels of spending on food, lodging, and other activities on a per-trip basis. Glen Canyon NRA and Lake Mead NRA had 96.3 percent and 88.3 percent of spending from nonlocal visitors, respectively (Flyr and Koontz 2024).

Total economic output for river-based recreation was $1,022 million in GCNP. This amount accounts for total visitor spending, which includes spending by local visitors who live in gateway regions and nonlocal visitors who travel to NPS sites from outside gateway regions. Spending by nonlocal visitors represents an influx of dollars from outside the local economy. In addition, nonlocal visitors typically have higher levels of spending on food, lodging, and other activities on a per-trip basis. GCNP had 98.8 percent of spending from nonlocal visitors (Flyr and Koontz 2024).

River-based recreation is a major component of visitor use and economic activity along the Colorado River corridor. Two activities stand out for their economic and experiential importance: angling in Glen Canyon and whitewater rafting in Grand Canyon. Angling in Glen Canyon below Glen Canyon Dam attracts visitors seeking high-quality trout fishing opportunities, which depend on stable flows and accessible river conditions. These trips generate spending on guide services, lodging, food, and equipment in nearby communities. Similarly, whitewater rafting in Grand Canyon is a nationally important recreational experience, drawing thousands of visitors annually for multiday trips that require specialized guides, equipment, and logistical support. These trips contribute to local economies through outfitter services, transportation, and hospitality sectors. For additional details on recreation and levels of use, see **TA 14**, Recreation.

Beyond direct spending, these activities provide considerable nonmarket recreational benefits, often expressed as consumer surplus. Consumer surplus represents the additional benefit participants receive beyond their actual costs, reflecting the unique quality and scarcity of these experiences. Flow conditions influence both angling success and rafting trip quality, making river operations an important factor in sustaining these values.

Recreational visits to Glen Canyon NRA and Lake Mead NRA correspond with a wide array of job sectors within local (predominately small town and rural) economies. **Table TA 16-21** shows the key sectors supported through recreation in Glen Canyon NRA and Lake Mead NRA. In 2023, Glen Canyon NRA recreation supported 6,300 jobs, including 1,467 indirect and induced jobs. In 2023, Lake Mead NRA recreation supported 3,131 total jobs, including 872 indirect and induced jobs (Flyr and Koontz 2024).

Table TA 16-21
Jobs by Sector Supported by Economic Contributions from NPS Lake-Based Recreation (2023)

Jobs	Glen Canyon NRA	Lake Mead NRA
Direct jobs by sector		
Camping	130	122
Gas	108	79
Groceries	145	155
Hotels	2,112	613
Recreational industries[1]	851	261
Restaurants	1,009	792
Retail	257	185
Transportation	221	52
Indirect and induced jobs	1,467	872
Total jobs	6,300	3,131

Source: Flyr and Koontz 2024

[1]Recreational industry jobs include those associated with expenditures on equipment rentals, amusement activities and guide/tour fees.

Table TA 16-22 shows that GCNP recreation supported 10,064 jobs, including 2,316 indirect and induced jobs, in 2023. In addition to the direct economic impact from gross revenues on GCNP and the NPS, it is estimated that the regional economic impact of commercial river trips supports hundreds of additional jobs and generates millions in additional revenue throughout the mostly rural communities and small businesses of northern Arizona and southern Utah each season.

Table TA 16-22
Jobs by Sector Supported by Economic Contributions from NPS River-Based Recreation (2023)

Jobs	GCNP
Direct jobs by sector	
Camping	156
Gas	99
Groceries	134
Hotels	2,630
Recreational industries	2,032
Restaurants	1,631
Retail	460
Transportation	606
Indirect and induced jobs	2,316
Total jobs	**10,064**

Source: Flyr and Koontz 2024

[1]Recreational industry jobs include those associated with expenditures on equipment rentals, amusement activities and guide/tour fees.

In addition to general recreation sector contributions, visitor use supports concessionaires, including those associated with water-based recreation, such as commercial river trips. In GCNP, commercial river trips hosted 17,313 passengers in 2023, which was a decrease from 19,990 passengers in 2022 and 20,749 passengers in 2021. From these river trips, river concessionaires contributed $63.6 million in 2023 in gross revenue, representing 29 percent of the total concessionaire revenue at GCNP, which amounted to $220 million that year. Gross revenue from river concessionaires remained relatively consistent from 2021 to 2023, with a small decrease from $66.4 million in 2021 to $61.8 million in 2022, followed by a small increase to $63.6 million in 2023 (2021 and 2022 values adjusted for inflation to 2023$). River concessioner franchise fees paid to the NPS in 2023 totaled $6.25 million, 80 percent of which stays at GCNP.[8] It should be noted that concessionaires include those operated by tribes, particularly at the Antelope Valley Marina, which is on the Navajo Nation's reservation.

National wildlife refuges (NWRs) also support economic contributions through expenditures from recreational visitors, such as expenditures for entrance fees, lodging near the refuges, and purchases from local businesses for items to pursue the visitors' recreational experience, including, but not limited to, food and recreational gear. This spending supports economic activity throughout the local economy (Caudill and Carver 2019). Three refuges receive Colorado River water: Imperial NWR, Cibola NWR, and Havasu NWR. Based on 2017 data, the most recent publicly available information, Imperial NWR, located in Arizona and California, had 274,159 visits and supported 100 jobs and $11.1 million in total economic output (see **Table TA 16-23**). Equivalent data are not available for Cibola and Havasu NWRs.

Table TA 16-23
Economic Contributions from NWRs (2017)[1]

NWR	Total Recreational Visits	Total Economic Output ($1,000)	Total Employment Income ($1,000)	Total Jobs
Imperial NWR (Arizona and California)	274,159	$11,069.8	$3,228.6	100

Source: Caudill and Carver 2019

[1] The data shown are presented for 2017, which is the most recent publicly available data.

TA 16.1.4 Demographics

Population is a driver of demand for consumptive water use. Populations throughout much of the western U.S. have followed trends of increasing populations over the past decade. Details of population trends and forecasts are provided in **TA 17**, Population and Land Use**.**

In addition to overall population trends, racial and ethnic composition can play a role in determining social and cultural groups with potential for impacts from changes to river operations. **Table TA 16-24**, Study Area Demographics (2023), shows the racial and Hispanic composition for the study area counties, as well as the composition for Arizona, California, Nevada, and Utah.

[8] Laurie Dyer, NPS supervisory concessions management specialist in the Commercial Services Division at GCNP, personal communication provided on September 27, 2024.

Several counties in the study area had American Indian and Alaska Native populations that were higher than the respective state level. In Arizona, Apache (72.1 percent), Coconino (25.2), Gila (13.2 percent), Graham (11.4 percent), La Paz (14.2 percent), and Navajo (43.1 percent) Counties had American Indian and Alaska Native populations far exceeding the state population of 4.1 percent.

According to 2023 census data, 13 of the study area counties had Hispanic or Latino populations exceeding 25 percent of the total population. In Arizona, the Hispanic or Latino population exceeds 25 percent in Graham (30.3 percent), La Paz (25.5 percent), Maricopa (30.9 percent), Pima (36.1 percent), Pinal (29.3 percent), and Yuma (64.4 percent) Counties. In California, the Hispanic or Latino population exceeded 31 percent in Imperial (85.6 percent), Los Angeles (48.3 percent), Orange (34.1 percent), Riverside (50.6 percent), San Bernardino (54.6 percent), and San Diego (34.3 percent) Counties. Clark County, Nevada, had a Hispanic or Latino population of 31.4 percent. In contrast, in the three Utah study area counties, the Hispanic or Latino population comprised between 4.8 percent and 7.0 percent of the total population.

TA 16.1.5 Social and Nonmarket Values

Nonmarket values refer to resource benefits that are not captured in market transactions or traditional economic measures. Along the Colorado River, these values include the enjoyment of natural scenery, opportunities for recreation and solitude, preservation of landscapes, and the symbolic and ecological importance of the river itself. Such values are important for understanding how river operations affect people's experiences, sense of place, and well-being, even when no direct economic exchange is involved.

Place-based communities along the Colorado River corridor derive nonmarket values from their proximity to the river and its resources. Gateway communities such as Page, Arizona; Boulder City, Nevada; Bullhead City, Arizona; and Lake Havasu City, Arizona, benefit from river-related recreation and tourism and identify with the surrounding landscape as part of their community character. Agricultural communities in counties in Arizona and California are closely tied to irrigated farmland supported by Colorado River water, and their identity is shaped in part by this long-standing relationship between land and water. Residents of these communities often emphasize quality of life, access to outdoor spaces, and continuity of traditional uses as nonmarket dimensions of the river.

In addition to supporting place-based communities, the river also supports nonmarket values for non-place-based communities. These include recreationists and visitors from across the U.S. who seek rafting, boating, angling, or other experiences on the river, as well as individuals who may never visit but who value the river for its ecological health, scenic integrity, or symbolic importance as a national resource. Conservation organizations and advocacy groups also emphasize the preservation of nonmarket values such as wilderness character and ecosystem health.

The expression of these values varies, but they generally encompass cultural identity, recreational quality, aesthetics, and existence values. For local communities, this may involve community identity or reliance on a healthy river system for recreational opportunities. For nonlocal stakeholders, it often reflects support for maintaining the river's ecological and scenic qualities. These values are not

measured through market activity but are nevertheless a critical part of how people interact with and assign meaning to the Colorado River.

Together, these social and nonmarket values establish a baseline for evaluating the social and cultural environment in the Colorado River Basin (Basin). They highlight that the river provides more than economic contributions; the river supports community identity, recreational experiences, and environmental quality that extend beyond direct market measures. These values provide important context for assessing potential changes under the post-2026 operational alternatives.

TA 16.2 Environmental Consequences

TA 16.2.1 Methodology

The following subsection outlines the methodology, impact analysis area, and assumptions used in the analysis of impacts on economic and social conditions from changes in agriculture and recreation as well as the analysis of impacts on ecosystem services and nonmarket values. For an analysis of impacts on hydropower, including impacts on energy generation, electricity rates, and market value, refer to **TA 15**, Dams and Electrical Power Resources. For an analysis of impacts on social and economic conditions from changes in domestic water, including impacts on municipal and industrial water users, refer to **TA 17**, Population and Land Use.

Agriculture

The purpose of the agricultural impact assessment is to estimate the change in economic conditions from changes in agricultural production from a reduction of irrigation water. The change in the value of agricultural production is directly related to the acres of cropland assumed to be fallowed and the estimated forgone revenue per acre of the fallowed crop. In addition to revenue loss from agricultural products, agricultural jobs and wages would potentially be lost. To analyze the impacts on economic conditions from these changes in agriculture, the U.S. Bureau of Reclamation (Reclamation) used a similar agricultural modeling framework that was applied in the Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead Final Environmental Impact Statement (2007 Final EIS; Reclamation 2007) and the Near-term Colorado River Operations Final Supplemental Environmental Impact Statement (2024 Final SEIS; Reclamation 2024), with some changes and updates as discussed below.

As described in **TA 4**, Water Deliveries, Reclamation used the Colorado River Simulation System to analyze water deliveries across the alternatives. Modeling details for each alternative are described in **Chapter 2**, Description of Alternatives and **Appendix S**, Additional Description of Alternatives. Additionally, as described in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation, Reclamation used Shortage Allocation Models and Alternative Distribution Models in addition to the Colorado River Simulation System to analyze the potential impacts of the alternatives on individual agricultural water users within each Lower Division State under different shortage scenarios. Based on the Shortage Allocation and Alternative Distribution Models, Reclamation estimated the change in agricultural revenue for each priority group by county and state in the analysis area where the individual agricultural and tribal agricultural water users were being

affected from water shortages at a variety of shortage levels across each alternative and comparative baseline.

Irrigated crops in the analysis area that were analyzed include field crops, vegetables, and fruit and nut trees and vines, separated out into agricultural crop group types, where at least approximately one percent of a county's harvested acres come from the crop group (USDA 2024; Reclamation 2016; Imperial County 2019, 2020, 2021, 2022, 2023; Riverside County 2020, 2021, 2022, 2023; San Bernardino County 2019, 2020, 2021, 2022, 2023). The methodology for estimating which crops would be fallowed first is the same as that used in the 2007 Final EIS and the 2024 Final SEIS and is based on the crops' water use and the farmer's ability to cover the variable cost of production of a given crop, which is based on the profitability of the crop (Dale and Dixon 1998; Frisvold et al. 2013). The analysis assumes that the least profitable crop would be fallowed first, analyzed for each priority group in each county separately. Crops would continue to be fallowed in the order of least profitable crop, until the full volume of water shortage is offset.

Calculation of crop profitability per acre-foot of water followed the method outlined in Appendix H of the 2007 Final EIS, which used the difference between revenue and the variable costs per acre of land required to grow a given crop. Based on the order of fallowing and the shortages analyzed across the alternatives, the following eight crop group types were analyzed: alfalfa, cotton, cruciferous vegetables, field grains, fruit and tree nuts and vines, other hay and haylage, small grains, and small vegetables.

To determine how much a farmer would be willing to pay for water before a choice is made to fallow a crop, the cost of irrigation for growing each crop was added back to the calculated revenue minus the variable production cost. To account for each crop's required amount of water (different for each crop), the estimated return plus the irrigation cost was divided by the amount of water per acre needed to grow that crop (USDA 2024; Reclamation 2016; University of Arizona 1999, 2001, 2023, 2025; University of Nevada 2004, 2007, 2010, 2012, 2022; University of California 1956, 1962, 1963, 1964, 1965, 1967, 1972, 1973, 1974, 1975, 1977, 1978, 1979, 1984, 1988, 1989, 1992, 1995, 1996, 1997, 1998, 2000, 2002, 2004, 2011). Based on this method, the order in which crops would be fallowed varied across the counties in the study area.

County-level operational cost data for each crop, including the difference in irrigation cost, are not updated frequently. To capture the difference in the irrigation cost for each crop in different counties in Arizona, California, and Nevada, variable costs-of-production estimates were based on historical crop and livestock budgets developed by the University of Arizona, University of California Davis, and University of Nevada Reno, respectively, for a range of years, depending on the type of crop and county for which it was developed (University of Arizona 1999, 2001, 2023, 2025; University of Nevada 2004, 2007, 2010, 2012, 2022; University of California 1956, 1962, 1963, 1964, 1965, 1967, 1972, 1973, 1974, 1975, 1977, 1978, 1979, 1984, 1988, 1989, 1992, 1995, 1996, 1997, 1998, 2000, 2002, 2004, 2011; USDA ERS 2025). For operational cost and irrigation cost data that were not available for specific crops grown in the county, estimated data were used based on data from nearby counties or from nearby states or regions for the same or similar crops. All dollar values were converted to 2022 dollars. The purpose of using the cost estimates was only to

determine the order in which crops would be fallowed; the estimates are not considered an accurate measure of the current cost and return estimates.

Forgone agricultural revenue from fallowed crops was estimated by multiplying the county-level revenue per acre by the number of acres reduced (or fallowed) for each crop. The county-level revenue was calculated based on the most recent available data on yields and prices. The number of acres reduced for each crop was modeled based on the order in which crops would be fallowed, the level of shortages and available water for each priority group by county and state, and the most recent available data on acres harvested (USDA NASS 2024; Reclamation 2016; Imperial County 2019, 2020, 2021, 2022, 2023; Riverside County 2020, 2021, 2022, 2023; San Bernardino County 2019, 2020, 2021, 2022, 2023). For data that were not available for specific crops grown in the county, estimated data were used based on statewide averages, data from nearby counties, or averages from nearby states or regions for the same or similar crops.

Reclamation acknowledges that it is difficult to project exactly how individual farmers, irrigation districts, or each Lower Division State may mitigate potential future agricultural impacts from shortages. For example, farmers may use groundwater and other surface water resources to mitigate impacts from allocated shortages; however, the amount of groundwater that the farmers would use to replace the surface water depends on many factors, such as the amount of groundwater available, local and state restrictions on groundwater pumping, and the cost of pumping. Therefore, similar to the assumption made in the 2007 Final EIS and the 2024 Final SEIS, the quantitative projected change in agricultural production did not include the use of groundwater as a replacement water source; however, the use of groundwater to replace the estimated water shortage is discussed qualitatively.

As in the 2007 Final EIS and the 2024 Final SEIS, impacts on economic conditions, such as jobs and income, from changes in agricultural production were analyzed using the IMPLAN input-output economic model. IMPLAN is a regional economic model that describes the flow of money, goods, and services from producers to intermediate and final consumers using a series of economic multipliers. The IMPLAN model provides annual average estimates of how a direct change in economic spending (such as through reduced agricultural revenues) would ripple through the broader economy and other industries. These ripple or multiplier effects include (1) indirect impacts resulting from changes in economic activity in industries that sell inputs to the industries that may be directly affected (for example, changes in supply purchases made by agricultural producers or farmers) and (2) induced impacts resulting from changes in household spending as households adjust their spending in response to changes in labor income supported by industries affected by management actions (for example, changes in purchases at local stores for personal groceries).

This analysis used IMPLAN Cloud and data from IMPLAN's 2023 data release (the most recent period of data available on the IMPLAN Cloud platform at the time of analysis; IMPLAN 2025). Prior to running the model, cost data were converted to a consistent dollar year (2025). Unless stated otherwise, monetary values are reported in the year 2025 dollars.

The modeled shortage volumes, based on the Shortage Allocation and Alternative Distribution Models, are presented in terms of consumptive use shortage relative to the consumptive use (or

modeled equivalent) entitlement, in order to allow for comparison across the alternatives and shortage distribution methods. This is a change to volumetric shortage modeling from the 2007 Final EIS and the 2024 Final SEIS, which modeled shortages relative to future demand schedule or recent history of use, respectively. However, the quantitative agricultural economic analysis in this Final Environmental Impact Statement (EIS) captures the impacts that occur from immediate reductions in available water; it does not capture impacts on future water consumption expansion and development opportunities for irrigation entitlement holders with current consumptive use that is less than their entitlement. Many uncertain factors impact future consumption, so impacts from shortages on water consumption expansion opportunities for irrigation entitlement holders with current consumptive use that is less than their entitlement will be discussed qualitatively.

Impact Analysis Area

Potential changes in economic contributions and social conditions from agricultural production within the analysis area due to estimated shortages were quantitatively assessed for the counties expected to experience impacts; these are Apache, Coconino, Gila, Graham, La Paz, Maricopa, Mohave, Navajo, Pima, Pinal, Yavapai, and Yuma Counties in Arizona; Imperial, Riverside, and San Bernardino Counties in California; and Clark County in Nevada.

Quantitative impacts were analyzed at the county level and presented at the state level, for comparison purposes.

Assumptions

For the purposes of this analysis, Reclamation included the assumptions listed below. Any future changes in these assumptions would change the impacts on economic contributions and social conditions associated with agriculture. The extent to which impacts on economic contributions and social conditions change due to changes in assumptions depends on many factors and future conditions that Reclamation cannot predict with sufficient certainty to quantify in this EIS; however, where possible and as stated below, a qualitative discussion on the impacts of changes in the assumptions is provided in the impacts analysis.

- All dollar values in the impacts analysis are reported in 2025 dollars, unless otherwise noted.
- Farmers would fallow irrigated crops in response to water shortages or an increased cost of irrigation. Farmers would fallow the land rather than switch from one crop to an alternative, more profitable or less water-intensive crop due to investments and institutional knowledge that have been made in plants, supply chains and relationships, and/or machinery that create barriers for changing crops. Reclamation understands there could be farmers who are able to switch crops rather than fallow; however, for the purpose of this analysis, this assumption provides a bound to the analysis, and any changes in this assumption would likely result in less impacts than discussed below.
- As discussed above, the analysis assumes the least profitable crop would be fallowed first, analyzed for each county separately, and crops were assumed to have constant profitability per acre of land and per acre-foot of water. Reclamation understands that often farmers will plant lower-valued crops on an annual or seasonal rotation to support or prepare the soil for higher-valued crops; additionally, Reclamation acknowledges that markets fluctuate and that reduced availability or production of crops could change the prices, which could change

crop profitability and farmers' decisions of which crop to plant or fallow. Reclamation cannot predict with sufficient certainty the crop rotation patterns that farmers may choose or how markets will react to changes in crop production. The analysis assumption that crops would be fallowed in order of profitability and that profitability is held constant provides an estimated benchmark to allow for a comparison of impacts across alternatives.

- Changes in irrigated crop acreages would result from changes in water deliveries from the Colorado River sources; they do not involve changes to allocations or to irrigation water from groundwater or other surface water sources. Due to the uncertainties associated with the quantity of Colorado River irrigation water that would switch to groundwater, as well as other market factors that affect groundwater availability and cost, it is not possible to quantify the impacts on social and economic conditions from switching to groundwater; however, the use of groundwater to replace the estimated water shortage is discussed qualitatively.
- Estimated shortages in the agricultural sector are based on the Shortage Allocation and Alternative Distribution Models (**Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation). Shortages to individual entitlement holders are measured in terms of consumptive use for a common basis of comparison with state apportionments and volumes of total shortage. Impacts on future opportunities to expand water use due to shortages for irrigation entitlement holders who currently use less than their entitlement are discussed qualitatively.
- The analysis does not assume that compensated conservation programs or other incentives for fallowing land are employed. This assumption provides a bound to the analysis; however, Reclamation acknowledges that conservation programs and adaptation measures could be implemented in the future and would lessen the impacts discussed below.
- In most cases, the contractor, subcontractor, or entitlement holder of an allocation is shown as the entity bearing shortage. In some cases, water allocated to an entitlement holder (for example, a tribal CAP contractor) may lease its allocation to other users (for example, to a non-Indian municipality). The Shortage Allocation and Alternative Distribution Models do not attempt to replicate those arrangements, and they only provide approximate estimates at the level of the entitlement holder, contractor, or subcontractor. The entitlement holder, contractor, or subcontractor to the leasing arrangements would have specific decisions to make during Shortage Conditions to administer those arrangements; Reclamation cannot predict these decisions with sufficient certainty to analyze in this EIS.
- If an entitlement holder leases water allocation to another type of user (for example, if an irrigation entitlement holder leases water to a tribal or non-tribal municipality or if a tribal or non-tribal CAP contractor leases to an agricultural water user), then a shortage in water deliveries would likely result in a financial impact on the entitlement holder. This would also result in an impact from a reduction in water availability on the end users; these impacts would be similar to those impacts discussed below for agricultural end users or as discussed in **TA 17**, Population and Land Use, for municipal and industrial end users.

Impact Indicators

- Change in acres of fallowed cropland
- Change in production value or revenue associated with fallowed cropland
- Change in jobs and income associated with agriculture
- Change in nonmarket values and social conditions associated with changes in agriculture

Recreation

The recreational economic impact analysis evaluates how operational changes under the alternatives may influence visitor spending and related economic activity in the Colorado River corridor (see **TA 14**, Recreation, for discussion of impacts on recreation). For an analysis of impacts of reservoir elevation on hydropower, including impacts on energy generation, refer to **TA 15**, Dams and Electrical Power Resources. For lake-based recreational economic contributions, the approach integrates estimates of baseline visitor use with spending profiles and applies a regional economic modeling framework, primarily IMPLAN, to estimate total economic contributions. Visitor use levels are derived from data reported by the NPS Public Use Statistics Office and Reclamation visitor counts, with visits categorized by activity type (for example, day use, overnight camping, and boating). Total visitor counts were divided by the average party-size data from the NPS to estimate the number of visiting parties for analysis; this is because the spending profile data are by party.

Visitors are further classified by type to reflect differences in recreational behavior and spending. Categories include local versus nonlocal visitors, day trips versus overnight stays, and distinctions among camping and lodging in nearby communities or other site-specific recreational activities. For each visit type, spending profiles are assigned based on available NPS and regional survey data. Profiles capture expenditures across categories such as lodging, food and beverages, transportation, recreational equipment and guide services, entrance and activity fees, and miscellaneous retail purchases.

Visitor spending estimates are then aggregated and input into the IMPLAN regional input-output model to estimate economic impacts. The model distinguishes among direct effects (visitor purchases in the local economy), indirect effects (business-to-business transactions, such as hotel purchases of supplies), and induced effects (household spending supported by recreation-related employment). Results are reported as total visitor spending, jobs supported, labor income, value added (contribution to gross regional product), and total sales. Impacts on direct, indirect, and induced economic contributions by alternative are discussed qualitatively.

A baseline assessment of economic contributions from river-based general recreation using the input-output analysis is included; it uses the same methodology as described above for lake-based recreation.

For the action alternatives, potential changes to recreation's contributions are discussed qualitatively, based on the Decision Making under Deep Uncertainty (DMDU) modeling output and conclusions related to Lake Powell and Lake Mead access to recreation and river-based recreation, as determined by river flow levels and fluctuations, as discussed in **TA 14**, Recreation.

In addition, for boating and angling, the socioeconomic analysis includes changes in the net economic value for a subset of activities, specifically angling in Glen Canyon and whitewater rafting in Grand Canyon. This approach follows the methods used in the Glen Canyon Dam Long-Term Experimental and Management Plan Final Supplemental Environmental Impact Statement (SEIS), where past survey research (Bishop et al. 1987; Neher et al. 2017) informed models to project the change in net economic value under different river flow scenarios. These models link willingness-to-pay estimates for anglers and boaters to hydrologic conditions, providing a measure of recreational benefits that extends beyond market spending (Bair 2026).

Reclamation used similar methods for the analysis of potential impacts on recreation as were used in the 2007 Final EIS and 2024 Final SEIS to assess the effects on recreational value associated with whitewater boating and angling. This analysis also incorporates additional DMDU concepts, specifically robustness heat maps and conditional box plots, developed to provide an indicator of an alternative's performance across many possible hydrologic futures. Refer to **Section TA 3.2.6** in **TA 3**, Hydrologic Resources, for an overview of interpreting the DMDU robustness heat maps and conditional box plots.

Impacts on river-based concessionaires are also assessed qualitatively using existing NPS and outfitters' data and informed by modeled flow thresholds from **TA 14**, Recreation.

For recreation at Imperial NWR and Bill Williams River NWR, baseline economic contribution data are drawn from U.S. Fish and Wildlife Service visitor spending reports, with impacts discussed qualitatively due to limited modeling inputs.

Impact Analysis Area

The analysis area is consistent with the general socioeconomic study area defined in **Chapter 3**. This includes major recreational hubs, gateway communities, and rural areas where economies rely heavily on river- and reservoir-based recreation. Specifically, the recreation impact analysis area encompasses three primary NPS units: Lake Mead NRA, Glen Canyon NRA, and GCNP.

Gateway counties associated with these areas include the following:

- Lake Mead NRA—Clark County and Lincoln County (Nevada); Mohave County (Arizona)
- Glen Canyon NRA (Lake Powell)—Coconino County (Arizona); Garfield, Kane, San Juan, and Wayne Counties (Utah)
- GCNP—Coconino, Mohave, Navajo, and Yavapai Counties (Arizona)

These counties represent the primary economic regions where visitor spending and recreation-related employment occur.

Assumptions

For the purposes of this analysis, Reclamation included the assumptions listed below. Any future changes in these assumptions would change the impacts on economic contributions associated with recreation. The extent to which impacts on economic contributions and social conditions change

due to changes in assumptions depends on many factors and future conditions that Reclamation cannot predict with sufficient certainty to analyze in this EIS.

- All dollar values in the impacts analysis are reported in 2025 dollars, unless otherwise noted.
- Lake-based recreational spending per visitor trip is based on the most recent NPS Visitor Spending Profiles.
- IMPLAN results represent regional effects, including direct, indirect, and induced economic activity associated with lake-based recreation.
- Recreational spending per trip for anglers and whitewater rafting (adjusted for inflation) would follow results from willingness-to-pay surveys (Gaston et al. 2015) with variation based on river flows.

Impact Indicators

- Changes in direct recreational visitor spending across the affected NPS units and recreation sites
- Changes in regional employment, labor income, value added, and total economic output from lake-based recreation-related activities
- Impacts on the recreational value associated with river-based boating and angling
- Effects on commercial outfitters, concessionaires, and permittees, especially in areas dependent on rafting, boating, and guided recreation

Ecosystem Services and Nonmarket Values

The discussion of ecosystem services and nonmarket values is provided in a qualitative format based on existing literature.

Impact Analysis Area

- The analysis area for social and nonmarket values is the Colorado River corridor from Lake Powell to the Southerly International Boundary, consistent with the overall socioeconomic study area.
- Consideration is focused on but not limited to geographic boundaries; this is because non-place-based communities also hold nonmarket values. Therefore, the area includes both local communities along the river and the broader public for whom the river holds symbolic, ecological, or recreational importance.

Assumptions

For the purposes of this analysis, Reclamation assumed the following:

- Nonmarket values are not directly quantifiable through market-based indicators; instead, they can be described qualitatively based on existing studies, stakeholder input, and related resource analyses.
- Changes in nonmarket values are assumed to be closely linked to conditions evaluated in the other technical appendixes, such as those for recreation, population and land use, cultural resources, and visual resources.

- Changing hydrology may influence how these values are perceived, particularly where access, scenic character, or ecological conditions are affected.

Impact Indicators

- Changes in the availability or quality of recreational opportunities not captured by direct spending
- Changes in the river's existence and symbolic values due to shifts in the scenic character or ecological conditions

TA 16.2.2 Issue 1: How would the anticipated water shortages affect the economic contributions and social conditions from agriculture?

Under all alternatives and the Continued Current Strategies (CCS) Comparative Baseline, anticipated shortages would result in increases in acres of fallowed cropland and agricultural production losses, and the modeled agricultural production loss would result in impacts on the associated jobs, income, and total economic output. However, there are regional differences as well as differences in magnitude of impacts across the alternatives and the CCS Comparative Baseline, as discussed below.

As shown in figures below (**Figure TA 16-1** through **Figure TA 16-10**), there are two sets of model results for the Representative Preferred Alternative: those for the first 2 years (2027-2028) and those for beyond the first 2 years (2029-2060). As described in **Chapter 2**, under the Representative Preferred Alternative in the first 2 years (2027 – 2028), the shortages are distributed via LB priority up to 1.5 million acre-feet (maf) and shortage volumes above 1.5 maf up to 3.6 maf are distributed using the priority system, and under the Representative Preferred (2029-2060) Alternative, all volumes of shortages are distributed via the priority system. Refer to **Appendix C**, Table C-27 and Table C-26 for shortage impacts for each irrigation and tribal entitlement holder, respectively, under the LB Priority distribution (up to 1.5 maf shortage). The 2027 and 2028 operating guidelines modeling is compared to the Representative Preferred Alternative in **Appendix T,** Preliminary Description and Analysis of Anticipated Operating Guidelines for 2027 and 2028. Expected impacts from beyond 2028 under the Preferred Alternative may be different from what is shown in the figures below for the Representative Preferred (2029-2060) Alternative, as this alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**.

Figure TA 16-1 presents the estimated number of agriculture acres fallowed for each alternative and the CCS Comparative Baseline, across a range of shortage volumes—0.6 maf to 4.0 maf—for non-tribal and tribal irrigation entitlement holders in Arizona, California, and Nevada (see **Figure TA 16-2** and the discussion below for impacts broken out by priority group, and shortages by individual entitlement holder are shown in **Appendix C**). The shading highlights the magnitude of fallowed croplands across the alternatives and the CCS Comparative Baseline and shortage levels for each state and entitlement holder group, with the darker shaded numbers representing larger magnitudes of fallowed croplands. Across the alternatives and the CCS Comparative Baseline, the greatest impacts on fallowed lands occur in Arizona on non-tribal and tribal agriculture entitlement holders as well as California non-tribal agriculture entitlement holders. On average, for non-tribal agriculture entitlement holders in Arizona and California with shortages less than or equal to 3.0 maf, the greatest impacts on fallowed lands occurs under the Enhanced Coordination or Supply Driven

(Lower Basin [LB] Pro Rata approach) Alternatives, compared with the CCS Comparative Baseline and the other alternatives, including the Representative Preferred Alternative. During shortages greater than 3.0 maf, for non-tribal agriculture entitlement holders in Arizona, the greatest impacts on fallowed lands occur under the Representative Preferred (2029-2060) and Maximum Operational Flexibility Alternatives, due to the larger maximum shortages allowed under these alternative. However, for non-tribal agriculture entitlement holders in California, the greatest impacts on fallowed lands, during shortages greater than 3.0 maf, occur under the Enhanced Coordination Alternative, due to the pro rata-based shortage distribution method. When comparing impacts due to maximum levels of shortages across all alternatives and the CCS Comparative Baseline, for Arizona non-tribal entitlement holders, the Maximum Operational Flexibility Alternative would result in the greatest level of impacts on fallowed lands (with an increase of about 103,000 acres of fallowed lands) during a maximum shortage of 4.0 maf, and for California non-tribal entitlement holders, the Enhanced Coordination Alternative would result in the highest level of impacts on fallowed lands (with an increase of about 283,000 acres of fallowed lands) during a maximum shortage of 3.0 maf. When the shortage is 0.6 maf, the smallest impacts on fallowed lands occurs under the Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred (2027-2028) Alternatives for Arizona non-tribal entitlement holders, and there would be no impacts on fallowed lands for California non-tribal entitlement holders under the CCS Comparative Baseline and the No Action, Representative Preferred, Basic Coordination, Maximum Operational Flexibility, and Supply Driven (LB Priority approach) Alternatives. During maximum levels of shortage, the lowest impacts on fallowed lands would occur under the CCS Comparative Baseline and the No Action and Basic Coordination Alternatives, with an increase in total fallowed land across Arizona and California non-tribal entitlement holders of about 6,000 acres (with a shortage of 1.0 maf) under the CCS Comparative Baseline, 1,000 acres (with a shortage of 0.6 maf) under the No Action Alternative, and 7,000 acres (with a shortage of 1.5 maf) under the Basic Coordination Alternative.

On average, across all Arizona tribal entitlement holders combined, when the shortage is 0.6 maf, the largest impacts on fallowed lands occurs under the Supply Driven Alternative (LB Pro Rata approach) and the smallest impacts on fallowed lands occurs under the Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred (2027-2028) Alternatives. For shortages greater than 0.6 maf but not more than 1.5 maf, impacts on fallowed lands would be largest under the Basic Coordination and Representative Preferred (2029-2060) Alternatives and smallest under the No Action Alternative, because the maximum shortage for this alternative is 0.6 maf. For shortages greater than 1.5 maf, impacts on fallowed lands would be greatest under the Representative Preferred (2029-2060) and Maximum Operational Flexibility Alternatives, with annual impacts as large as an increase in fallowed lands of about 67,000 acres (occurring during a shortage of 3.6 maf under the Representative Preferred (2029-2060) Alternative) and 68,000 acres (occurring during a shortage of 4.0 maf under the Maximum Operational Flexibility Alternative). The maximum level of impacts on fallowed lands due to shortages for Arizona tribal entitlement holders were the lowest under the No Action Alternative (with about 12,000 acres fallowed under a shortage of 0.6 maf; see **Figure TA 16-1**). However, as discussed below, these impacts vary across priority groups.

Figure TA 16-1
Annual Acres of Fallowed Cropland in the Analysis Area by Alternative and Shortage Level, in Thousand Acre-feet (kaf)

State, Water Entitlement Holders	Shortage Level (kaf)	600	1,000	1,500	1,800	2,000	2,100	2,300	3,000	3,600	4,000

Source: IMPLAN 2025

Note: The highlighting shows the values from the smallest (in white or no highlighting) to the largest (in yellow highlighting). The cells with hash-marks represent the values above shortages; these values are outside of the scope of this analysis. See **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation for more information on the shortage values for each entitlement holder type above shortages.

[1] Due to its fixed shortage volumes for CCS Comparative Baseline, shortages for 600K and 1,000K are actually associated with 613K and 1,013K in CCS Comparative Baseline. Greater shortages are based on an extension of priority beyond the levels of shortage provided by the pertinent documents.

[2] The maximum shortage for the Basic Coordination Alternative is 1.48 maf; however, the table above shows the maximum shortage as 1.5 maf for ease of comparison across the alternatives.

[3] The distribution of shortages up to 1.5 maf in 2027-2028 in the Representative Preferred Alternative reflects the May 1 proposal by the Lower Division States. Although not specified in their proposal, the Representative Preferred assumes shortages and their distribution above 1.5 maf in 2028 as necessary to avoid critically low elevations in Lake Mead. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative and their representation in the Representative Preferred Alternative).

[4] Expected impacts from 2029 – 2060 under the Preferred Alternative may be different from what is shown for the Representative Preferred (2029-2060) Alternative, as this alternative provides a framework that allows for shortage distributions to be negotiated in different ways, consistent with sideboards described in **Chapter 2**.

Source: IMPLAN 2025

Note: The highlighting shows the values from the smallest (in white or no highlighting) to the largest (in yellow highlighting). The cells with hash-marks represent the values above shortages; these values are outside of the scope of this analysis. See **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation for more information on the shortage values for each entitlement holder type above shortages.

[1] Due to its fixed shortage volumes for CCS Comparative Baseline, shortages for 600K and 1,000K are actually associated with 613K and 1,013K in CCS Comparative Baseline. Greater shortages are based on an extension of priority beyond the levels of shortage provided by the pertinent documents.

[2] The maximum shortage for the Basic Coordination Alternative is 1.48 maf; however, the table above shows the maximum shortage as 1.5 maf for ease of comparison across the alternatives.

[3] The distribution of shortages up to 1.5 maf in 2027-2028 in the Representative Preferred Alternative reflects the May 1 proposal by the Lower Division States. Although not specified in their proposal, the Representative Preferred assumes shortages and their distribution above 1.5 maf in 2028 as necessary to avoid critically low elevations in Lake Mead. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative and their representation in the Representative Preferred Alternative).

[4] Expected impacts from 2029 – 2060 under the Preferred Alternative may be different from what is shown for the Representative Preferred (2029-2060) Alternative, as this alternative provides a framework that allows for shortage distributions to be negotiated in different ways, consistent with sideboards described in **Chapter 2**.

For California and Nevada tribal entitlement holders, impacts on fallowed lands would only occur under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives. The largest impacts would occur under the Enhanced Coordination Alternative, during a shortage of 3.0 maf, with an increase in fallowed lands of about 6,000 acres (about 5,000 acres and 700 acres of fallowed lands in California and Nevada, respectively). There are no expected impacts on fallowed lands under all other alternatives and the CCS Comparative Baseline for California and Nevada tribal entitlement holders, including under the Representative Preferred Alternative (see **Figure TA 16-1**).

Overall, across all entitlement groups and states, during maximum levels of shortage, there would be large impacts on the agriculture sector, including large reductions in harvested acres and crop production, under the Maximum Operational Flexibility, the Representative Preferred (2029-2060), the Enhanced Coordination, and the Supply Driven (LB Pro Rata approach) Alternatives. Under the Maximum Operational Flexibility Alternative, during a shortage of 4.0 maf, about half of all harvested acres in Yuma County, Arizona would be fallowed (including almost all harvested acres of alfalfa, cotton, other hay and haylage, and small grains) as well as over 40 percent of all harvested acres in Pima County, Arizona and over 60 percent of all harvested acres in Riverside County, California would be fallowed. During a shortage of 3.6 maf under the Representative Preferred (2029-2060) Alternative, over 40 percent of all harvested acres in Yuma County, Arizona would be fallowed (including almost all harvested acres of alfalfa, cotton, and small grains) as well as over 40 percent of all harvested acres in Pima County, Arizona and over 60 percent of all harvested acres in Riverside County, California would be fallowed. During a shortage of 3.0 maf under the Enhanced Coordination Alternative, almost half of the harvested acres in Imperial County, California would be fallowed (including all harvested acres of alfalfa, crucifers, and field grains in the county), about half of all harvested acres in Clark County, Nevada would be fallowed (including about 80 percent of harvested acres of alfalfa), all harvested acres of alfalfa and cotton in Yuma County, Arizona would be fallowed, about 90 percent of field grain and small grain crops in La Paz, Arizona would be fallowed, and over 80 percent of alfalfa would be fallowed in Riverside, California. During a shortage of 2.1 maf under the Supply Driven Alternative (LB Pro Rata approach), about one third of the harvested acres would be fallowed in Clark County in Nevada and Mohave and Yuma Counties in Arizona (including all harvested acres of alfalfa and cotton in Yuma County) as well as all harvested acres of crucifers and field grains in Imperial County, California and about 90 percent of field grain and small grain crops in La Paz, Arizona would be fallowed.

Within each state and tribal and non-tribal agricultural entitlement group, impacts on fallowed cropland from change in water shortages across the alternatives and the CCS Comparative Baseline vary across priority groups. **Figure TA 16-2** reports the estimated number of agricultural acres fallowed for each priority group across alternatives and the CCS Comparative Baseline at a range of shortage volumes (Priorities 2 and 3 for California non-tribal agricultural entitlement holders were grouped together, as were the CAP Indian and 4(i) priorities for Arizona tribal agricultural entitlement holders, due to the similarities in the distribution of shortages). See **Appendix C** for shortages by individual entitlement holder.

Impacts on fallowed cropland from changes in water availability for the present perfected right (PPR) priority entitlement holders (both tribal and non-tribal agricultural entitlement holders) in Arizona, California, and Nevada followed the same trends across alternatives and the CCS

Comparative Baseline as discussed for California and Nevada tribal entitlement holders, above. The greatest impacts would occur under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, and there are no expected impacts on fallowed lands under all other alternatives and the CCS Comparative Baseline (see **Figure TA 16-2**).

For Arizona priority 3 tribal and non-tribal agricultural entitlement holders, during shortages less than or equal to 2.0 maf, the greatest impacts on fallowed lands would occur under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives and there are no expected impacts on fallowed lands under all other alternatives and the CCS Comparative Baseline. For shortages greater than 2.0 maf, in addition to the impacts that would occur under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, there would also be impacts on fallowed cropland under the Representative Preferred (2029-2060) alternative, and for shortages greater than or equal to 3.0 maf, there would be impacts on fallowed lands under the Maximum Operational Flexibility Alternative and potential impacts on fallowed lands under the Representative Preferred (2027-2028) Alternative. During a maximum level of shortage, across all alternatives and the CCS Comparative Baseline, the Maximum Operational Flexibility Alternative would result in the greatest level of impacts on fallowed lands, with an increase of about 6,000 acres and 93,000 acres of fallowed lands for Arizona priority 3 tribal and non-tribal agricultural entitlement holders, respectively, during a maximum shortage of 4.0 maf.

For Arizona priority 4(i) non-tribal and Arizona CAP Indian and 4(i) priority tribal agricultural entitlement holders, during shortages of 0.6 maf, the greatest impact on fallowed lands occurs under the CCS Comparative Baseline and the No Action, Basic Coordination, and Representative Preferred (2029-2060) Alternatives; during shortages greater than 0.6 and less than or equal to 2.0 maf, the greatest impact occurs under the Basic Coordination and Representative Preferred (2029-2060) Alternatives; during shortages greater than 2.0 maf, the greatest impact on fallowed lands occurs under the Maximum Operational Flexibility and Representative Preferred (2029-2060) Alternatives, with the greatest increase in fallowed lands of about 10,000 acres and 62,000 acres for Arizona priority 4(i) non-tribal and Arizona CAP Indian and 4(i) priority tribal agricultural entitlement holders, respectively, during a shortage of 4.0 maf under the Maximum Operational Flexibility Alternative or during a shortage of 3.6 maf under the Representative Preferred (2029-2060) Alternative. During the maximum levels of shortage, the smallest impact on fallowed croplands would occur under the No Action Alternative for Arizona priority 4(i) non-tribal and Arizona CAP Indian and 4(i) priority tribal agricultural entitlement holders (with an increase in fallowed land of about 1,000 acres and 12,000 acres, with a shortage of 0.6 maf, for Arizona priority 4(i) non-tribal and Arizona CAP Indian and 4(i) priority tribal agricultural entitlement holders, respectively).

For California priorities 2 and 3 non-tribal agricultural entitlement holders, the greatest impact on fallowed lands, during shortages under 3.0 maf, occurs under the Enhanced Coordination Alternative, and the greatest impact, during shortages greater than or equal to 3.0 maf, occurs under the Maximum Operational Flexibility and Representative Preferred Alternatives, with the largest increase in fallowed land under the Maximum Operational Flexibility Alternative of about 227,000 acres, with a shortage of 4.0 maf. The No Action and Basic Coordination Alternatives would result in the lowest impacts on fallowed lands due to maximum levels of shortage, with no expected

increase in fallowed land across California priorities 2 and 3 non-tribal agricultural entitlement holders (see **Figure TA 16-2**).

For more information on impacts on changing land use and water deliveries due to potential long-term water shortages to irrigation entitlement holders, see **TA 4**, Water Deliveries, and **TA 17**, Population and Land Use.

Figure TA 16-3 shows the estimated loss in market value of crops due to water shortages and fallowed lands for each alternative and the CCS Comparative Baseline across a range of shortage volumes (0.6 maf to 4.0 maf) for Arizona, California, and Nevada non-tribal and tribal irrigation entitlement holders, and **Figure TA 16-4** presents the estimated loss in market value of crops separated by priority group in each state in the analysis area (see **Appendix C** for shortages by individual entitlement holder). The patterns in loss of market values across regions, non-tribal and tribal entitlement holders, and shortage levels are similar to those discussed for fallowed acres, except for California non-tribal agricultural entitlement holders, as discussed below. On average, for Arizona non-tribal and tribal entitlement holders, the Maximum Operational Flexibility Alternative would result in the largest level of impacts on market value of crops during a maximum level of shortage compared with the other alternatives and CCS Comparative Baseline, with a reduction in market value of crops of about $150.8 million and $113.2 million, during a shortage of 4.0 maf, for Arizona non-tribal and Arizona tribal entitlement holders, respectively. Under the Representative Preferred (2029-2060) Alternative, Arizona non-tribal and tribal entitlement holders could see a reduction in market value of crops of about $133.1 million and $111.9 million, respectively, during a maximum level of shortage of 3.6 maf. The smallest level of impacts on market value of crops during a maximum level of shortage would occur under the No Action Alternative for Arizona non-tribal and tribal entitlement holders, on average, with a reduction in market value of crops of about $1.8 million and $17.4 million, during a shortage of 0.6 maf, for Arizona non-tribal and Arizona tribal entitlement holders, respectively. However, this varies for certain priority groups within Arizona non-tribal and tribal entitlement holders. For Arizona priority 4(i) non-tribal entitlement holders and Arizona CAP Indian and 4(i) priority tribal agricultural entitlement holders, the trends in impacts on market value of crops during a maximum level of shortage across alternatives would be the same as discussed above for all Arizona non-tribal and tribal entitlement holders, with the largest level of impacts on market value of crops occurring under the Maximum Operational Flexibility and Representative Preferred Alternatives (with a maximum level of reduction in market value of crops of about $32.3 million and $103.5 million, for Arizona priority 4(i) non-tribal entitlement holders and Arizona CAP Indian and 4(i) priority tribal entitlement holders, respectively) and the smallest level of impacts on market value of crops during a maximum level of shortage occurring under the No Action Alternative (with a reduction in market value of crops of about $1.8 million and $17.4 million, for Arizona priority 4(i) non-tribal entitlement holders and Arizona CAP Indian and 4(i) priority tribal entitlement holders, respectively). For Arizona priority 3 tribal and non-tribal agricultural entitlement holders, the largest level of impacts on market value of crops would occur under the Maximum Operational Flexibility Alternative (with a reduction in market value of crops of about $118.4 million and $9.7 million for Arizona priority 3 tribal and non-tribal agricultural entitlement holders, respectively) and there are no expected impacts on market value of crops under the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (LB Priority approach) Alternatives. For Arizona PPR priority tribal and non-tribal agricultural

entitlement holders, the only impacts on market value of crops would occur under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives.

For California non-tribal entitlement holders, although the Enhanced Coordination Alternative had the highest level of impact on fallowed lands during the maximum level of shortage, the Maximum Operational Flexibility Alternative would result in the largest level of impacts on market value of crops during a maximum level of shortage (with a reduction in market value of crops of about $1,094.3 million) due to a greater number of acres of higher-valued crops being fallowed (especially for the entitlement holders within priorities 2 and 3). Under the Representative Preferred (2029-2060) Alternative, California non-tribal entitlement holders could see a reduction in market value of crops of about $812.7 million, during a maximum level of shortage of 3.6 maf. There are not expected to be impacts on market value of crops under the No Action and Basic Coordination Alternatives for California non-tribal entitlement holders. As discussed above for Arizona, these impacts on market value of crops for California non-tribal agriculture entitlement holders vary across priority groups. For California priority group 2 and 3 non-tribal agricultural entitlement holders, the largest level of impacts on market value of crops would occur under the Maximum Operational Flexibility Alternative (with a reduction in market value of crops of about $1,094.3 million), whereas for California PPR priority non-tribal agricultural entitlement holders, the largest level of impacts on market value of crops would occur under the Enhanced Coordination Alternative (with a reduction in market value of crops of about $546.8 million).

As discussed above for impacts on fallowed lands, for the tribal agricultural entitlement holders in California and Nevada (all of whom have PPR priority), impacts on the market value of crops would only occur under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, with the largest level of impacts on market value of crops during a maximum level of shortage occurring under the Enhanced Coordination Alternative.

Note: The highlighting shows the values from the smallest (in white or no highlighting) to the largest (in yellow highlighting). The cells with hash-marks represent the values above shortages; these values are outside of the scope of this analysis. See **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation for more information on the shortage values for each entitlement holder type above shortages.

[1] Due to its fixed shortage volumes for CCS Comparative Baseline, shortages for 600K and 1,000K are actually associated with 613K and 1,013K in CCS Comparative Baseline. Greater shortages are based on an extension of priority beyond the levels of shortage provided by the pertinent documents.

[2] The maximum shortage for the Basic Coordination Alternative is 1.48 maf; however, the table above shows the maximum shortage as 1.5 maf for ease of comparison across the alternatives.

[3] The distribution of shortages up to 1.5 maf in 2027-2028 in the Representative Preferred Alternative reflects the May 1 proposal by the Lower Division States. Although not specified in their proposal, the Representative Preferred assumes shortages and their distribution above 1.5 maf in 2028 as necessary to avoid critically low elevations in Lake Mead. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative and their representation in the Representative Preferred Alternative).

[4] Expected impacts from 2029 – 2060 under the Preferred Alternative may be different from what is shown for the Representative Preferred (2029-2060) Alternative, as this alternative provides a framework that allows for shortage distributions to be negotiated in different ways, consistent with sideboards described in **Chapter 2**.

As agricultural entitlement holders fallow lands due to water shortages, the loss in market value of crops would likely lead to reductions in economic contributions in the region across agricultural-related sectors as well as sectors that supply goods and services to the farmers and their households. The impacts on economic contributions, such as jobs, labor income and total economic output, across the alternatives and the CCS Comparative Baseline would follow similar patterns as those described for impacts on fallowed lands and market values of crops.[9] **Figure TA 16-5**, **Figure TA 16-7**, and **Figure TA 16-9** show the results of the impact analysis on total jobs, labor income, and economic output, respectively, including direct, indirect, and induced impacts, by state and type of entitlement holder, and **Figure TA 16-6**, **Figure TA 16-8**, and **Figure TA 16-10** present the impacts on total jobs, labor income, and economic output, respectively, separated by priority group (see **Appendix C** for shortages by individual entitlement holder). On average, for non-tribal and tribal entitlement holders in Arizona, the greatest impacts on jobs, labor income, and total economic output due to a maximum level of shortage occurs under the Maximum Operational Flexibility Alternative, during a shortage of 4.0 maf, with annual reductions of about 1,000 jobs, $56.5 million in labor income, and $237.7 million in economic output for non-tribal agricultural entitlement holders in Arizona, and annual reductions of about 1,000 jobs, $64.7 million in labor income, and $222.6 million in economic output for tribal entitlement holders in Arizona. Under the Representative Preferred (2029-2060) Alternative, Arizona non-tribal entitlement holders could see a reduction of about 900 jobs, $50.5 million in labor income, and $210.7 million in economic output and Arizona tribal entitlement holders could see a reduction of about 1,000 jobs, $64.0 million in labor income, and $220.0 million in economic output, during a maximum level of shortage of 3.6 maf. The lowest impacts on jobs, labor income, and economic output for non-tribal and tribal entitlement holders in Arizona, during a maximum level of shortage, occurs under the No Action Alternative, during a shortage of 0.6 maf, with annual reductions of about 10 jobs, $0.6 million in labor income, and $2.8 million in economic output for non-tribal agricultural entitlement holders in Arizona, and annual reductions of about 140 jobs, $10.7 million in labor income, and $34.8 million in economic output for tribal entitlement holders in Arizona. However, as discussed under impacts on market values of crops, the impacts on jobs, labor income, and economic output vary across priority groups within Arizona non-tribal and tribal entitlement holders. For Arizona priority 4(i) non-tribal entitlement holders and Arizona CAP Indian and 4(i) priority tribal agricultural entitlement holders, the trends in impacts on jobs, labor income, and economic output during a maximum level of shortage across alternatives would be the same as discussed above for all Arizona non-tribal and tribal entitlement holders, with the largest level of impacts on jobs, labor income, and economic output occurring under the Maximum Operational Flexibility and Representative Preferred Alternatives and the smallest level of impacts on jobs, income, and output during a maximum level of shortage occurring under the No Action Alternative. For Arizona priority 3 tribal and non-tribal agricultural entitlement holders, the largest level of impacts on jobs, labor income, and economic output would occur under the Maximum Operational Flexibility Alternative and there are no expected impacts on jobs, income, and output under the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (LB Priority approach) Alternative. For Arizona

[9] Some third-party studies have been conducted on the impacts on economic conditions from changes in agriculture under specific scenarios and assumptions. For example, Imperial County Workforce and Economic Development conducted an analysis that highlights the potential ranges of impacts on Imperial County's economy from changes in irrigation water. Because this study is scenario-specific and not directly comparable to the Draft EIS modeling framework, the FEIS does not adopt quantified estimates from this study.

PPR priority tribal and non-tribal agricultural entitlement holders, the only impacts on jobs, labor income, and economic output would occur under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives.

For non-tribal entitlement holders in California, the greatest impacts on jobs, labor income, and total economic output due to a maximum level of shortage occurs under the Maximum Operational Flexibility Alternative, during a shortage of 4.0 maf, with annual reductions of about 11,000 jobs, $824.7 million in labor income, and $1,755.2 million in economic output. Under the Representative Preferred (2029-2060) Alternative, California non-tribal entitlement holders could see a reduction of about 9,000 jobs, $718.1 million in labor income, and $1,343.9 million in economic output, during a maximum level of shortage of 3.6 maf. There are not expected to be impacts on jobs, labor income, and total economic output under the No Action and Basic Coordination Alternatives for California non-tribal entitlement holders. As discussed above for Arizona, these impacts on jobs, labor income, and economic output for California non-tribal agriculture entitlement holders vary across priority group. For California priority group 2 and 3 non-tribal agricultural entitlement holders, the largest level of impacts on jobs, labor income, and economic output would occur under the Maximum Operational Flexibility Alternative, whereas for California PPR priority non-tribal agricultural entitlement holders, the largest level of impacts on jobs, labor income, and economic output would occur under the Enhanced Coordination Alternative.

For California and Nevada tribal entitlement holders (all of whom have PPR priority), impacts on economic contributions such as jobs, labor income, and economic output, would be greatest under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, with impacts as large as a reduction of over 60 jobs, about $3.9 million in labor income, and $15.9 million in total economic output for tribal entitlement holders in California, under the Enhanced Coordination Alternative, with a shortage of 3.0 maf; for Nevada tribal entitlement holders, under the same alternative and shortage level, there would be an estimated reduction of over 10 jobs, about $0.1 million in labor income, and $0.9 million in total economic output. There are no expected impacts on economic contributions under all other alternatives, including the CCS Comparative Baseline and Representative Preferred Alternative.

Source: IMPLAN 2025

Note: The highlighting shows the values from the smallest (in white or no highlighting) to the largest (in yellow highlighting). The cells with hash-marks represent the values above shortages; these values are outside of the scope of this analysis. See **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation for more information on the shortage values for each entitlement holder type above shortages.

[1] Due to its fixed shortage volumes for CCS Comparative Baseline, shortages for 600K and 1,000K are actually associated with 613K and 1,013K in CCS Comparative Baseline. Greater shortages are based on an extension of priority beyond the levels of shortage provided by the pertinent documents.

[2] The maximum shortage for the Basic Coordination Alternative is 1.48 maf; however, the table above shows the maximum shortage as 1.5 maf for ease of comparison across the alternatives.

[3] The distribution of shortages up to 1.5 maf in 2027-2028 in the Representative Preferred Alternative reflects the May 1 proposal by the Lower Division States. Although not specified in their proposal, the Representative Preferred assumes shortages and their distribution above 1.5 maf in 2028 as necessary to avoid critically low elevations in Lake Mead. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative and their representation in the Representative Preferred Alternative).

[4] Expected impacts from 2029 – 2060 under the Preferred Alternative may be different from what is shown for the Representative Preferred (2029-2060) Alternative, as this alternative provides a framework that allows for shortage distributions to be negotiated in different ways, consistent with sideboards described in **Chapter 2**.

Source: IMPLAN 2025

Note: The highlighting shows the values from the smallest (in white or no highlighting) to the largest (in yellow highlighting). The cells with hash-marks represent the values above shortages; these values are outside of the scope of this analysis. See **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation for more information on the shortage values for each entitlement holder type above shortages.

[1] Due to its fixed shortage volumes for CCS Comparative Baseline, shortages for 600K and 1,000K are actually associated with 613K and 1,013K in CCS Comparative Baseline. Greater shortages are based on an extension of priority beyond the levels of shortage provided by the pertinent documents.

[2] The maximum shortage for the Basic Coordination Alternative is 1.48 maf; however, the table above shows the maximum shortage as 1.5 maf for ease of comparison across the alternatives.

[3] The distribution of shortages up to 1.5 maf in 2027-2028 in the Representative Preferred Alternative reflects the May 1 proposal by the Lower Division States. Although not specified in their proposal, the Representative Preferred assumes shortages and their distribution above 1.5 maf in 2028 as necessary to avoid critically low elevations in Lake Mead. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative and their representation in the Representative Preferred Alternative).

[4] Expected impacts from 2029 – 2060 under the Preferred Alternative may be different from what is shown for the Representative Preferred (2029-2060) Alternative, as this alternative provides a framework that allows for shortage distributions to be negotiated in different ways, consistent with sideboards described in **Chapter 2**.

Source: IMPLAN 2025

Note: The highlighting shows the values from the smallest (in white or no highlighting) to the largest (in yellow highlighting). The cells with hash-marks represent the values above shortages; these values are outside of the scope of this analysis. See **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation for more information on the shortage values for each entitlement holder type above shortages.

[1] Due to its fixed shortage volumes for CCS Comparative Baseline, shortages for 600K and 1,000K are actually associated with 613K and 1,013K in CCS Comparative Baseline. Greater shortages are based on an extension of priority beyond the levels of shortage provided by the pertinent documents.

[2] The maximum shortage for the Basic Coordination Alternative is 1.48 maf; however, the table above shows the maximum shortage as 1.5 maf for ease of comparison across the alternatives.

[3] The distribution of shortages up to 1.5 maf in 2027-2028 in the Representative Preferred Alternative reflects the May 1 proposal by the Lower Division States. Although not specified in their proposal, the Representative Preferred assumes shortages and their distribution above 1.5 maf in 2028 as necessary to avoid critically low elevations in Lake Mead. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative and their representation in the Representative Preferred Alternative).

[4] Expected impacts from 2029 – 2060 under the Preferred Alternative may be different from what is shown for the Representative Preferred (2029-2060) Alternative, as this alternative provides a framework that allows for shortage distributions to be negotiated in different ways, consistent with sideboards described in **Chapter 2**.

In addition to the impacts on jobs, labor income, and economic output presented above, reductions in irrigation water would also lead to impacts on economic conditions through increased costs incurred when fallowing lands, increased strain on farmers' ability to pay fixed costs, and reduced national supply of agricultural crops produced in the analysis area. An increase in fallowing lands would lead to an increase in costs associated with maintaining the fallowed lands, such as costs for controlling and mitigating weeds, pests, and wind erosion. After fallowing lands, there would be additional costs to prepare and return the land to farming crops, such as costs to repair and reestablish irrigation ditches and infrastructure, especially after multiple years of continued fallowing. Farmers could also face financial strains from the reduced revenue associated with increased fallowing lands, if the revenue farmers receive for crop production no longer covers the fixed costs needed to continue and maintain operations. Additionally, increases in fallowed lands could impact the national supply of crops that are largely produced in the analysis area. For example, Arizona is the largest supplier of leafy greens in the U.S. during winter months, and in 2024, Arizona produced over 20 percent of the U.S. lettuce supply throughout the year (Arizona Farm Bureau 2026, USDA NASS 2025, Duval et al. 2024). An increase in fallowed lands due to a reduction in water for irrigation would lead to a reduction in supply of these crops throughout the U.S., which could lead to reduced availability and a potential increase in prices that consumers face for the produce. The magnitude of these impacts depends on several economic and market factors that are outside of the scope of this EIS. The alternatives with the greatest and smallest impacts on the economic conditions discussed above are the same as those discussed for impacts on fallowed lands.

The analysis on economic contributions provides estimated impacts per year of shortage. If shortages continue over multiple years, there will continue to be impacts on economic conditions, including reductions in jobs, labor income, and economic output. Depending on the magnitude of the water delivery shortages each year and the number of years of shortage, impacts on economic contributions could lead to farms ceasing operations permanently, especially for small farmers with limited resources for withstanding multiple years of fallowed lands. If farms cease operating, there could be large, cascading impacts throughout the local and regional economies, especially in regions that heavily rely on agriculture to support livelihoods and well-being throughout the communities. For more information on long-term impacts on changing land use and water deliveries due to water shortages to irrigation entitlement holders, see **TA 4**, Water Deliveries, and **TA 17**, Population and Land Use.

Long-term and deep Colorado River water shortages could result in further impacts on the economic contributions to entitlement holders that have unused water entitlement above their current consumptive use. As discussed in the *Methodology* section above, as well as in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation, the analysis of impacts on economic conditions due to changes in agriculture in this EIS is based on modeled shortage volumes to irrigation entitlement holders in terms of consumptive use shortage relative to the consumptive use (or modeled equivalent) entitlement, in order to allow for comparison across the alternatives and shortage distribution methods. On average, from 2019 to 2023, consumptive use was estimated at 87 percent and 85 percent of the consumptive use (or equivalent) entitlements of non-tribal irrigation entitlement holders in Arizona and California, respectively. Consumptive use as a percentage of the consumptive use (or equivalent) entitlements was considerably less for tribal irrigation entitlement holders across the analysis area, with consumptive use making up

approximately 66 percent of the consumptive use (or equivalent) entitlements for tribal irrigation entitlement holders, on average, across Arizona, California, and Nevada (Reclamation 2019, 2020, 2021, 2022, 2023). Irrigation entitlement holders who currently use less than their entitlement (measured in terms of diversion, consumptive use, or both) might not immediately experience impacts on economic contributions from water shortages; however, long-term, continued shortages would limit future opportunities to expand the irrigation entitlement holders' water use, which would result in impacts on economic contributions through reduced opportunities for future development, expansion of crop production, or additional opportunities to lease water.

The analysis of impacts on economic conditions discussed above examines the impacts of shortages on agriculture entitlement holders. If there is not enough water in Lake Mead to fully meet downstream demands and/or if Hoover Dam infrastructure constraints result in releases below the demand volume, other measures would be taken in the Lower Basin, such as water conservation or dead pool–related reductions. During some instances of dead pool–related reductions, these unplanned reductions occur because Lake Mead is approaching dead pool (elevation 895 feet) and in some cases it occurs earlier (up to elevation 950 feet). If there are dead pool–related reductions, the impacts on acreages fallowed would likely extend to more high-valued crops as well as result in entire crops or all croplands in certain counties being fallowed. Increases in fallowed lands of these high-valued types of crops would likely lead to greater and longer-term effects on the production value as well as the jobs, labor income and economic output associated with the loss of crop production. The magnitude of these impacts depends on many factors, including the water distribution methods and conservation measures that are implemented; the approach to distributing reductions associated with dead pool is not addressed in this analysis. See the subsection *Shortage vs. Dead Pool–Related Reductions: Comparison for Full Lower Basin,* under **TA 4**, Water Deliveries, for a discussion on the relationship between shortages and dead pool–related reductions for water deliveries across all entitlement holders.

In addition to impacts on economic conditions, increases in water shortages would likely lead to changes in quality and access to nonmarket values and social conditions associated with changes in agriculture. As more land is fallowed due to shortages in water delivered from the Colorado River, the livelihoods, the way of life, and the health of individuals throughout the surrounding communities could change, which can impact how the individuals perceive their sense of place and interact with the local communities, land, and individuals around them. Many communities, especially tribes in the surrounding regions, value the use of Colorado River water for irrigation for the food that it supports as well as for access to cultural, traditional, and spiritual purposes, and impacts on agriculture can greatly reduce access to and quality of these values (Curtis et al. 2023). Additionally, impacts on agriculture due to water shortages can affect the well-being of communities through effects on access to affordable health and dental care and funding to support public services such as education, especially for tribes and farmers who rely on agricultural revenues to pay for healthcare and for communities that rely on agriculture to support the economy and public services. Increases in fallowed agricultural lands could be a source of fugitive dust, particularly under dry and unvegetated conditions, which could also impact the well-being and quality of life for communities in the analysis area (for more detail on impacts on fugitive dust emission, see **TA 7**, Air Quality). Fallowing of land with fruit or nut trees would lead to reduced sources of shade, which could result in impacts on quality of life of neighboring communities through urban heat impacts (such as heat

related illness; see **TA 17**, Population and Land Use, for more information on impacts to communities related to loss of urban and suburban trees due to reductions in domestic water). The alternatives with the greatest and smallest impacts on social conditions and access and quality of nonmarket values are the same as those discussed for impacts on fallowed lands. On average, for non-tribal entitlement holders in Arizona and California, when the total shortages are less than or equal to 3.0 maf, the greatest impacts on social conditions and access and quality of nonmarket values associated with agriculture are likely to occur under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives; with shortages greater than 3.0 maf, the greatest impacts on social conditions and nonmarket values due to changes in agriculture are likely to occur under the Maximum Operational Flexibility, Enhanced Coordination, and Representative Preferred (2029-2060) Alternatives, for non-tribal agriculture entitlement holders in Arizona and California. On average, for Arizona tribal entitlement holders, during shortages of 0.6 maf, impacts on social conditions and access to and quality of nonmarket values associated with agriculture would be the greatest under the Supply Driven Alternative (LB Pro Rata approach); with shortages greater than 0.6 maf but not more than 2.0 maf, impacts on social conditions and access to and quality of nonmarket values would be greatest under the Basic Coordination and Representative Preferred (2029-2060) Alternatives; with shortages greater than 2.0 maf, impacts on social conditions and access and quality of nonmarket values would be the biggest under the Maximum Operational Flexibility and Representative Preferred (2029-2060) Alternatives. For California and Nevada tribal entitlement holders, impacts on social conditions and access and quality of nonmarket values would be greatest under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, and there would be little to no impacts on social conditions and access and quality of nonmarket values under all other alternatives and the CCS Comparative Baseline. For more information on the impacts on tribal interests and tribal entitlement holders, see **TA 13**, Tribal Resources, and **TA 18**, Indian Trust Assets.

As discussed above in the *Assumptions* subsection, under *Agriculture*, the analysis of impacts on economic and social conditions due to changes in agriculture assumes that water shortages would lead to an increase in fallowed lands rather than a change in water sources—for example, a switch to use groundwater or other surface water sources for irrigation. If other surface water or groundwater sources are used instead of fallowing agriculture acreages, the impacts on economic and social conditions due to lost agriculture production are likely to be lessened, at least in the short term. However, the reliance on more pumped groundwater to offset delivery shortages can lead to substantial additional pumping costs, particularly for electricity (for an analysis of impacts on hydropower, including impacts on energy generation, refer to **TA 15**, Dams and Electrical Power Resources). The magnitude of the increase in costs due to pumping groundwater depends on several factors including the proximity of the agriculture land to the Colorado River. If there are large increases in cost for agriculture production—for example, on land near the Colorado River and for farmers who previously had low costs for Colorado River water delivery—the increase in cost would lead to reduced profitability of crops and could lead to an increase in fallowed lands and reduced agriculture production, especially for small farmers who are not able to absorb higher operating costs or who produce low-profitable or water-intensive crops. Additionally, in the long term, if water delivery shortages continue over multiple years and there is more sustained reliance on groundwater for irrigation, resulting in the depletion of aquifers, the water supply of both groundwater as well as the surface water from the Colorado River could reduce, which would likely lead to greater levels of

fallowed lands, a decrease in market value of crops produced, and a reduction in jobs, labor income, and economic output. A greater demand for groundwater could also lead to impacts on users and tribes who rely on groundwater for irrigation and domestic needs, similar to those impacts on economic and social conditions discussed above.

TA 16.2.3 Issue 2: How would operational changes affect economic contributions and the value associated with lake-based and river-based recreation?

The economic contribution analysis is presented below in **Table TA 16-25** for lake-based recreation and **Table TA 16-26** for river-based recreation for the CCS Comparative Baseline. A qualitative analysis is provided by action alternative based on potential changes to recreational visitation data.

Table TA 16-25
Economic Contributions- Lake-Based Recreation — CCS Comparative Baseline, 2025$

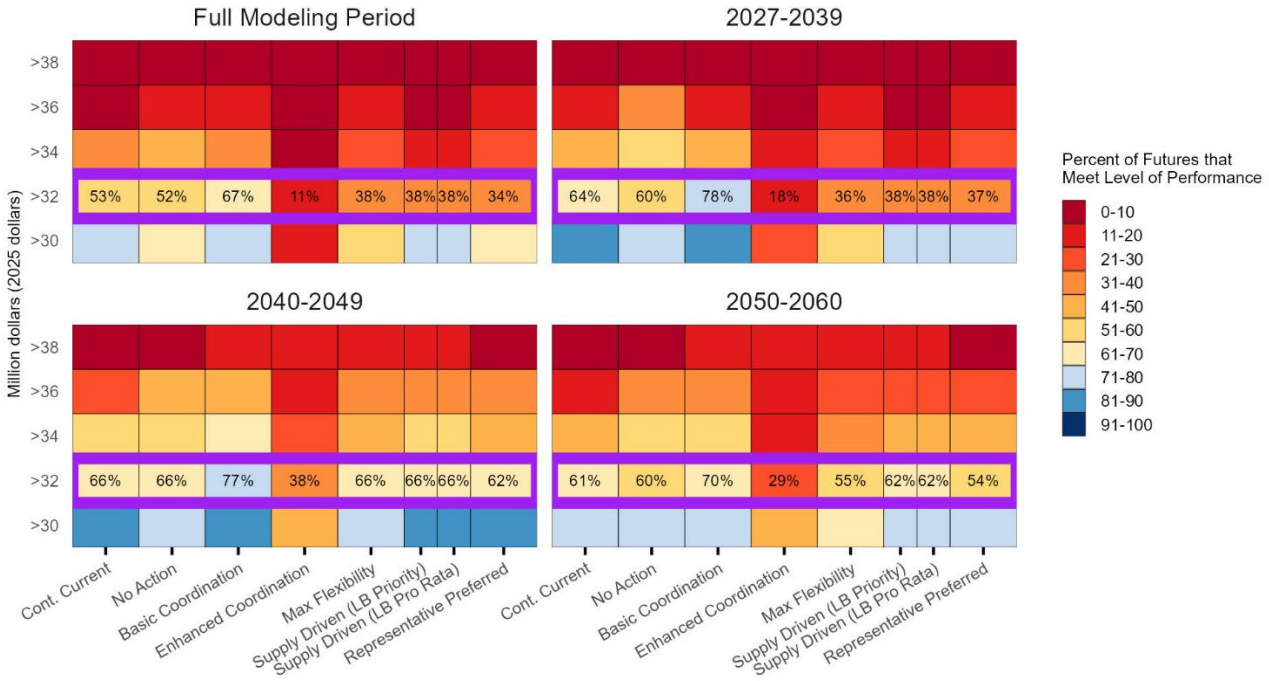
Figure TA 16-11 and **Figure TA 16-12** illustrate how the different Post-2026 operational alternatives perform in maintaining angling and boating recreational value across a wide range of plausible future hydrologic conditions. For whitewater boating, the lower reference line ($31.65 million of annual value) represents a "bad year" for economic value of whitewater rafting. It is calculated by modeling CCS Comparative Baseline in 2000–2023 hydrology and taking the

Figure TA 16-11
Annual Value of Whitewater Rafting Conditional Box Plot (2025 dollars)

Source: Bair 2026

Figure TA 16-12
Annual Value of Angling Conditional Box Plot (2025 dollars)



Source: Bair 2026

10th percentile (that is, only 10 percent of years resulted in less than or equal to a value of $31.65 million). The upper reference line ($35.69 million) represents a "normal year" and is calculated as the 50th percentile of CCS Comparative Baseline tested in the 2000–2023 hydrology. The same approach is taken for angling values, with the lower reference line (lowest 10th percentile) of $1.73 million representing poor past performance and $1.84 million (50th percentile) for the upper reference line of a "normal" year (Bair 2026). Below these levels, impacts on overall recreational values from these uses would be anticipated. It should be noted that the conditional box plots for all alternative exhibit a high range of variability of data, particularly in the case of angling value, with outliers at the high and low ends of the economic value output. As a result, the alternative comparison below focuses primarily on median and the interquartile range.

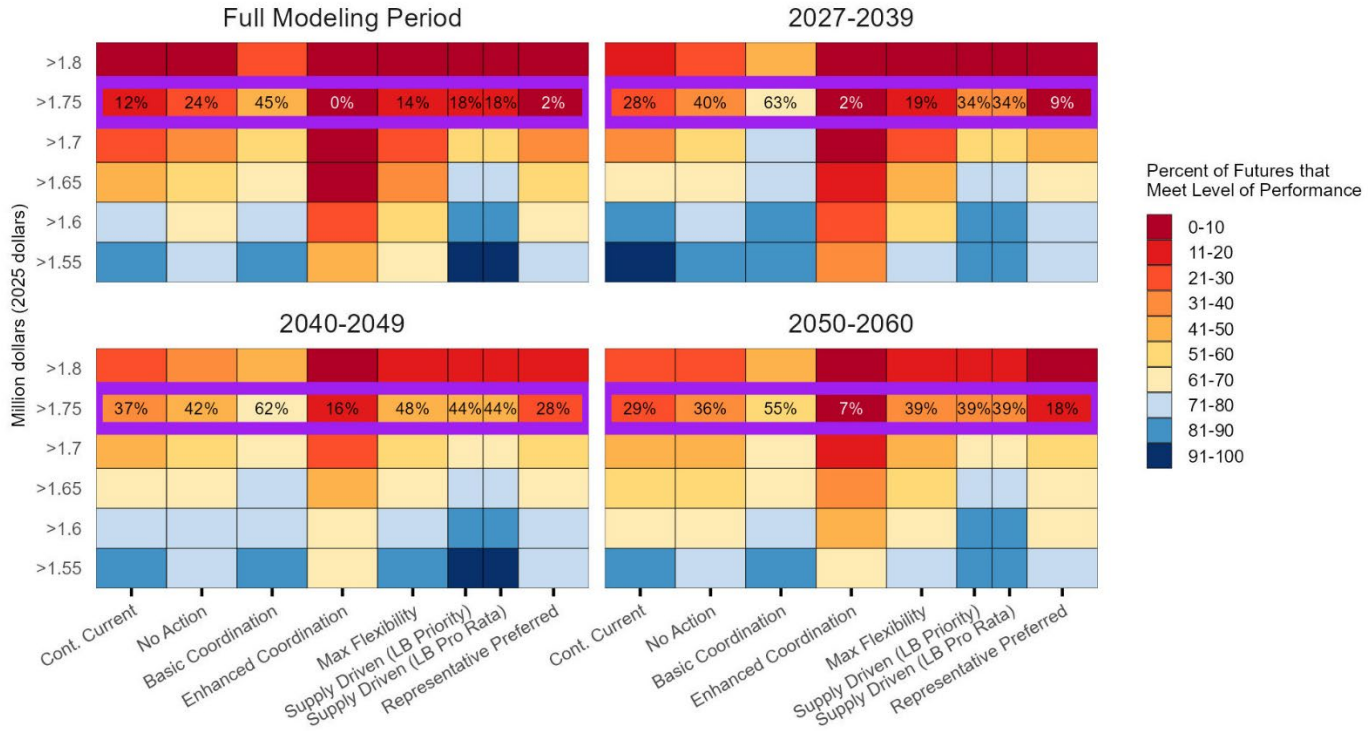


Figure TA 16-13 and **Figure TA 16-14** carry forward the minimum performance threshold representing the worst 10 percent of recreational value outcomes (that is, $32 million for whitewater boating and $1.8 million for angling), as indicated in the purple highlighted row. These figures show a heatmap for the complete modeling period, with a summary in the graph in the upper left of the figure, with the percentage of futures indicated which meet the specified level of performance for at least 90 percent of years.

Angling Economic Value: Robustness.
Percent of futures in which the annual value of angling exceeds the value specified in each row in at least 90 percent of years

Source: Bair 2026

Operational changes influence recreation primarily through their effects on reservoir elevations and river flows, which in turn shape visitor access, trip quality, and spending patterns. The following discussion examines how these dynamics affect economic contributions and recreational value across lake-based and river-based settings. Summary information is included below for summer recreation site access in both Lake Mead and Lake Powell, as well as thresholds for navigation for both reservoirs. In addition, ability to maintain flow levels to support commercial whitewater rafting is examined. More details, including additional recreation thresholds, are examined in **TA 14**, Recreation.

For lake-based recreation, under the CCS Comparative Baseline, recreation-related economic contributions are shaped by projected reservoir conditions that affect access and participation. Across the full modeling period, and the 2027–2039 subperiod none of the alternatives or the CCS Comparative Baseline would maintain at least 60 percent of Lake Powell recreational sites open during the summer months at Lake Powell. These results translate to widespread closures of Lake Powell recreation sites and boat launch ramps over the next decade and potential for reduced economic contributions (see **Figure TA 14-1** in **TA 14**, Recreation). In terms of navigation, the CCS Comparative Baseline would be slightly less robust than the No Action Alternative, with 49 percent and 58 percent of futures, respectively, over the full analysis period and 42 and 47 percent

respectively over the first decadal period meeting the threshold of 3,620 feet, which corresponds to the critical threshold navigation in Lake Powell (see **Figure 14-3** in **TA 14**, Recreation).

Similarly, for Lake Mead all alternatives exhibit poor performance at maintaining at least 80 percent of Lake Mead recreational sites open during the summer months, indicating that widespread reductions in recreation site availability are likely under a broad range of future conditions, with potential for reduced economic contributions as a result. (**TA 14**, Recreation). The No Action Alternative would support recreation access in 2 percent of futures while the CCS Comparative Baseline was successful in 7 percent of futures over the full modeling period (3 and 12 percent over the first decadal period respectively). In terms of critical thresholds for navigation, the CCS Comparative Baseline would be similar to the No Action Alternative, with 27 percent and 28 percent of futures, respectively, over the full analysis period and only 13 and 12 percent over the first decadal period meeting the critical threshold for navigation (see **TA 14**, Recreation).

IMPLAN results for the CCS Comparative Baseline (**Table TA 16-25**) show current recreational activity supports approximately 3,697 jobs and $484.1 million in output related to recreation at Glen Canyon NRA, and 1,768 jobs and $266.8 million related to recreation at Lake Mead NRA. These totals reflect direct visitor spending and the indirect and induced effects that ripple through gateway economies. The CCS Comparative Baseline serves as the benchmark for comparing the action alternatives' potential impacts on recreation-related employment and economic activity.

As described in **TA 14**, Recreation (**Figures TA 14-1** and **14-2**), Lake Powell elevations for much of the analysis period are expected to remain below critical thresholds for some launch facilities and navigational routes across all alternatives, resulting in reduced reservoir boating opportunities. Lake Mead faces similar challenges across all alternatives in maintaining elevations above navigational hazard thresholds (**Figures TA 14-3** and **14-4**). These access limitations are expected to suppress lake-based recreational spending. Research supports the link between lake levels and recreational spending and employment. Water-based recreation represents a large share of visitor activity at Lake Powell, with 46 percent of visitors participating in motorized boating (NPS 2018). Studies have found lake volume to be a predictor of visitation and spending: a 100 thousand acre feet (kaf) increase in Lake Powell volume was associated with 5,280 additional visits and $374,000 in spending in Coconino County (Nehr et al. 2013). Duvel et al. (2022), found that reservoir elevation for Lake Powell had a positive, statistically significant effect on total monthly recreational visits, and a negative correlation with unemployment. Conversely, reductions in elevation from 3,675 to 3,625 feet were estimated to result in more than a 25 percent decline in visitation (Johnson et al. 2016). Similar patterns are expected at Lake Mead, where low water levels would render most boat launches inaccessible and increase navigational hazards, reducing visitor experience and spending (Reclamation 2024), although some studies suggest this relationship may be less robust than that in Lake Powell. Reservoir elevation was estimated to have a positive, but not statistically significant effect on total monthly recreational visitors in a study by Duval et al. (2022). These changes could affect concessionaire viability and reduce revenue streams for gateway businesses reliant on extended recreational seasons (Reclamation 2024). These impacts include potential impacts on tribal concessionaries as discussed in **Section TA 16.1.3** and **TA 18**, Indian Trust Assets.

River-based recreation, including angling in Glen Canyon and whitewater rafting in Grand Canyon, is sensitive to flow conditions below Glen Canyon Dam. As noted in **TA 14**, Recreation, flows below 10,000 cubic feet per second (cfs) and above 45,000 cfs are considered less than optimal for rafting, while flows between 20,000 and 26,000 cfs are optimal. Commercial guides identify 8,000–9,000 cfs as the minimum level necessary for safe trips. Analysis for impacts of proposed management on flow indicates that the No Action Alternative is slightly less robust than the CCS Comparative Baseline at maintaining daytime flows of at least 8,000 cfs, with 67 percent of futures across the full modeling period meeting defined thresholds under the No Action Alternative compared to 58 percent under the CCS Comparative Baseline (75 percent and 55 percent when the first decadal period is examined) . This suggests the No Action Alternative may provide less consistent support for preferred rafting conditions than current conditions (see **Table TA 14-5** in **TA 14**, Recreation). Variability in flows could influence trip quality and safety, which in turn affects both the value associated with the recreational experience and economic contributions from commercial river trips and related services in gateway communities.

IMPLAN output for CCS Comparative Baseline for GCNP estimates support for 6,805 jobs and $846.1 million. As for lake-based recreation, these totals reflect direct visitor spending and the indirect and induced effects that ripple through gateway economies.

The CCS Comparative Baseline and the No Action Alternative are successful at keeping both whitewater boating values above determined thresholds feet 90 percent of the time in 53 percent and 52 percent of futures, respectively. When just the first decadal modeling period is examined, these values are slightly improved at 64 percent of futures for CCS and 60 percent for the No Action Alternative. For angling, the CCS Comparative Baseline and the No Action Alternative are successful at keeping values above determined thresholds in 12 percent and 24 percent of traces respectively. When just the first decadal modeling period is examined, performance is slightly improved, with the CCS has values above determined thresholds in 28 percent of traces and the No Action Alternative has values above thresholds 40 percent. When examining conditional box plots, under wet and moderate hydrologic conditions, all alternatives and the CCS Comparative Baseline maintain recreational value associated with boating and angling above the established critical threshold ranges. Under dry hydrologic conditions, the CCS Comparative Baseline and the No Action Alternative maintain median values within the minimum threshold levels for whitewater boating and angling. Under critically dry conditions, the CCS Comparative Baseline median is below the defined thresholds for angling recreational value; under the No Action Alternative, the median is just above the minimum range. For whitewater boating recreational value, the median is just above the minimum range for both the No Action Alternative and the CCS Comparative Baseline. This data indicates that under the No Action Alternative and the CCS Comparative Baseline, under dry hydrological conditions future recreational values are likely to be maintained but under critically dry conditions impacts may occur.

Under the Basic Coordination Alternative, greater flexibility in releases begins to shift the frequency and duration of low-elevation periods, with implications for both lake access and river flow stability. The Basic Coordination Alternative introduces shortages up to 1.48 maf and allows Lake Powell releases to fall to 7.0 maf in low-storage years. These operational changes increase the frequency and duration of low-elevation conditions at Lake Mead and Lake Powell, reducing marina operability and

shortening boating seasons. As noted previously, summer recreation site access is limited under all alternatives. For Lake Powell, in terms of navigation, the Basic Coordination Alternative is slightly less robust than the CCS Comparative Baseline and slightly more robust than No Action Alternative, with a 55 percent success rate over the full analysis period (50 percent over the first decadal period) (see **TA 14**, Recreation). For Lake Mead, the Basic Coordination Alternative succeeded in only 6 percent of futures for summer recreational site access over the full modeling period and the first decadal period, similar performance to the CCS Comparative Baseline (7 percent) and slightly more robust than the No Action Alternative (2 percent) (see **TA 14**, Recreation). Navigation thresholds were achieved in 35 percent of futures over the full modeling period (19 percent over the first decadal period), more robust than the CCS Comparative Baseline and No Action Alternative. These data indicate that overall economic contributions from reservoir recreational activities may be similar under the Basic Coordination Alternative to the CCS Comparative Baseline and No Action Alternative.

For river-based recreation, the Basic Coordination Alternative has a higher level of robustness for whitewater boating value as compared to the No Action Alternative (67 percent of futures having a value above the defined threshold, with 78 percent above the threshold for the first decadal period). This is the most robust of any alternative. Similarly, for angling recreational value, the Basic Coordination Alternative is more robust than any other alternative, with 45 percent of futures maintaining values above the defined threshold for 90 percent of modeled years compared to 24 percent in the No Action Alternative (for the first decadal period performance under the Basic Coordination Alternative is further improved at 63 percent of traces). When examining conditional box plots, under dry hydrologic conditions, for whitewater boating the Basic Coordination Alternative performs slightly worse than the No Action Alternative, with the median just below the identified upper critical threshold; however, there is less variability in the range of outcomes under this alternative. For angling, the Basic Coordination Alternative performs the best of all Alternatives under dry hydrologic conditions, with the median just above the identified threshold range. DMDU analysis performed in **TA 14**, Recreation (**Figure TA 14-5**) also indicates that the Basic Coordination Alternative performs more robustly than the No Action Alternative in maintaining daytime flows of at least 8,000 cfs, which are considered minimally adequate for rafting (80 percent of futures over the full modeling period and 90 percent of futures over the first decadal period), supporting continued or increased economic contributions from commercial river trips over the full modeling period.

For reservoir-based recreation, the Enhanced Coordination Alternative introduces proactive storage balancing and shortages up to 3.0 maf. This alternative is among the most robust in terms of meeting thresholds navigation in Lake Powell (82 percent of futures over the full modeling period and 64 percent over the first decadal period) (see **TA 14**, Recreation). Consequently, economic contributions from lake-based recreation would likely be higher than the CCS Comparative Baseline and No Action Alternative. For Lake Mead, analysis indicates that summer recreational site access thresholds would be achieved in only 4 percent of futures over the full modeling period (5 percent over the first decadal period), and navigation thresholds achieved in 55 percent of futures over the full modeling period (32 percent over the first decadal period). This performance is more robust than both the CCS Comparative Baseline and No Action Alternative for navigation but less robust than CCS Comparative Baseline for recreation site access. As noted above, as under all alternatives,

however, access to launch facilities and safe navigation routes for Lake Powell and navigational challenges in Lake Mead would continue to impact lake-based recreational opportunities and the associated spending, though storage balancing may help limit the duration of extreme low-elevation periods compared to the other action alternatives.

For river-based recreation, the Enhanced Coordination Alternative would be the least robust in maintaining or exceeding minimum desired daytime flows to support boating in Grand Canyon (only 8 percent of futures would meet the defined threshold over the full modeling period and one percent of the first decadal period; **Figure TA 14-5** in **TA 14**, Recreation). DMDU modeling output for angling and boating value aligns with these findings, with whitewater boating and angling values having the least robust performance of all alternatives, with only 11 percent and 0 percent of futures meeting or exceeding defined thresholds for recreational value for boating and angling respectively (18 percent and 2 percent for the first decadal period for boating and angling respectively). When examining conditional box plots, under dry hydrologic conditions, this is the worst performing alternative for angling, with the median falling below the identified minimum threshold. For the recreational value associated with whitewater boating, the median value is slightly below the median seen in the No Action Alternative, but still above the critical thresholds, and higher than other action alternatives. However, this alternative has the widest range for potential outcomes under dry conditions. As a result, this alternative would result in the greatest potential for a reduction in recreational value for angling as well as the associated regional economic contributions associated with this use, and would have an unpredictable level of reduction in economic contributions from whitewater boating.

The Maximum Operational Flexibility Alternative allows shortages up to 4.0 maf and Lake Powell releases as low as 5.0 maf. For river-based recreation, in terms of flow conditions, daytime flows below Glen Canyon Dam under this alternative are more volatile than under the CCS Comparative Baseline and No Action Alternative, increasing the likelihood of extended periods below 8,000 cfs and even near 5,000 cfs, which are considered adverse for rafting (31 percent of futures would meet threshold conditions over the full modeling period and 22 percent over the first decadal period) (see **Figure TA 14-2** in **TA 14**, Recreation). These conditions would diminish trip quality and safety, reducing long-run economic contributions from river-based recreation and nonmarket values tied to scenic quality and experience as compared to the CCS Comparative Baseline and No Action Alternative. DMDU modeling output for angling indicates that the Maximum Operational Flexibility Alternative is slightly more robust than the CCS Comparative baseline but less robust than the No Action Alternative for angling, with 14 percent of futures meeting the minimum defined thresholds over the full modeling period. When only the first decadal period is examined, however, the Maximum Operational Flexibility Alternative is less robust than both the CCS Comparative Baseline and the No Action Alternative for angling (19 percent of futures meeting defined thresholds compared with 28 percent under the No Action Alternative). For whitewater boating, the Maximum Operational Flexibility Alternative is consistently less robust than the No Action Alternative and CCS Comparative Baseline, with 38 percent of futures over the full modeling period meeting or exceeding the defined threshold for recreational value (36 percent in the first decadal period). When examining conditional box plots, under dry hydrologic conditions, for angling value the Maximum Operational Flexibility Alternative performs similar to the No Action Alternative and better than the CCS Comparative Baseline. For whitewater boating the Maximum Operational Flexibility

Alternative performs worse than the No Action Alternative and similar to the CCS Comparative Baseline.

In terms of reservoir elevations, **TA 14**, Recreation, indicates that under the Maximum Operational Flexibility Alternative, maintenance of critical thresholds for navigation in Lake Powell is among the most robust alternatives, with access maintained in 80 percent of futures over the full modeling period (69 percent over the first decadal period). For Lake Mead, recreation access and navigation are similarly more robust than the No Action Alternative and the CCS Comparative Baseline (64 percent over the full modeling period and 36 percent over the first decadal period). As discussed under for the Maximum Operational Flexibility Alternative, consequently, economic contributions from lake-based recreation would likely be higher than the CCS Comparative Baseline and No Action Alternative. Under all alternatives, however, access to launch facilities and safe navigation routes for Lake Powell and navigational challenges in Lake Mead would continue to impact lake-based recreational opportunities and the associated spending.

The Supply Driven Alternative ties Powell releases to a percentage of 3-year average natural flow and applies Mead shortage tiers up to 2.1 maf. Within this framework, two approaches for the Supply Driven Alternative were considered: a Pro Rata approach, which distributes available Colorado River water supplies proportionally across entitlement holders, and a Priority approach, which distributes available Colorado River water supplies in accordance with statutes, case law, and contracts. For reservoir-based recreation, for Lake Powell both the Priority and Pro Rata approaches would be less robust in terms of maintenance of critical thresholds for navigation than the No Action Alternative and the CCS Comparative Baseline which could further impact recreational spending and gateway businesses and concessionaire associated with Lake Powell. In contrast, for Lake Mead, the Supply Driven Alternative modeling represents the most robust outcomes for recreational site access and navigation, supporting continued or increased spending associated with recreational activities for this reservoir.

For river-based recreation, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust at maintaining or exceeding daytime flows of 8,000 cfs below Glen Canyon Dam over the full modeling period and among the most robust over the first decadal period, providing the strongest support for maintained or improved recreational value for boating and angling, and economic contributions associated with river-based recreation. DMDU modeling output for angling indicates that the Supply Driven Alternative (both the LB Priority and Pro Rata approaches) are slightly more robust than the CCS Comparative Baseline and less robust than the No Action Alternative, with 18 percent of futures meeting the minimum defined thresholds for 90 percent of future years over the full modeling period (34 percent when just the first decadal period is examined). For whitewater boating the Supply Driven Alternative is less robust than both the CCS Comparative Baseline and the No Action Alternative, with 38 percent of futures meeting or exceeding the defined threshold for recreational value (under both the LB Priority and Pro Rata approaches). When examining conditional box plots, under dry hydrologic conditions, for angling value both the LB Priority and Pro Rata perform similarly to the No Action Alternative and better than the CCS Comparative Baseline, with the median values slightly below that of the No Action Alternative, although there is a smaller range of variability in the Supply Driven Alternative. For whitewater boating value both the LB Priority and Pro Rata perform similarly to the CCS

Comparative Baseline and slightly worse than the No Action Alternative. As for angling recreational value, modeling indicates a smaller range of variability in the Supply Driven Alternative.

As discussed in **Chapter 2**, the Preferred Alternative is a multi-year decision framework that establishes the process and criteria that would govern development and adoption of operating guidelines through 2036. The decision framework is anticipated to be implemented in two-year operating intervals. Unlike other alternatives, the operating guidelines for each interval are not specified in this Final EIS. The sideboards provide a basis for assumptions included in the Representative Preferred Alternative which captures the range of operating guidelines that may be adopted during each interval, but exact operations would be subject to the guidelines in place during each interval. While some impacts are influenced by how the Representative Preferred Alternative distributes Lower Basin shortages in 2027-2028 vs. 2029-2060, issue is either minimally sensitive or not sensitive to this distinction, so the different time periods are not discussed.

For reservoir-based recreation on Lake Powell, the Representative Preferred Alternative would be slightly more robust in terms of maintenance of critical thresholds for navigation than the No Action Alternative and CCS Comparative Baseline over both the full modeling period (61 percent of futures above defined thresholds) and the first decadal period (55 percent above defined thresholds). Compared to other action alternatives, this is better than the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), but less robust than the Enhanced Coordination and Maximum Operational Flexibility Alternatives. For reservoir-based recreation on Lake Mead, the Representative Preferred modeling represents less robust outcomes for recreational site access as compared to the CCS Comparative Baseline but slightly more robust outcomes than the No Action Alternative (6 percent for the full modeling period and 7 percent over the first decadal period above defined thresholds). This is a similar level of performance to the other action alternatives, with only the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) showing a more than 2 percent difference in success rate of meeting defined thresholds. For navigation, the Representative Preferred Alternative is more robust at meeting defined thresholds than both the No Action Alternative and CCS Comparative Baseline (48 percent over the first decadal period and 31 percent over the first decadal period). Compared to other action alternatives, the Representative Preferred is less robust than all but the Basic Coordination Alternative in meeting navigational thresholds for Lake Mead, but the performance is more similar to other alternatives when only the first decadal period is examined. Similar to all alternatives, however, access to launch facilities and safe navigation routes for Lake Powell and navigational challenges in Lake Mead would continue to impact lake-based recreational opportunities and the associated spending.

For river-based recreation, the Representative Preferred Alternative is less robust in terms of maintaining or exceeding daytime flows of 8,000 cfs below Glen Canyon Dam than the No Action Alternative and CCS Comparative Baseline over both the full modeling period (51 percent of futures above defined thresholds) and the first decadal period (60 percent above defined thresholds). Compared to other action alternatives, this is less robust performance than the Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, but more robust than the Maximum Flexibility and Enhanced Coordination Alternatives. DMDU modeling output for angling indicates that the Representative Preferred Alternative is less robust than all alternatives other than the Enhanced Coordination Alternative with only 2 percent of modeling futures

exceeding defined thresholds (9 percent over first decadal period). For whitewater boating recreational value performance is also less robust than all alternatives other than the Enhanced Coordination Alternative, although the percent of futures is similar to that in the Supply Driven and Maximum Flexibility Alternatives. When examining conditional box plots, under dry hydrologic conditions, for angling value the Representative Preferred Alternative performs similarly to the No Action Alternative and better than the CCS Comparative Baseline, with the median values slightly below that of the No Action Alternative, although there is a smaller range of variability. For whitewater boating value the Representative Preferred Alternative performs similarly to the CCS Comparative Baseline and slightly worse than the No Action Alternative. As for angling recreational value, modeling indicates a larger range of variability under the Representative Preferred. For both angling and boating, performance is also similar to the Maximum Flexibility Alternative and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), although the Representative Preferred Alternative has a higher range of variability compared to these alternatives. This data suggests overall river-based recreational outcomes and the associated recreational value and economic contributions are likely to experience a high range of variability, which may impact the ability of local communities and concessionaries to depend on this economic activity.

TA 16.2.4 Issue 3: How would anticipated water shortages and changes in water levels in reservoirs and river segments affect access and quality of nonmarket values?

Nonmarket values with potential to be affected by operations generally encompass cultural identity, recreational quality, aesthetics, and existence values, and may vary based on site-specific conditions, user preferences, and other factors. Values specific to tribes are further explored in **TA 18**, Indian Trust Assets, and **TA 13**, Tribal Resources.

In general, the alternatives that facilitate higher reservoir elevations, and maintain more consistent flows along the Colorado River including through Grand Canyon would result in the reduced impacts on identified nonmarket values. There may be exceptions to this generalization; for example, alternatives which provide better support for river-based recreation and associated values may result in less preferable outcomes for reservoir-based recreation and vice versa.

During wet hydrologic conditions, the range of alternatives would generally produce conditions where lake levels and flows along the Colorado River would result in minimal impacts on nonmarket values. However, this varies by resource. For example, nonmarket values such as scenic integrity, solitude, and cultural connections to the river corridor would be maintained at a level similar to current conditions (**TA 19** Visual Resources). Ecological services, including riparian habitat and wildlife viewing opportunities, remain similar to current conditions (see **TA 8**, Biological Resources – Fish and Other Aquatic Species), and cultural landscapes retain the factors which are associated with nonmarket values (see **TA 11**, Cultural Resources). Recreational experiences for boating, angling, and rafting however, may be impacted under all alternatives in their quality and support for sense of place for gateway communities and visitor, as modeling indicates that periods of reservoir elevations below thresholds for recreation facility access and navigation would be more likely than that under historic conditions.

As conditions become drier, the No Action Alternative and CCS Comparative Baseline would result in the most modeled futures where impacts could occur to resources with nonmarket values. For example, nonmarket values for recreation and ecosystem services could be reduced in instances of prolonged drought, which could reduce shoreline aesthetics and diminish the opportunities for solitude at Lake Powell and Lake Mead over time (see **TA 14**, Recreation). Extended low-flow periods could also impact river-based experiences in Grand Canyon due to changes in setting which could impact perceived naturalness (see **TA 3**, Hydrologic Resources). Cultural and spiritual values tied to iconic landscapes and cultural artifacts could also be affected in low-hydrologic flow periods (see **TA 11**, Cultural Resources). Ecological services such as riparian habitat stability may decline, influencing nonuse values related to wildlife and vegetation communities (see **TA 8**, Biological Resources – Fish and Other Aquatic Species).

Under drier conditions, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would be more robust in terms of the support for some nonmarket values, particularly for values associated with Lake Powell. Reservoir levels which are maintained at thresholds that support access for boating and camping in more modeled futures, support experiential benefits and cultural connections (see **TA 11**, Cultural Resources). The quality of river-based recreation is expected to remain high, due to increased stability with flow-dependent activities (see **TA 14**, Recreation); however, a lower average flow may impact some values. Nonuse values tied to ecosystem services, such as wildlife habitat and riparian vegetation, would also be supported (see **TA 8**, Biological Resources – Fish and Other Aquatic Species). As conditions become drier, Lake Powell and Lake Mead landscape character would be better supported under the Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives as compared to the No action Alternative and CCS Comparative Baseline (**TA 19,** Visual Resources).

More frequent reservoir low-elevation conditions could occur in the Basic Coordination Alternative, which could noticeably affect nonmarket values tied to lake-based recreation and scenic quality (see **TA 14**, Recreation) although at a reduced level compared with the No Action Alternative and the CCS Comparative Baseline. Reduced reservoir levels may expose previously submerged areas, altering visual character and diminishing the opportunities for solitude. River-based recreation could experience flow variability that affects trip quality and angling success (see **TA 3**, Hydrologic Resources); however, higher average flows may support some river-based values.

Outcomes produced by the Supply Driven Alternative vary depending on the hydrology and location. In wet years, the nonmarket values remain similar to those under the CCS Comparative Baseline; however, in dry sequences, reduced reservoir elevations and altered flow regimes would diminish the scenic quality and access for boating and angling (see **TA 14**, Recreation), for Lake Powell. For Lake Mead, the Supply Driven Alternative is the most robust for supporting reservoir levels at Lake Mead, which support the nonmarket values. River-based recreation would experience moderate variability in trip quality, while ecosystem services and the associated nonuse values would fluctuate with water availability (see **TA 8**, Biological Resources – Fish and Other Aquatic Species). Cultural and spiritual values tied to river corridors may also be affected during extended drought periods (see **TA 11**, Cultural Resources). Similar to the Basic Coordination Alternative, however, higher average flows may support some river-based values.

As discussed in **Chapter 2**, the Preferred Alternative is a multi-year decision framework that establishes the process and criteria that would govern development and adoption of operating guidelines through 2036. The decision framework is anticipated to be implemented in two-year operating intervals. Unlike other alternatives, the operating guidelines for each interval are not specified in this Final EIS. The sideboards provide a basis for assumptions included in the Representative Preferred Alternative which captures the range of operating guidelines that may be adopted during each interval, but exact operations would be subject to the guidelines in place during each interval. While some impacts are influenced by how the Representative Preferred Alternative distributes Lower Basin shortages in 2027-2028 vs. 2029-2060, this issue is either minimally sensitive or not sensitive to this distinction, so the different time periods are not discussed.

The Representative Preferred Alternative generally performs in the middle of the range of alternatives for both Lake Powell and Lake Mead elevations as well as river flow, showing moderate robustness in terms of overall support for recreation associated benefits (**TA 14**, Recreation). Overall, this alternative would provide moderate protection for riverine habitat to support cultural values (see **TA 13**, Tribal).

TA 16.2.5 Summary Comparison of Alternatives

Issue 1: How would anticipated water shortages affect economic contributions and social conditions from agriculture?

The lowest impacts on economic and social conditions from reductions in agricultural production and increases in fallowed lands due to shortages in irrigation water, across all alternatives, states, priority groups, and tribal and non-tribal irrigation entitlement holders, would occur under the No Action Alternative due to the low maximum shortage of 0.6 maf; however, across the action alternatives, impacts on economic and social conditions from changes in agriculture would vary across irrigation priority groups and tribal and non-tribal entitlement holders, based on the maximum shortage levels and water shortage distribution methods.

Under low shortage levels, on average across all priority groups, for all irrigation entitlement holders except Arizona tribal (Arizona non-tribal, California non-tribal, California tribal, and Nevada tribal irrigation entitlement holders), impacts on the economic and social conditions due to reductions in agricultural production would tend to be lower under the alternatives with priority shortage distribution methods (such as under the Basic Coordination, Maximum Operational Flexibility, and Supply Driven [LB Priority approach] Alternatives), and impacts would tend to be higher under the alternatives with pro rata shortage distribution methods (under the Enhanced Coordination and Supply Driven [LB Pro Rata approach] Alternatives). In contrast, under low shortage levels, for Arizona tribal irrigation entitlement holders, impacts on the economic and social conditions due to reductions in agricultural production would be similar across all action alternatives. During times of extensive drought, when maximum shortage levels are implemented, on average across all priority groups, for all irrigation entitlement holders except Arizona tribal, impacts on the economic and social conditions from agricultural activity would tend to be lower under the alternatives with a low maximum shortage level and priority shortage distribution methods (such as under the Basic Coordination Alternative), and impacts would tend to be higher under the alternatives with a high maximum shortage level or pro rata shortage distribution methods (such as the Enhanced

Coordination, Maximum Operational Flexibility, or Supply Driven [LB Pro Rata approach] Alternatives), compared with the other action alternatives. However, for Arizona tribal entitlement holders, during times of maximum shortage levels, lower impacts on the economic and social conditions due to reductions in agricultural production would occur under the alternatives with pro rata shortage distribution methods (such as under the Enhanced Coordination and Supply Driven [LB Pro Rata approach] Alternatives) and higher impacts would occur under the alternatives with priority shortage distribution methods (such as under the Basic Coordination, Maximum Operational Flexibility, and Supply Driven [LB Priority approach] Alternatives), compared with the other action alternatives. These impacts vary across priority groups. The largest impacts on economic and social conditions during a maximum shortage level, for tribal and non-tribal PPR priority holders, would tend to occur under the action alternatives with a pro rata shortage distribution methods, while the largest impacts for the more junior priority holders (Arizona non-tribal priorities 4(i), and Arizona tribal priorities CAP Indian, 4(i), and 3) would tend to occur under the action alternatives with a priority shortage distribution method and higher maximum shortage level (such as the Maximum Operational Flexibility Alternative). In contrast, the largest impacts for non-tribal and tribal priority group 3 in Arizona and non-tribal priority groups 2 and 3 in California would tend to occur under alternatives with pro rata shortage distribution methods, during periods of low shortages, and would tend to occur under alternatives with a priority shortage distribution method and higher maximum shortage level (such as the Maximum Operational Flexibility Alternative) during period of severe droughts and maximum shortages levels. Overall, the alternatives demonstrate a trade-off between shortage distributions across irrigation entitlement holders, flexibility in the maximum allowable shortage implementation, and the ability to support stable agricultural production and social well-being.

Issue 2: How would operational changes affect economic contributions and value associated with lake-based and river-based recreation?

Recreation-based economies are highly sensitive to changes in reservoir elevations and river flow conditions. Under the alternatives that sustain more stable water levels, boating and shoreline access would remain consistent, supporting steady visitation and related spending that currently contributes about 12,000 jobs and $1.6 billion in output across the Basin.

Operational changes under the proposed alternatives would influence these conditions in different ways. The alternatives that maintain higher and more consistent water levels would preserve boating access, marina operations, and shoreline recreational opportunities. This stability would support continued visitation and minimize disruptions to businesses dependent on tourism. Conversely, the alternatives that result in greater variability in lake elevations and river flows would affect the recreational quality and access and the related levels of contributions.

Under all alternatives, restrictions on summer recreation access and safe navigation routes for Lake Powell and navigational challenges in Lake Mead would continue to impact lake-based recreational opportunities and the associated spending. As a result, outfitters and concessionaires operating in these areas would face increased uncertainty, affecting employment and revenue streams under all alternatives. Research indicates that declines in lake elevation can reduce visitation by more than 25 percent, amplifying economic losses for local communities (Johnson et al. 2016). Lake Mead would experience similar constraints, with boating access severely limited during extended drought periods.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) poses the greatest risk to recreation-based economies relying on economic contributions from reservoir-based recreation in Lake Powell, while the CCS Comparative Baseline and the No Action Alternative have the least robust modeled performance for supporting recreational opportunities and spending associated with Lake Mead recreation. In contrast, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would result in more consistent reservoir levels at Lake Powell to support recreation, and the Supply Driven Alternative would support the greatest level of contributions from recreation in Lake Mead. Under the Representative Preferred Alternative, support for navigation in Lake Powell would be slightly more robust in terms of maintenance of critical thresholds for navigation than the No Action Alternative and CCS Comparative Baseline. For Lake Mead, the Representative Preferred would be less robust outcomes for recreational site access as compared to the CCS Comparative Baseline but slightly more robust outcomes than the No Action Alternative. For navigation, the Representative Preferred Alternative is more robust at meeting defined thresholds than both the No Action Alternative and CCS Comparative Baseline. Compared to other action alternatives, the Representative Preferred is less robust than all but the Basic Coordination Alternative in meeting navigational thresholds, but the performance is more similar to other alternatives when only the first decadal period is examined.

River-based recreation is also vulnerable to operational changes. Activities such as angling in Glen Canyon and whitewater rafting in Grand Canyon depend on stable flows to ensure safety and trip quality. Reduced flows shorten rafting seasons and diminish the overall experience, leading to lower recreational value and reduced demand for outfitter services and the associated hospitality sectors. The Basic Coordination Alternative would provide the most support for continued or increased economic value associated with boating and angling and related economic contributions. The Enhanced Coordination Alternative would be the least robust at maintaining or exceeding the minimum desired daytime flows to support boating in Grand Canyon; it also would result in the greatest potential for a reduction in recreational value for whitewater rafting and angling as well as the associated regional economic contributions associated with these uses. Impacts would be most pronounced under dry hydrologic conditions.

The Representative Preferred Alternative would provide reduced support for economic contributions from river-based angling and boating compared to most other action alternatives; DMDU modeling output for angling and boating indicates that the Representative Preferred Alternative is less robust than all alternatives other than the Enhanced Coordination Alternative.

Economic impacts extend beyond direct visitor spending. Gateway communities, often small and rural, rely heavily on tourism-related income to sustain local businesses and municipal services. When lake levels drop or river flows decline, these communities experience cascading effects, including reduced tax revenues and job losses in sectors such as lodging, food service, and transportation. The magnitude of these impacts would depend on the frequency and duration of low-elevation conditions, which would vary significantly across the alternatives.

Issue 3: How would anticipated water shortages and changes in water levels in reservoirs and river segments affect access and quality of nonmarket values?

Changes in reservoir elevations and river hydrology also influence nonmarket values such as scenic quality, solitude, and cultural and spiritual connections to the river corridor. More stable operating conditions preserve visual continuity and access to culturally important sites, supporting a sense of place and maintaining the experiential qualities associated with national parks, recreation areas, and other designated lands (see **TA 11**, Cultural Resources). In wet hydrologic conditions, all alternatives support the preservation of conditions which support nonmarket values, although the level of support varies by resource. Under dry hydrologic conditions, however, the No Action Alternative and CCS Comparative Baseline would result in reductions in reservoir levels and greater variability in river flow especially as compared to the Enhanced Coordination and Maximum Operational Flexibility Alternatives. This would result in more frequent exposure of drawdown zones and shifts in shoreline character, diminishing the aesthetic and spiritual values tied to the river's natural appearance. Variability in flows and elevations could also affect the timing and accessibility of traditional practices for tribes and local communities. In general, the alternatives that moderate elevation changes better sustain these nonmarket benefits, while those allowing greater fluctuation introduce tradeoffs between resource protection and system adaptability.

TA 17. Population and Land Use

This section explores the baseline conditions and potential impacts from different Colorado River operational strategies on analysis area population dynamics and land-use changes, with a focus on potential changes in developed lands and lands used for irrigated agriculture.

Baseline information is provided to characterize the existing setting and trends related to population, general landownership and management, and developed land patterns. Information is also provided for municipal water, which supports developed land use. Data are provided related to historical agricultural land use to support the discussion of irrigated agriculture.

Due to the influence of municipal water availability on developed lands, the impacts analysis examines changes to water availability for municipal supply and the related impacts on population and land-use changes. Due to the influence of irrigation water availability on agricultural land use, the impacts analysis examines changes to irrigation water availability and related impacts on acres of lands in agriculture.

TA 17.1 Affected Environment

The analysis area for the population and land-use section is separated by state and is the same for both population and land-use issues. The impact analysis area is defined by those counties that may be affected by management direction that could result in water shortages to domestic and irrigation users. Because both issue statements rely on the Shortage Allocation Models (SAMs), the analysis area is informed by the SAMs and includes the counties represented in the SAMs. For more detailed information on the SAMs, see **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation. For more information on water deliveries, including those for irrigation, refer to **TA 4**, Water Deliveries.

The Arizona analysis area consists of Apache, Coconino, Gila, La Paz, Maricopa, Mohave, Navajo, Pima, Pinal, and Yuma Counties. These include counties that are directly adjacent to Lake Powell, Lake Mead, or the Colorado River and counties in which shortages would likely occur.

The California analysis area consists of Imperial, Los Angeles, Orange, Riverside, San Bernardino, and San Diego Counties. These counties were selected because they are either directly adjacent to the Lower Colorado River, or they are within the Metropolitan Water District of Southern California (MWD) service area. Although Ventura County is also in the MWD service area, it does not receive any water from the Colorado River; therefore, it is not included in the analysis area.

The Nevada analysis area consists of Clark County. The analysis area was limited to Clark County because Clark County is adjacent to Lake Mead and encompasses the Southern Nevada Water

Authority's (SNWA) service area and other individual water providers. Shortages in Nevada would be limited to the SNWA's service area.

The Utah analysis area consists of Kane, Garfield, and San Juan Counties. Although these counties are not in the Lower Colorado River Basin (Lower Basin) and thus would not experience shortages, baseline information on population and land use is included to provide content for analysis of social and economic impacts from recreation associated with the Colorado River, Lake Powell, and Lake Mead (see **TA 16**, Socioeconomics).

Across the states, these counties were selected for inclusion in the analysis area because they represent the counties in which there is potential for direct impacts from shortages, based on modeled domestic (municipal) delivery outcomes and the service areas of major municipal providers. Secondary impacts could also occur in adjacent counties, across states as a whole, in adjacent states, and/or on the national scale (for example, through economic linkages and supply chains). However, due to analytical constraints and the focus of this technical appendix on an assessment of modeled domestic shortage outcomes for selected municipal providers informed by Decision Making under Deep Uncertainty (DMDU), the population and land-use analysis focuses on direct impacts within the counties that correspond to municipal service areas and areas where delivery reductions could most directly influence land-use-related conditions.

This approach is consistent with the socioeconomic framing (**TA 16**, Socioeconomics), which defines the analysis areas using counties adjacent to reservoirs and the Colorado River and counties containing major municipal service areas that receive water from the Colorado River (for example, in California, counties within the MWD service area that receive Colorado River water).

TA 17.1.1 Population

Population trends provide important context for understanding water supply (domestic and irrigation), demand, and use within the analysis area. Although population growth can influence municipal water demand, population is not a direct proxy for consumptive water use because conservation, reuse, demand-management measures, water-use efficiency, local policy, and land-use patterns can affect per-capita demand. As a result, population and water demand may not increase at the same rate. Communities throughout much of the western United States (U.S.) have followed trends of increasing population over the past decade. In the analysis areas, the population growth rate has generally been positive or stable. County- and state-level population changes are discussed below (see **Table TA 17-1** through **Table TA 17-4**).

Arizona

Except La Paz and Apache Counties, which saw a decrease in population (of 18.8 percent and 6.1 percent, respectively), and Navajo County, which maintained its population, all counties in the analysis area followed the trend of increasing population from 2010 to 2022; the biggest increase was in Pinal County (31.6 percent). **Table TA 17-1** provides an overview of populations by county in the Arizona analysis area. Arizona's population is anticipated to continue to increase over the analysis period, with similar county-level trends continuing. Drivers of population increase in Pinal County included low housing costs and workforce increases from new manufacturing, logistical, and distribution facilities (Arizona Office of Economic Opportunity 2024).

Table TA 17-1
Arizona Population 2010–2040

Geographic Area	Population 2010[1]	Population 2022[2]	Percent Change 2010–2022	Estimated Population 2040[3]	Estimated Percent Change 2022–2040
Apache County	70,312	66,054	-6.1	64,449	-2.4
Coconino County	131,824	144,705	9.8	159,557	10.3

Arizona	6,246,816	7,172,282	14.8	9,206,879	28.4

Sources: U.S. Census Bureau 2012,[1] 2023;[2] Arizona Office of Economic Opportunity 2023[3]

California

In California, the population increased by 7.4 percent from 2010 to 2022. With the exception of Los Angeles, Imperial, and Orange Counties, the analysis area counties' growth all surpassed that of the state. The largest increase in population was in Riverside County (15.2 percent; see **Table TA 17-2**). Historical trends are expected to continue over the next 20 years, with the largest increases forecasted for Imperial and Riverside Counties; notably, a decrease in population of 2.1 percent is anticipated for Los Angeles County. Factors influencing population loss likely include the cost of housing leading to out-migration, as well as other demographic factors such as population aging and low birth rate (Johnson et al. 2023).

Table TA 17-2
California Population 2010–2040

Geographic Area	Population 2010[1]	Population 2022[2]	Percent Change 2010–2022	Estimated Population 2040[3]	Estimated Percent Change 2022–2040
Imperial County	168,052	179,578	6.9	203,470	13.3
Los Angeles County	9,758,256	9,936,690	1.8	9,732,175	-2.1
Orange County	2,965,525	3,175,227	7.1	3,243,240	2.1

San Diego County	3,022,468	3,289,701	8.8	3,424,184	4.1
California	36,637,290	39,356,104	7.4	40,968,090	4.1

Sources: U.S. Census Bureau 2012,[1] 2023;[2] California Department of Finance 2023[3]

Nevada

In terms of population increases, Nevada represented some of the largest in the analysis areas. Nevada's population grew by 17.9 percent from 2010 through 2022. Clark County's population changed 19.5 percent, which was higher than that of the state overall. Trends are expected to continue with a change of 28.7 percent anticipated in Clark County by 2040 (see **Table TA 17-3**).

Table TA 17-3
Nevada Population 2010–2040

Geographic Area	Population 2010[1]	Population 2022[2]	Percent Change 2010–2022	Estimated Population 2040[3]	Estimated Percent Change 2022–2040
Clark County	1,895,521	2,265,926	19.5	2,916,000	28.7
Nevada	2,633,331	3,104,817	17.9	3,889,575	25.3

Sources: U.S. Census Bureau 2012,[1] 2023;[2] Center for Business and Economic Research 2025; Wright 2025[3]

Utah

Population changes in Utah are moderate compared with other states' analysis area counties. While Kane County had a 9.7 percent increase from 2010 to 2022, the population decreased in Garfield County (1.0 percent) and San Juan County (1.5 percent) over the same time period. Over the next 20 years, the population change is anticipated to accelerate, with a 25.0 percent increase in population predicted for Kane County, 11.4 percent for San Juan County, and 3.4 percent for Garfield County (see **Table TA 17-4**).

For Kane County, the main driver of population growth was net migration to the region of people 65 years and older, with quality-of-life indicators such as outdoor recreation being cited as main factors drawing people to the area (Utah Population Committee 2022).

Table TA 17-4
Utah Population 2010–2040

Geographic Area	Population 2010	Population 2022	Percent Change 2010–2022	Population 2040	Percent Change 2022–2040
Garfield County	5,172	5,121	-1.0	5,294	3.4
Kane County	7,125	7,814	9.7	9,769	25.0
San Juan County	14,746	14,524	-1.5	16,186	11.4
Utah	2,763,885	3,283,809	18.8	4,440,560	35.2

TA 17.1.2 Industrial and Municipal (Domestic) Water Uses

This section provides a brief overview of municipal water supply, demand, and use trends within the U.S. and the Lower Basin. This section also provides information on the municipalities within

Arizona, California, and Nevada with the potential to be affected by changes in domestic water availability.

Domestic water use includes the use of water for "household, stock, municipal, mining, milling, industrial, and other like purposes," 1922 Colorado River Compact, section II(h). More granularly, this includes indoor and outdoor uses at residences, and uses such as drinking, food preparation, bathing, washing clothes and dishes, flushing toilets, watering lawns and gardens, and maintaining pools. Domestic water use includes potable and non-potable water provided to households by a public water supplier (domestic deliveries) and self-supplied water use.

Domestic Water Supply, Demand, and Use Trends

Urbanization has increased the percentage of the U.S. population served by municipal water supplies from 70 percent in 1960 to 83 percent in 2021 (Liu et al. 2025). Per capita domestic water use in southwestern states varies regionally: residents in Arizona and Nevada use approximately 126–150 gallons per day, while California residents use 76–100 gallons per day (Chinnasamy et al. 2021; EPA 2025).

Although existing and ongoing municipal water management strategies do not change domestic water entitlement amounts, they illustrate how municipal systems have adapted—and may continue to adapt—to evolving water supply and demand conditions. This context is important for understanding how communities in the region respond to variability in water availability under different future conditions. Municipal water systems in these regions face growing pressures from population growth, climate trends, and uncertainties in future water availability, demand, and technological or policy adoption (Liu et al. 2025). Communities throughout the region have long implemented a range of water management strategies—including conservation programs, demand-side measures, operational changes, and infrastructure investments—to maintain municipal reliability under these evolving conditions.

Structural approaches such as dams, diversions, reservoirs, wastewater treatment facilities, and hydropower systems have historically played a critical role in supporting municipal water supply, while some more recent approaches involve building on existing infrastructure while emphasizing demand-side management through institutional, technological, and behavioral changes (Larson et al. 2016). Strategies can range from implementation of water-use efficiencies, changes to system operations, and demand reduction through water conservation programs. Implementation of water conservation programs has significantly decreased per capita water use (Chinnasamy et al. 2021; DeOreo et al. 2016; Finley and Basu 2020; Price et al. 2014). Water conservation programs in urban areas of the southwestern U.S., including Arizona, California, and New Mexico, have reduced per capita residential water use through targeted demand-side measures (Gleick 2010; Kennedy et al. 2012; Olmstead and Stavins 2009). Programs implementing high-efficiency appliances, leak detection, landscape irrigation restrictions, and tiered pricing reduced per capita demand by roughly 10–15 percent in some cities (Chinnasamy et al. 2021; DeOreo et al. 2016; Finley and Basu 2020; Price et al. 2014).

Across the analysis areas, municipal providers employ a range of adaptation measures to manage supply variability and shortages. In Arizona, measures commonly include demand management and

conservation; increased reliance on groundwater and stored supplies, including recharge and banking, where available; reclaimed water for non-potable demands; and system interconnections or operational changes. In California, measures commonly include conservation; recycled water expansion; stormwater capture and local recharge; groundwater management; interties and transfers, where available; and targeted supply or treatment improvements. In Nevada (Clark County), measures commonly include incentives to reduce outdoor water use, extensive reuse and return-flow management, and storage and exchange arrangements coupled with operational and infrastructure modifications to improve drought resilience. Many measures involve substantial capital costs and multiyear implementation timelines and may be constrained by legal or contractual availability, physical system capacity, water quality and treatment requirements, permitting, energy demands, and environmental considerations, which can limit feasibility or timing for some communities.

The availability of and access to domestic water can influence both population dynamics and land use and development. Population growth can increase the demand for water for domestic, agricultural, and industrial use and increase pressure on existing water sources. Studies have shown that population growth can be a dominant driver of long-term municipal water demand (Liu et al. 2025). Insufficient water supply can constrain population growth and development by limiting an area's capacity to support residents.

Peer-reviewed studies have documented the relationships between population growth, land-use patterns, and domestic water delivery. Urban sprawl, characterized by low-density development and increased impervious surfaces, has been shown to elevate per capita water demand through higher outdoor water use (Heidari et al. 2021). In contrast, high-density development often reduces water use per capita and can lessen the frequency and severity of water shortages. Rapid urbanization and population growth can also increase pressure on existing water infrastructure, creating challenges in maintaining consistent domestic water delivery.

Municipal water demand within the analysis areas is not solely a function of population or economic growth; it can reflect long-term trends in conservation, efficiency, reuse, land-use patterns, the climate, and provider policies. Many municipal providers in the Lower Basin have implemented demand management programs and operational practices that have reduced per capita use over time, such that total municipal demand may remain stable or grow more slowly than the population in some communities. Conversely, the magnitude of realized conservation and the remaining potential for additional cost-effective savings vary by provider due to differences in the existing program maturity, customer mix, climate, built environment, system losses, regulatory constraints, and local supply portfolios.

Municipal planning and development within the Lower Basin counties in the analysis areas rely on assumptions about the reliability, timing, and quality of water supplies used to serve existing and future demands. Within the analysis areas' counties, local governments and water providers typically integrate water supply expectations into general plans, zoning and subdivision decisions, capital improvement programs, and long-range utility master planning. These assumptions inform the sizing and sequencing of major infrastructure (for example, treatment, conveyance, storage, and pressure zones), operational and drought contingency planning, and the ability to maintain service standards under variable hydrologic conditions. Because many providers in these counties manage portfolio

supplies that may include Colorado River–derived deliveries alongside local surface water, groundwater, conservation, reuse, and interconnections, reliability expectations are often expressed not only as an annual volume but also in terms of operational availability during peak demand, drought response triggers, and constraints associated with treatment and regulatory compliance. Accordingly, changes in the reliability of Colorado River supplies can be relevant to municipal planning baselines and the context for evaluating potential effects related to domestic water shortages discussed in **Section TA 17.2.2**.

Water supply has influenced land use and development within the analysis areas. The Arizona Department of Water Resources' (ADWR) Assured and Adequate Water Supply Programs provide a concrete example of how water availability can constrain development. While not directly related to Colorado River water, these programs require developers within active management areas (AMAs) to demonstrate assured or adequate water supplies before recording plats or selling parcels. The Assured Water Supply Program requires that the following seven criteria be met: physical, continuous, and legal availability of water; water quality; financial capability; consistency with AMA management plans, and consistency with AMA management goals. The Adequate Water Supply Program requires demonstration of all criteria, excluding consistency with AMA management plan(s) and goal(s).

The Arizona Department of Real Estate will not issue the public report needed to market lots without such determinations (ADWR 2025). The ADWR's programs illustrate the role of water supply in constraining development, requiring developers to demonstrate reliable water before proceeding (ADWR 2025). This context provides one example of how planning assumptions for water supply relate to residential and commercial development and helps frame how communities might respond to changes in water availability under future conditions.

Domestic water supply reliability also supports baseline employment and community functions across the socioeconomic analysis area. **Section TA 16.1.2** in **TA 16**, Socioeconomics, provides baseline employment by sector for the Arizona, California, Nevada, and Utah counties included in the socioeconomic analysis area for 2010 and 2022 (see **Tables TA 16-1, 16-2, 16-6, 16-7, 16-11**, and **16-14**). These tables provide context for the composition of employment in the analysis areas, including sectors that typically rely on continuous municipal water service to support day-to-day operations and public services. Examples of these sectors include, but are not limited to, information; healthcare and social assistance; retail trade; real estate; arts, entertainment, and recreation; construction; finance and insurance; manufacturing; professional, scientific, and technical services; state and local government; and accommodation and food services. While county-level employment data do not distinguish among the water sources supporting certain sectors and the associated economic activity and public services, the sector employment helps frame domestic water supply, demand, and use trends in the counties included in the socioeconomic analysis area. In models of projected water yield and demand in the western U.S. to 2070, data indicate that demands for municipal water are increasing across the socioeconomic analysis area, while projected water availability is decreasing (see, for example, Warziniack and Brown 2019). While this trend is seen throughout the western U.S., the Colorado River region has the largest percentage increases in projected domestic water use and the greatest percentage decreases in projected water yield from all sources, including Colorado River water (Warziniack and Brown 2019).

TA 17.1.3 Study Area Municipalities

The analysis area is informed by the SAMs and includes the counties represented in the SAMs. Further, the municipalities described below include those represented in the SAMs.

Arizona

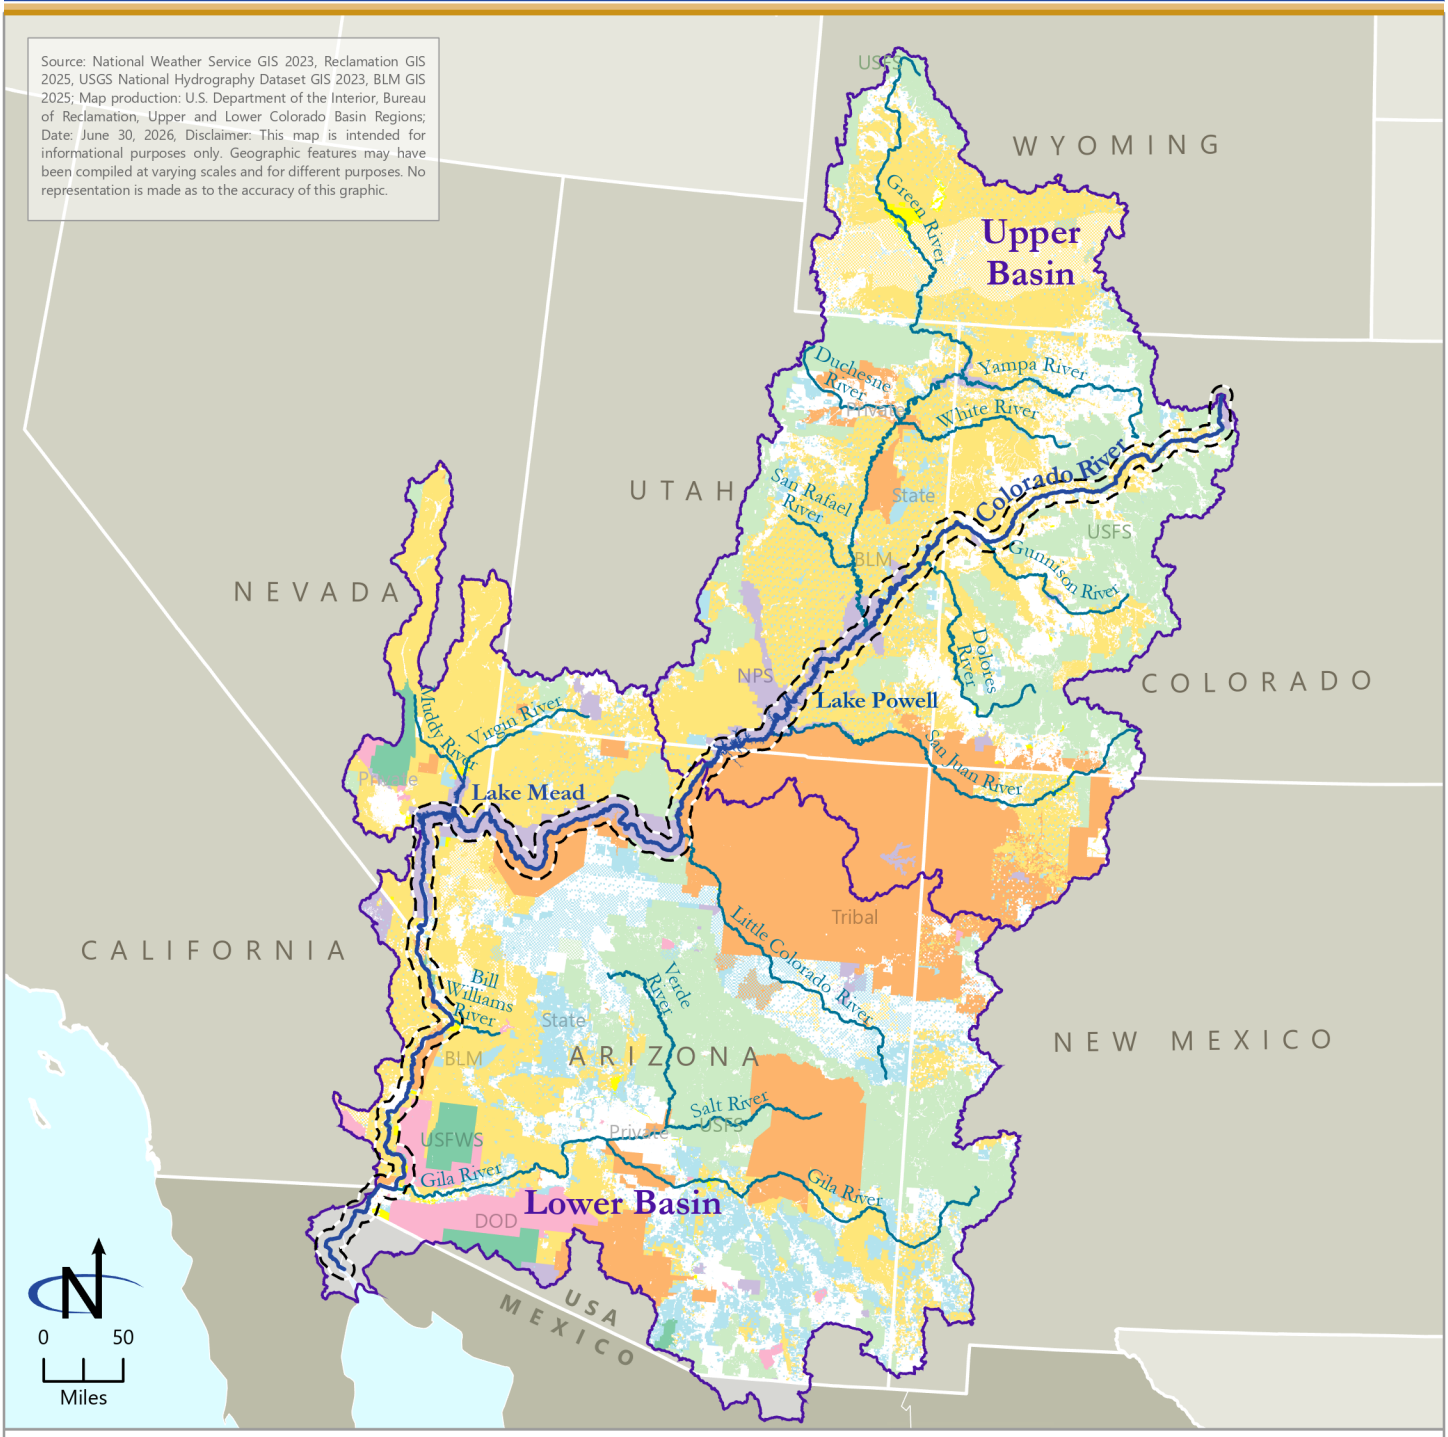
Municipalities potentially affected by the alternatives include Arizona municipalities along the Colorado River that have Colorado River water delivery contracts, such as Lake Havasu City, Yuma, and Bullhead City, as well as Phoenix, Tucson, Scottsdale, and other Arizona municipalities and tribal communities within the Central Arizona Project (CAP) service area, which includes more than 80 percent of the state's population (Central Arizona Project 2024). In Arizona, land uses on the Colorado River include the major power facilities of Glen Canyon Dam in Coconino County, Hoover and Davis Dams on the Arizona-Nevada border in Mohave County (and Clark County, Nevada), and Parker Dam in La Paz County (and San Bernardino County, California).

California

Municipalities potentially affected by the alternatives include 7 cities in Imperial County, 88 cities in Los Angeles County, 34 cities in Orange County, 28 cities in Riverside County, 24 cities in San Bernardino County, and 18 cities in San Diego County, as well as many more rural communities around the analysis area that are served by entities that use the Colorado River for water supply (California State Association of Counties 2024). These entities in California that use the Colorado River for water supply include the MWD, Imperial Irrigation District, Desert Water Agency, Coachella Valley Water District, Palo Verde Irrigation District, and tribal reservations (Metropolitan Water District of Southern California 2024).

Nevada

Municipalities potentially affected by the alternatives include Boulder City, Henderson, Las Vegas, Laughlin, and North Las Vegas due to their reliance on Colorado River water supplied by SNWA, which serves more than two million people in Clark County (Southern Nevada Water Authority 2024).



TA 17.1.4 Land Use

Introduction and Scope

This section describes existing land-use conditions along the mainstream Colorado River from Glen Canyon Dam to the U.S.-United Mexican States (Mexico) border. Land use includes recreation, agriculture, tribal land use, conservation and habitat management, residential and urban development, and utility and infrastructure corridors. **Map TA 17-1** shows the landownership.

— BUREAU OF —
RECLAMATION

Map TA 17-1
Land Ownership of the Colorado River Basin

Landownership and Management

Landownership along the Colorado River is highly variable and includes federal (National Park Service [NPS], Bureau of Land Management, U.S. Fish and Wildlife Service, and Reclamation), tribal, state, and private lands. Federal agencies manage much of the land in the upper and middle portions of the river corridor, particularly in areas surrounding Glen Canyon National Recreation Area, Grand Canyon National Park, Lake Mead National Recreation Area, and multiple national wildlife refuges. Tribal lands are prominent in both Arizona and California. State and private lands are more common in the Lower Basin, especially in urban areas like Bullhead City and Yuma, and along agricultural corridors in California and Arizona.

Developed Land Use

Land development has continued across the analysis areas over the past two decades. **Table TA 17-5** to **Table TA 17-8** summarize the number of acres classified as developed in 2001 and 2023 for each county in the analysis area, along with the percentage change during this period. The data are based on U.S. Geological Service (USGS) land cover classifications and provide a snapshot of how developed land has expanded over time. The table shows that most counties experienced growth in developed acreage, though the magnitude of change varies. State- and local-level details are provided in the state sub-sections below. This information establishes a baseline for understanding patterns of land use change within the socioeconomic analysis area and provides context for evaluating potential interactions between land development and Colorado River operations.

Table TA 17-5
Acres of Development from 2001 to 2023 in the Arizona Analysis Area

County in Arizona	Acres Developed[1] in 2001	Acres Developed in 2023	Percent Change
Apache County	45,500	67,400	48
Coconino County	81,000	104,300	29
Gila County	25,100	33,300	33
Maricopa County	544,800	727,400	34
Mohave County	106,100	137,600	30
Navajo County	47,300	65,700	39
Pima County	168,500	227,500	35
Pinal County	129,300	147,800	14
Yuma County	55,100	67,100	22
La Paz County	32,200	35,100	9

Source: USGS 2023

[1] Acreages classified as "developed" include low-, medium-, and high-intensity development or roads. Low-intensity development can include mixed forest, herbaceous, and shrubland cover.

Arizona

Counties in the Arizona analysis area all had an increase in developed land use in the last 20 years. The largest increase was in Apache (48 percent) and Navajo (39 percent) Counties, while Maricopa, Pima, Gila, and Mohave Counties also had 30 percent or more of growth. The smallest increase was in Pinal County (14 percent) and La Paz County (9 percent; **Table TA 17-5**).

California

A few counties in the California analysis area, including Los Angeles, San Diego, and Orange Counties, showed slight declines in developed acreage between 2001 and 2023. These decreases may reflect land reclassification or changes in land-use patterns rather than large-scale removal of development. San Bernardino County had the largest increase in the California analysis area, with 14 percent growth from 2001 to 2023 (see **Table TA 17-6**).

Table TA 17-6
Acres of Development from 2001 to 2023 in the California Analysis Area

County in California	Acres Developed[1] in 2001	Acres Developed in 2023	Percent Change
Imperial County	83,100	86,100	4
Los Angeles County	861,800	833,100	-3
Orange County	305,800	293,400	-4
Riverside County	407,700	425,600	4
San Bernardino County	424,200	483,000	14
San Diego County	479,400	469,600	-2

Source: USGS 2023

[1] Acreages classified as "developed" include low-, medium-, and high-intensity development or roads. Low-intensity development can include mixed forest, herbaceous, and shrubland cover.

Nevada

Compared with other counties in the region, Clark County, Nevada, had robust growth in the past 20 years. At 37 percent, this increase was met or exceeded by only one county in Utah and one in Arizona (see **Table TA 17-7**).

Table TA 17-7
Acres of Development in the Nevada Analysis Area from 2001 to 2023

County in Nevada	Acres Developed[1] in 2001	Acres Developed in 2023	Percent Change
Clark County	214,800	294,000	37

Source: USGS 2023

[1] Acreages classified as "developed" include low-, medium-, and high-intensity development or roads. Low-intensity development can include mixed forest, herbaceous, and shrubland cover.

Utah

Development in some portions of the Utah analysis area, notably Garfield County (37 percent) and Kane County (18 percent), were higher than regional averages from 2001 to 2023. San Juan County, in contrast, saw only a 10 percent increase in developed acres (**Table TA 17-8**).

Table TA 17-8
Acres of Development in the Utah Analysis Area from 2001 to 2023

County in Utah	Acres Developed[1] in 2001	Acres Developed in 2023	Percent Change
Garfield County	28,900	39,700	37
Kane County	17,300	20,400	18
San Juan County	31,000	34,200	10

[1] Acreages classified as "developed" include low-, medium-, and high-intensity development or roads. Low-intensity development can include mixed forest, herbaceous, and shrubland cover.

TA 17.1.5 Agricultural Land Use

Arizona

In the western U.S., agriculture represents a relatively small share of overall land use, but it requires large amounts of irrigation water. The most water-intensive crops include crops for food, feed, and fiber production. In Arizona, in 2015, irrigated agriculture accounted for about 74 percent of the state's water use; more than 50 percent of this is from surface waters (Dieter et al. 2018). Implementation of certain recent strategies and techniques in the western U.S. has reduced agriculture's share of water consumption. These methods include improvements in irrigation technology, voluntary fallowing programs that compensate farmers who reduce water consumption, and utilization of more effective irrigation strategies, such as changes to irrigation timing and using cover crops to protect the soil (Presson and Eden 2023). However, conservation methods do not reduce the legal water entitlement held by agricultural users.

Pinal, Maricopa, and Pima Counties account for approximately 50 percent of statewide irrigated, harvested cropland (USDA NASS 2024). Colorado River water in these counites is associated primarily with tribal agricultural users receiving CAP water. Agricultural resources in western Arizona are primarily along the Colorado River in Mohave, La Paz, and Yuma Counties and along the Gila River Valley in Yuma County. These western counties account for approximately 32 percent of irrigated agricultural land in Arizona. **Table TA 17-9** provides a summary of county-wide irrigated agricultural lands within the Arizona analysis area.

Production of winter vegetables and leafy greens in the U.S. is seasonally concentrated in the irrigated desert production regions of the Southwest. The U.S. Department of Agriculture's (USDA) Economic Research Service notes that from mid-November through early April, most lettuce sold in the U.S. is sourced from Southern California's Imperial County and the Yuma area of Arizona, and that shipments from Florida help fill in regional market gaps during winter and spring months (Weber 2023).

Table TA 17-9
Irrigated Acres of Harvested Cropland in the Arizona Analysis Area (2022)

Area	Irrigated Harvested Cropland (Acres)	Total Harvested Cropland (Acres)	Percent Irrigated Harvested Cropland to Total Harvested Cropland	Percentage of Statewide Irrigated Harvested Cropland
Maricopa County	202,086	202,092	100	23

(D) = The USDA determined the data are too sensitive to disclose.
— = not applicable
[1] The totals for the Arizona analysis area do not include data for Mohave County because the USDA determined the data were too sensitive to disclose; however, the totals for Arizona include data for Mohave County.

Table TA 17-10 shows changes between 2017 and 2022 in acres of irrigated harvested cropland and in acres of total harvested cropland in each county in the Arizona analysis area. In all counties where data were disclosed, except Maricopa County, there was a decrease in acreage of harvested cropland. In Pima, Pinal, and Gila Counties, this decrease in acreage of harvested cropland corresponded with a similar percent decrease in irrigated harvested cropland. In Navajo and Yuma Counties, the reduction in harvested cropland was largely made up of non-irrigated cropland. In Apache County, the reduction in harvested cropland was fully made up of non-irrigated cropland, and irrigated harvested cropland saw an increase from 2017 to 2022. In Maricopa County, where there was an increase in total harvested cropland, the increase corresponded to an increase in irrigated cropland (USDA NASS 2024).

Table TA 17-10
Irrigation Trend for Harvested Cropland in the Arizona Analysis Area (2017–2022)

Area	Percent Change in Irrigated Harvested Cropland	Percent Change in Total Harvested Cropland
Maricopa County	13.5	7.8
Pima County	-5.6	-5.7

[1] The totals for the Arizona analysis area do not include data for Coconino, Mohave, and La Paz Counties because the USDA determined the data were too sensitive to disclose; however, the totals for Arizona include data for all counties in the state.

Table TA 17-11 shows the proportion of irrigation water that came from all surface water resources in each county in the analysis area in 2015. In Apache County and Maricopa County, where there were increases in irrigated harvested cropland from 2017 to 2022, approximately 94 percent and 21 percent of the irrigated water comes from surface waters, respectively. In Gila County and Navajo County, which had the largest percentage decrease in irrigated harvested cropland from 2017 to 2022, approximately 30 percent and 54 percent of the irrigation water comes from surface waters, respectively (see **Table TA 17-10** and **Table TA 17-11**).

Table TA 17-11
Percentage of Irrigated Water from Surface Water Sources (2015)[1]

Area	Percentage of Irrigated Water Withdrawal for Crops from Surface Waters

[1] The 2015 USGS water use (for specific purposes, such as irrigation) data by source (surface water or groundwater, etc.) are the most recent available county-level data.
[2] CAP values are the aggregated values of Maricopa, Pima, and Pinal Counties. Surface water sources include all sources; they are not exclusive to the Colorado River.

California

About 96 percent of harvested cropland in the California analysis area is irrigated, which is the same as the percentage of irrigated harvested cropland for California. However, the percentage varies across the counties in the analysis area, ranging from a low of 68 percent in Los Angeles County to a high of 99 percent in San Bernardino County. The proportion of irrigated croplands within the California analysis area represents approximately 11 percent of total irrigated croplands in the state. **Table TA 17-12** shows the acres of irrigated harvested and total harvested cropland within the California analysis area.

Table TA 17-13 shows changes between 2017 and 2022 in acres of irrigated harvested cropland and in acres of total harvested cropland in each county in the analysis area. In Imperial, Los Angeles, and Riverside Counties, there was an increase in the number of acres of harvested cropland and in irrigated harvested cropland. However, in Orange, San Bernardino, and San Diego Counties, there was a decrease in the number of acres of harvested cropland that corresponded to a similar decrease in the number of irrigated harvested cropland acres (USDA NASS 2024).

Table TA 17-12
Irrigated Acres of Harvested Cropland in the California Analysis Area (2022)

Area	Irrigated Harvested Cropland (Acres)	Total Harvested Cropland (Acres)	Percent Irrigated Harvested Cropland to Total Harvested Cropland	Percentage of Statewide Irrigated Harvested Cropland

[1] The 2015 USGS water use (for specific purposes, such as irrigation) data by source (surface water or groundwater, etc.) are the most recent available county-level data.

Nevada

Agriculture in the Nevada analysis area—Clark County—is small, with only 2,322 total acres for harvested cropland (USDA NASS 2024). Of the total harvested agricultural lands in Clark County, 100 percent were irrigated cropland, which is similar to the percentage of irrigated cropland in Nevada (99.8 percent; see **Table TA 17-15**). In Nevada, in 2015, irrigated agriculture accounted for about 71 percent of the state's water use; approximately 53 percent of this was from surface waters (Dieter et al. 2018). Approximately 35 percent of the irrigated water in Clark County comes from surface waters (see **Table TA 17-16**).

TA 17.1.6 Land Use and Management by Reach

Upper Reach (Glen Canyon Dam to Lees Ferry)

This reach is dominated by federal lands managed by the NPS as part of Glen Canyon National Recreation Area. Land use is primarily recreational, with boating, fishing, and sightseeing as the dominant uses. Infrastructure in this reach includes the Glen Canyon Dam and associated access roads. These facilities are sensitive to reservoir elevation changes, and declining water levels may in reduced functionality, relocation needs, or closure.

Grand Canyon Reach (Lees Ferry to Lake Mead)

The NPS manages most land in this reach as part of Grand Canyon National Park. Land use is regulated to preserve natural and cultural resources and to provide for controlled public recreation. Access is limited, and development is minimal. This reach includes tribal lands, which are used for tourism and cultural purposes.

Lower Basin Reach (Hoover Dam to U.S.–Mexico Border)

Land use in this reach is more varied. It includes the following:

- Urban development near Las Vegas, Bullhead City, Lake Havasu City, and Yuma
- Extensive irrigated agriculture in areas such as the Palo Verde and Imperial Valleys
- Recreation and habitat management within national wildlife refuges (Cibola, Havasu, and Imperial)
- Transportation and utility corridors, including transmission lines and canals

Landownership in this reach includes a greater proportion of state and private land, and land use is more intensive compared with upstream reaches. Also, fluctuating water levels can affect the usability of the reach's recreation facilities and require adaptive management, such as ramp extensions, marina relocations, or temporary closures. These infrastructure elements are vital to supporting recreation and tourism in the region and may be affected under the alternatives that result in lower Lake Mead elevations.

Water delivery constraints may influence future land-use decisions in this reach. Some counties could experience changes in agricultural viability and development patterns due to reduced water reliability (see **TA 4**, Water Deliveries).

TA 17.2 Environmental Consequences

TA 17.2.1 Methodology

The analysis of population and land-use impacts evaluates (1) how operational changes and changes to domestic water delivery could affect the overall population and land-use patterns, including developed lands for residential and commercial uses, and (2) how operational changes and changes to irrigation water delivery could affect lands used for irrigated agriculture.

To analyze how operational changes may affect population and land-use patterns (Issue 1), DMDU was applied to the modeled shortage to domestic users provided by the SAMs and Alternative Distribution Models (ADMs). There are three unique SAMs and five Alternative Distribution Models to capture the nuances of the alternatives and sensitivity analyses; these are further explained in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation. **Table C-1** in **Appendix C** provides a crosswalk between the alternatives and SAMs and ADMs. The application of DMDU to analyze domestic water impacts involved multiple steps. First, to capture variation in modeled shortage by priority across the SAMs, the following priority groupings were established: Arizona CAP non-Indian agriculture (NIA)-A and NIA-B (Group 1), Arizona CAP municipal and industrial (M&I) and Priority 4(i) (Group 2), Arizona Priorities 2 and 3 (Group 4), Arizona present perfected right (PPR) (Group 5), California Priority 4 (Group 6), California PPR (Group 7), Nevada Priority 8 (Group 8), Nevada Priorities 1–7 (Group 9). Second, the modeled domestic shortage was analyzed for each of these priority groups, to identify at which shortage level, the average percentage shortage across a given priority group equals approximately 20, 40, 60, 70, 80, or 100 percent of the priority group's total entitlement.

DMDU was then applied to generate **Figure TA 17-1** through **Figure TA 17-8**. These figures are the result of applying SAM-based, volumetric thresholds of the Lower Basin shortage to annual shortage volumes computed from the Colorado River Simulation System. The figures display the percentage of modeled futures in which annual domestic water delivery to a given priority group are always the specified percentage of "normal delivery," across the alternatives. For purpose of this analysis, "normal delivery" is defined as a full Colorado River or CAP entitlement supply. The figures provide a comparison of impacts on domestic water by priority group across the action alternatives. While this appendix focuses on domestic shortage impacts to priority groups, domestic shortage impacts for each entitlement can be found in **Appendix C**. Refer to **Table C-1** and the following tables in **Appendix C** for entitlement-level impacts:

- **Table C-19**, Priority Shortage Allocation Model Domestic Summary
- **Table C-24**, Continuing Current Strategies Shortage Allocation Model Domestic Summary
- **Table C-29**, Lower Basin Priority Shortage Allocation Model Domestic Summary
- **Table C-41**, Pro Rata Alternative Distribution Model Domestic Summary
- **Table C-46**, Lower Basin Pro Rata Alternative Distribution Model Domestic Summary

To analyze how operational changes may affect agricultural land use (Issue 2), the analysis relied on modeled shortages to irrigation users at the state level, produced by the SAMs. For more detailed information on the SAMs and consumptive impacts on irrigation users, see **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation**.** For more information on water deliveries and shortage impacts, including those for irrigation, refer to **TA 4**, Water Deliveries.

For analysis of how operational changes may impact socioeconomic conditions related to agriculture, recreation, and nonmarket values and associated county-level socioeconomic data, refer to **TA 16**, Socioeconomics. Because baseline county-level socioeconomic data do not distinguish among water sources supporting economic activity (including non-Colorado River sources or blended supplies), and comparable utility-specific financial and economic modeling inputs are not uniformly available across all municipal providers and service areas in the analysis areas, the analysis in this technical appendix provides a qualitative discussion of municipal impact pathways using the modeled delivery-reliability and shortage outputs from **TA 4**, Water Deliveries. With respect to hydropower and reservoir elevation thresholds, **TA 15**, Dams and Electrical Power Resources, evaluates how the alternatives affect the frequency of operations that would fail to meet customary or desirable firm capacity, energy generation, facility operability, and electricity rate and market value outcomes.

Impact Analysis Areas

The analysis area for the population and land-use section is separated by state and is the same for both population and land-use issues. The impact analysis area is defined by those counties that may be affected by management direction that could result in water shortages to domestic and irrigation users. As described above, both issue statements rely on the SAMs. As a result, the analysis area is informed by the SAMs and includes the counties represented in the SAMs. The Arizona analysis area consists of Apache, Coconino, Gila, La Paz, Maricopa, Mohave, Navajo, Pima, Pinal, and Yuma Counties. These are counties that are directly adjacent to Lake Powell, Lake Mead, or the Colorado River and counties in which shortages would likely occur. The California analysis area consists of Imperial, Los Angeles, Orange, Riverside, San Bernardino, and San Diego Counties. The Nevada analysis area consists of Clark County. The Nevada analysis area was limited to Clark County because Clark County is adjacent to Lake Mead and encompasses SNWA's service area and other individual water providers. Shortages in Nevada would be limited to SNWA's service area.

Assumptions

- Colorado River operations do not directly control population change, but they may indirectly influence migration patterns.
- Local socioeconomic conditions and demographic trends may also be influenced by factors outside river operations, such as housing costs, infrastructure investment, local attitudes toward water conservation, and regional employment patterns.
- In most cases, the contractor, subcontractor, or entitlement holder of an allocation is shown as the entity bearing shortage. In some cases, water allocated to an entitlement holder (for example, a tribal CAP contractor) may lease its allocation to other users (for example, to a non-Indian municipality). The SAMs and ADMs do not attempt to replicate those arrangements, and they only provide approximate estimates at the level of the entitlement

holder, contractor, or subcontractor. The entitlement holder, contractor, or subcontractor to the leasing arrangements would have specific decisions to make during Shortage Conditions to administer those arrangements; Reclamation cannot predict those decisions with sufficient certainty to analyze them in this Final Environmental Impact Statement (EIS).

Impact Indicators

- Shortage to domestic water users
- Acres of developed land within the analysis areas and the potential for changes based on municipal water availability
- Acres of irrigated agricultural land within the analysis areas and the potential for changes based on agricultural water availability

TA 17.2.2 Issue 1: How would operational changes affect population and developed land-use patterns?

This issue examines how different operational strategies may influence population dynamics and developed land-use patterns in communities that rely on Colorado River water for municipal water uses. While Colorado River operations do not directly determine population movement or developed land-use patterns, long-term changes in water availability and recreational access may influence migration patterns and developed land patterns. This issue statement is analyzed by first presenting the DMDU figures and a detailed analysis for domestic water delivery and then by assessing how domestic water delivery changes would impact population and developed land-use patterns.

The analysis for this issue statement evaluates how modeled changes in domestic (municipal) delivery reliability may influence population- and land-use-related outcomes, including constraints on residential and commercial development and potential qualitative effects on existing communities reliant on municipal water supplies. The analysis uses modeled changes in domestic water delivery reliability to understand how communities and land-use-related conditions may be constrained. DMDU results are interpreted as indicators of exposure to domestic shortage and associated impacts; they are not direct forecasts of economic output or sector-specific impacts. Additionally, population is not treated as a direct proxy for consumptive use because conservation, reuse, and local policy can substantially mediate demand. Modeled domestic shortage outcomes are derived from the water deliveries analysis in **TA 4**, Water Deliveries and the shortage allocation frameworks documented in **Appendix C**; because allocations are modeled based on entitlement structures and assumptions, results may not capture all potential place-of-use transfers or future programmatic adjustment that could occur through separate agreements or actions. Quantitative economic impact estimates at the municipality level were not developed across the full analysis area due to inconsistent availability of comparable economic, utility finance, and sector-specific data across all municipal providers; therefore, this appendix describes pathways qualitatively and references related analyses in other sections and appendixes, where applicable.

TA 16, Socioeconomics, provides baseline socioeconomic context for the analysis area, including employment by sector for 2010 and 2022 (**Tables TA 16-1, 16-2, 16-6, 16-7, 16-11**, and **16-14** in **Section TA 16.1.2**). These baseline data describe economic conditions and the composition of

employment in the counties included in the socioeconomic analysis area; however, baseline county-level socioeconomic data do not distinguish among water sources supporting economic activity (including non-Colorado River sources or blended municipal portfolios), and comparable utility-specific financial and economic modeling inputs are not uniformly available across municipal providers and service areas. Accordingly, this appendix does not forecast sector-specific production or employment impacts. Instead, this appendix uses the modeled domestic delivery outcomes and delivery-reliability results reported in **TA 4**, Water Deliveries, together with the modeling frameworks documented in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation, discuss qualitative pathways by which reduced municipal delivery reliability may affect community conditions and land-use-related outcomes.

Domestic water delivery impacts are discussed in the context of a DMDU analysis framework. Additional information on the DMDU robustness and vulnerability concepts used to interpret these results is provided in **Appendix E**, DMDU Overview and Approach. Modeling assumptions and shortage allocation frameworks that inform domestic delivery outcomes are documented in **TA 4**, Water Deliveries, and the Final EIS discussion recognizes that adaptation feasibility and constraints vary by location and provider.

In addition to potential constraints on future development, reductions in municipal delivery reliability could affect existing residents and essential services. Severe or abrupt delivery reductions can create operational challenges for conveyance and treatment systems and may affect service reliability depending on local infrastructure and operational constraints. For instance, damage to CAP infrastructure or other diversion facilities can occur under low- or no-flow conditions. In addition, depending on local system configuration and available alternative supplies, severe or abrupt delivery reductions may require additional conservation measures or development of replacement supplies over time. The degree to which these effects would occur, and the time required to adapt, varies by community and is influenced by existing conservation achievements, infrastructure, regulatory requirements, and local hydrologic conditions.

As described in **Section TA 17.1**, water supply reliability is a key input to municipal planning and development. Municipal providers within the analysis area may have structured infrastructure investments, regulatory compliance strategies, and economic development assumptions around continued Colorado River supplies and delivery reliability. Where domestic water shortages reduce available Colorado River deliveries, potential effects may include the need to revise supply planning assumptions; changes in the timing, scale, or sequencing of infrastructure and compliance investments; and constraints or delays affecting planned development or other investments that rely on a defined level of Colorado River domestic water supply. The degree to which these effects may occur would vary by community because municipal supply portfolios, contractual arrangements, demand management capacity, and regulatory contexts differ by provider. Although utility- and project-specific decisions (for example, local growth management actions, capital programming, and rate-setting) would occur outside the scope of this EIS, reduced supplies could increase reliance on alternative sources and require adaptation measures (for example, additional supplies, treatment upgrades, system interconnections, conservation actions, and financing). Such measures can require substantial time and resources to plan, permit, fund, and implement and may not be achievable on the same schedule for all communities.

Similarly, reductions in municipal delivery may result in secondary impacts that may affect the socioeconomic setting and quality of life in affected communities. These impacts may include but are not limited to changes to public and private space landscaping, changes to the quality or availability of recreational opportunities which require water use, impacts to property value, and changes to economic contributions and employment opportunities associated with businesses which rely on domestic water. As noted above, the degree to which these effects would occur varies by community and is influenced by geography (on-river and rural areas), existing conservation achievements, infrastructure, regulatory requirements, adaptation capacity, and local hydrologic conditions.

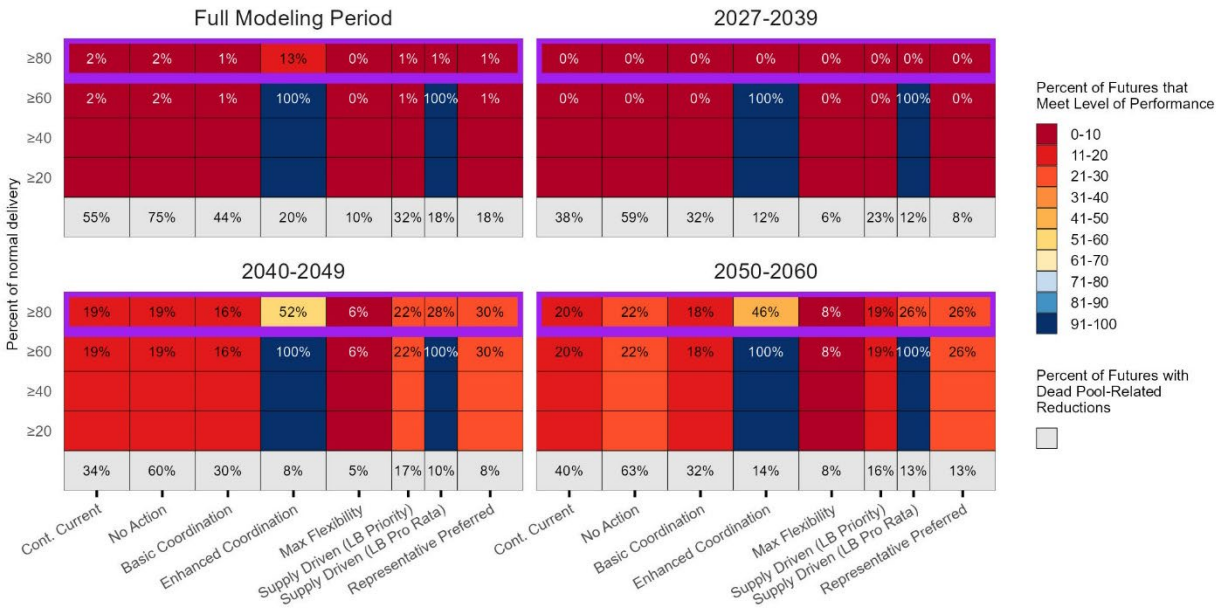
In evaluating these outcomes, it is important to recognize that the DMDU framework highlights the potential for a wide range of plausible future conditions that cannot be predicted with confidence. Factors such as climate trends, hydrologic change, and evolving population or land-use trends may interact in complex ways that influence domestic water delivery. Therefore, while robustness provides an indicator of how well an alternative performs across many possible futures, decision makers should consider these uncertainties when interpreting results and determining which management approaches are most adaptive and resilient under changing conditions.

Incorporating DMDU principles supports a transparent and adaptive evaluation by considering a range of plausible futures rather than a single forecast. This approach helps decision makers understand the trade-offs, vulnerabilities, and adaptive capacity of each alternative, enhancing the resilience of long-term management strategies.

The alternatives with greater robustness would likely result in fewer potential indirect impacts on population growth and developed land. Greater robustness corresponds to a higher percentage of futures in which domestic water delivery remains consistent with normal conditions and shortages occur less frequently. In contrast, less robust alternatives are more susceptible to reductions in domestic water availability because modeled shortages occur more frequently or the volume of shortage is higher. These shortages could manifest as reduced water deliveries, delivery restrictions, or the need for additional conservation measures, which could in turn limit the capacity to meet domestic water demand. A more robust alternative would therefore help ensure that domestic water supplies remain reliable to support existing populations and accommodate anticipated future growth, thereby minimizing potential secondary impacts on development patterns and land use.

Figure TA 17-1 through **Figure TA 17-8** display potential impacts on domestic water deliveries by presenting the percentage of normal domestic water deliveries that can be achieved across a range of modeled futures. Specifically, each figure shows the percentage of normal domestic water deliveries that can be achieved in 90 percent of years, over a 34-year modeling period, across different percentages of potential futures for each priority group. The metric of 90 percent of years was selected for this analysis, rather than 100 percent of years, because it better displays variation between the alternatives. For each figure, the rows represent different performance thresholds, as percentages of normal domestic water delivery. Higher rows indicate a higher volume of delivery (closer to normal conditions) and are therefore more difficult to achieve across a large percentage of potential futures, while lower rows represent lower levels of delivery that are easier to achieve because they allow for more frequent modeled shortages to domestic water delivery. For this

analysis, greater than 80 percent of normal delivery in 90 percent of years was selected as the minimum level of performance. This row was highlighted because it represents the performance level closest to normal domestic water delivery of the thresholds displayed in the figures, while also representing the earliest point at which differences among alternatives begin to emerge in the DMDU results. In other words, the greater than 80 percent row reflects the least amount of modeled shortage to domestic water users displayed in the figures and is the first row where shortages begin to manifest across alternatives.



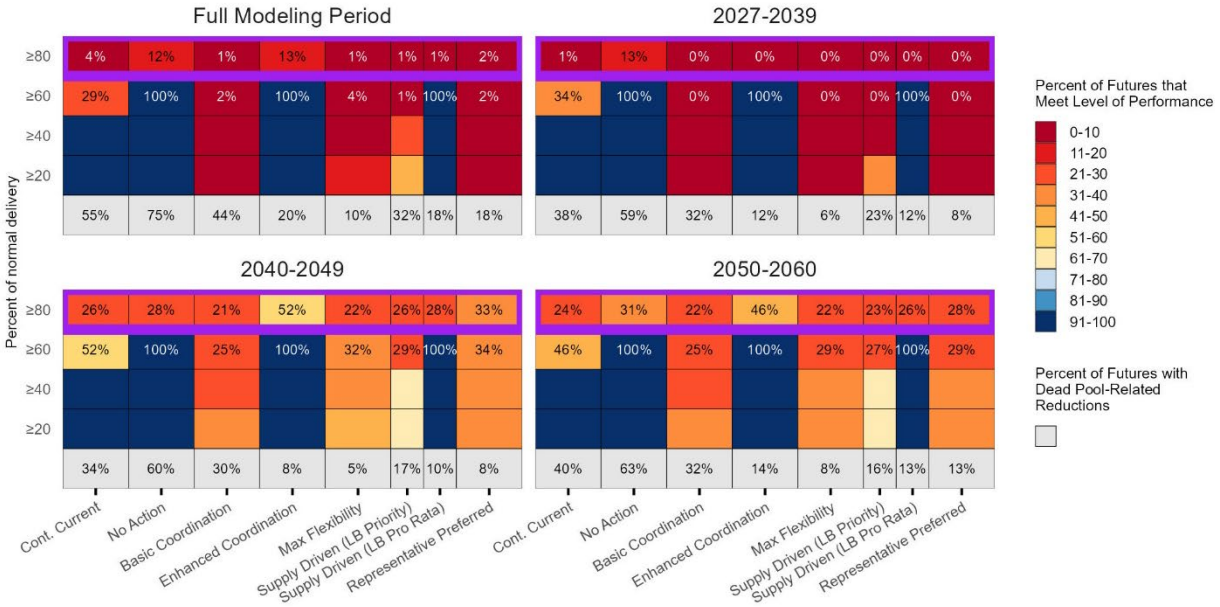
Each figure also displays a row at the bottom for percent futures with dead pool–related reductions. As described in **TA 4**, Water Deliveries, dead pool–related reductions occur when there is not enough water in Lake Mead to fully meet downstream demands and/or when Hoover Dam infrastructure constraints result in releases below the demand volume. In some cases, this occurs because Lake Mead is approaching dead pool (elevation 895 feet) and in some cases it occurs earlier (up to elevation 950 feet). The approach to distributing reductions associated with dead pool is not addressed in this analysis. By providing the information on dead pool–related reductions in the domestic water, the DMDU figures provide additional context on the robustness of the alternatives. **Figure TA 17-1** through **Figure TA 17-8** are described in further detail below.

Figure TA 17-1 through **Figure TA 17-8** display the full modeling period and each of the decadal subperiods within the full modeling period. Across all priority groups, the DMDU modeling results displayed in **Figure TA 17-1** through **Figure TA 17-8** follow a pattern: performance across all alternatives is poorest in the first decade of the modeling period (2027 – 2039). This is because 2027 begins with relatively low reservoir elevations, which results in poorer first decade performance. This is an expected consequence of the initial system state and observed data from the years immediately prior to the modeling rather than a modeling anomaly.

Figure TA 17-1 presents potential shortage impacts on domestic water deliveries to Arizona CAP NIA-A and NIA-B priorities.

Across the first decade of the modeling period (2027–2039), there are no potential futures in which any of the alternatives meet the preferred minimum performance (greater than 80 percent of normal domestic water is delivered in 90 percent of years) for the Arizona CAP NIA-A and NIA-B priorities. Therefore, all alternatives would result in similar impacts on shortage for domestic deliveries to Arizona CAP NIA-A and NIA-B priorities. Under these alternatives, shortages would be high for these users, and domestic deliveries would not be consistent with annual normal delivery.

Figure TA 17-1
Arizona CAP, NIA-A & NIA-B: Robustness
Percentage of futures in which annual delivery is the percentage of normal domestic delivery specified in each row in at least 90 percent of years



The next level below the preferred minimum performance is greater than 60 percent of normal domestic water delivery to Arizona CAP NIA-A and NIA-B priorities. When considering this next level of performance, the Enhanced Coordination and Supply Driven (Lower Basin Pro Rata [LB Pro Rata] approach) Alternatives are the most robust alternatives for CAP NIA-A and NIA-B priorities compared with all other alternatives, with greater than 60 percent of normal delivery in 90 percent of years occurring in 100 percent of potential futures across the first decade of the modeling period (2027 – 2039). The Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives perform well for CAP NIA-A and NIA-B priorities at lower volumes of delivery because they apply pro rata distribution of Lower Basin shortage (shortage is distributed evenly across entitlement holders). Note that with a priority-based distribution, water is distributed to those with more senior water entitlements first, with senior water entitlements facing less shortage. In contrast, with pro rata distribution, shortage is distributed proportionately across all entitlements, regardless of their seniority, with all users bearing some shortage. Therefore, it makes sense that these two alternatives would be the most robust alternative in terms of domestic water delivery to junior priority pools such as the Arizona CAP NIA-A and NIA-B, compared with the other alternatives. If dead pool–related reductions, which may impact these users, are considered, the Enhanced Coordination Alternative remains the most robust alternative compared with the Continued Current Strategies (CCS) Comparative Baseline and the No Action Alternative (as well as all action alternatives).

Under the Representative Preferred Alternative, there are no potential futures in which there is any percentage of normal domestic water delivery to Arizona CAP NIA-A and NIA-B priorities.

However, the modeling results in 2027-2039 for the Representative Preferred Alternative displayed in **Figure TA 17-1**, above, are not necessarily the anticipated impacts in 2027-2028 under the Preferred Alternative for Arizona CAP NIA-A and NIA-B based on the May 1 proposal by Lower Division States, which represents the best available information at the time of publication. This proposal would distribute shortage according to the Lower Basin Priority (LB Priority) approach. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results are heavily influenced by shortages in 2029-2039, which are distributed according to the Priority distribution. See **Chapter 2** and **Appendix C**, **Table C-1** for additional information. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage).

Figure TA 17-2, below, presents potential shortage impacts on domestic water deliveries to Arizona CAP Indian, CAP M&I, and 4(i) priorities.

Figure TA 17-2
Arizona CAP Indian, CAP M&I and 4(i): Robustness
Percentage of futures in which annual delivery is the percentage of normal domestic delivery specified in each row in at least 90 percent of years

Across the first decade of the full modeling period (2027–2039), there are no or minimal (less than 0-13 percent) potential futures in which any of the alternatives, meet the selected level of performance (greater than 80 percent of normal domestic water is delivered in 90 percent of years) for the Arizona CAP Indian, CAP M&I, and 4(i) priorities. As displayed in **Figure TA 17-2** above, greater than 80 percent of normal delivery occurs in 13 percent of potential futures under the No Action Alternative and 1 percent of potential futures under the CCS Comparative Baseline. There are no potential futures in which greater than 80 percent of normal delivery to Arizona CAP Indian, CAP M&I and 4(i) priority holders occurs under the Basic Coordination, Maximum Operational Flexibility, and the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives.

Under the Enhanced Coordination Alternative, greater than 80 percent of normal delivery occurs in 12 percent and 13 percent of potential futures, respectively. Therefore, when compared with the No Action Alternative, all other alternatives are less robust. While greater than 80 percent of normal delivery occurs in the highest number of potential futures under the No Action Alternative, making it the most robust alternative, it is important to note that this is still a minimal percentage of futures (13 percent). Therefore, there would be potential shortage impacts on domestic water deliveries to Arizona CAP Indian, CAP M&I and 4(i) priority holders across all alternatives.

The next row below the preferred minimum performance is greater than 60 percent of normal domestic water delivery to Arizona CAP Indian, CAP M&I, and 4(i) priorities. When considering this next level of performance, the No Action, Enhanced Coordination, and Supply Driven (LB Pro Rata approach) Alternatives are the most robust for these users compared with the other alternatives, with greater than 60 percent of normal domestic water delivery occurring in 100 percent of futures across the first decade of the modeling period (2027–2039). Under the CCS Comparative Baseline, greater than 60 percent of normal delivery occurs in 34 percent of potential futures. Generally, deeper shortages do not occur for the No Action and Basic Coordination Alternatives and the CCS Comparative Baseline. For the CCS Comparative Baseline and the No Action Alternative, this is because the shortages do not extend far into the apportionments of the Lower Division States. However, it is important to note that for the No Action Alternative and the CCS Comparative Baseline, across the first decade of the modeling period the percentage of futures with dead pool–related reductions are 38 percent and 59 percent, respectively. The No Action, Enhanced Coordination, and Supply Driven (LB Pro Rata approach) Alternatives would result in similar impacts on shortage for Arizona CAP M&I and Priority 4(i). However, if dead pool–related reductions, which may impact these users, are considered, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives are the most robust alternatives for these users compared with the CCS Comparative Baseline and the No Action Alternative (as well as all action alternatives). These two alternatives perform well for domestic entitlement holders at lower volumes of delivery because they use pro rata distributions.

Under the Representative Preferred Alternative, there are no potential futures in which there is any percentage of normal domestic water delivery to Arizona CAP M&I and Priority 4(i) priorities. However, the modeling results in 2027-2039 for the Representative Preferred Alternative displayed in **Figure TA 17-2**, are not necessarily the anticipated impacts in 2027-2028 under the Preferred Alternative for Arizona CAP M&I and Priority 4(i) based on the May 1 proposal by Lower Division States, which represents the best available information at the time of publication. This proposal would distribute shortage according to the LB Priority approach. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results are heavily influenced by shortages in 2029-2039, which are distributed according to the Priority distribution. See **Chapter 2** and **Appendix C**, **Table C-1** for additional information. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage).

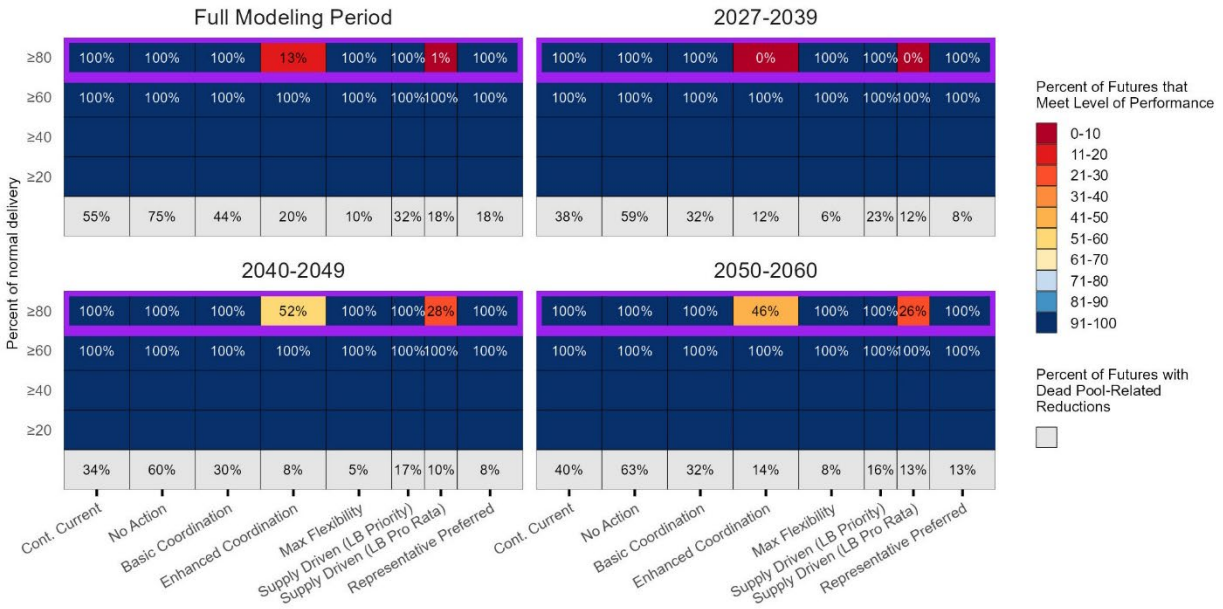
Figure TA 17-3, below, presents potential shortage impacts on domestic water deliveries to Arizona Priorities 2 and 3.

Across the first decade of the full modeling period (2027 – 2039), greater than 80 percent of normal domestic water delivery to Arizona Priorities 2 and 3 would occur in 100 percent of potential futures under all the alternatives, excluding the Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (LB Pro Rata approach), and Representative Preferred Alternatives. Under the Maximum Operational Flexibility and Representative Preferred Alternatives, on average over the first decade of the modeling period, greater than 80 percent of normal delivery occurs in 26 percent and 54 percent of potential futures, respectively. This is because the Maximum Operational Flexibility and Representative Preferred Alternatives apply priority-based distribution with higher maximum shortage volumes. Under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, greater than 80 percent of normal delivery to Arizona Priorities 2 and 3 occurs in no potential futures. This is because the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives use a pro rata distribution, thus shortage is distributed evenly across entitlement holders regardless of the seniority of water entitlements. Overall, the Supply Driven Alternative (LB Pro Rata approach) is the least robust for these users, followed by the Enhanced Coordination Alternative compared with the other alternatives. Under these alternatives, shortages would be higher, and domestic deliveries would not be consistent with normal annual delivery.

Figure TA 17-3
Arizona Priorities 2 and 3: Robustness
Percentage of futures in which annual delivery is the percentage of normal domestic delivery specified in each row in at least 90 percent of years

Across the first decade of the modeling period (2027–2039), under the No Action, Basic Coordination, and Supply Driven (LB Priority approach) Alternatives and the CCS Comparative Baseline, greater than 80 percent of normal domestic water is delivered to Arizona Priorities 2 and 3 in 100 percent of potential futures. There would be no impacts on domestic shortage for Arizona Priorities 2 and 3, except under the Enhanced Coordination, Maximum Operational Flexibility,

Supply Driven (LB Pro Rata approach), and Representative Preferred Alternatives. Therefore, the No Action, Basic Coordination, and Supply Driven (LB Priority approach) Alternatives and the CCS Comparative Baseline would result in similar impacts on shortage for Arizona Priorities 2 and 3. However, if dead pool–related reductions, which may impact these users, are considered, the Supply Driven Alternative (LB Priority approach) is the most robust alternative compared with the CCS Comparative Baseline and No Action Alternative (as well as all action alternatives).



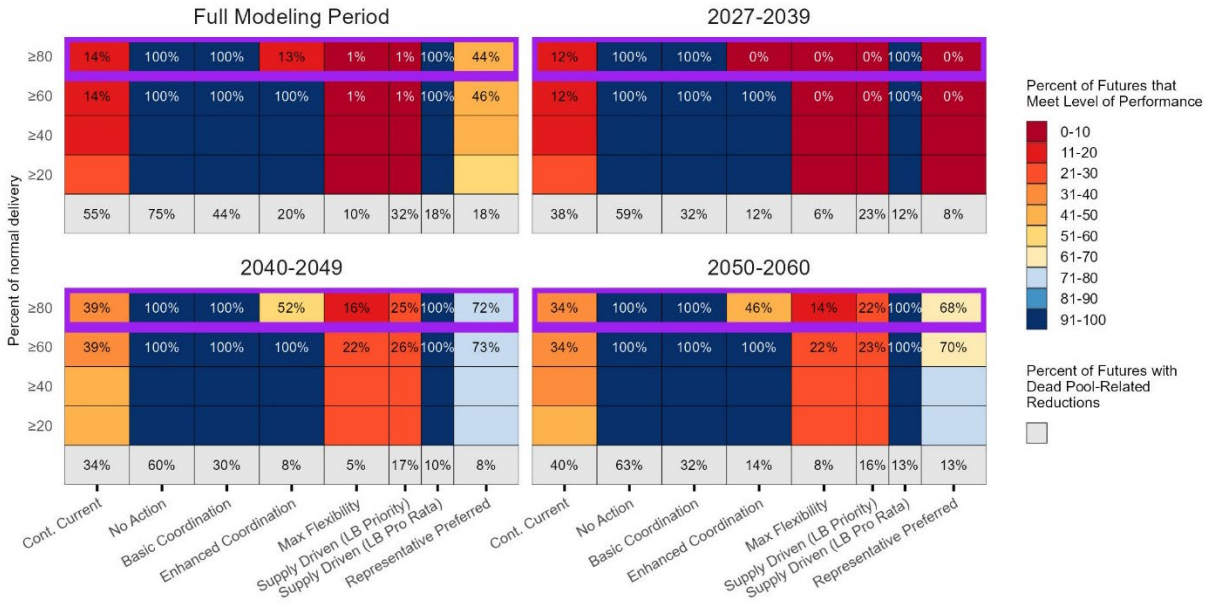
Across the first decade of the modeling period (2027–2039), greater than 80 percent of normal domestic water is delivered to Arizona Priorities 2 and 3 in 54 percent of potential futures under the Representative Preferred Alternative. Greater than 60 percent of normal domestic water is delivered to Arizona Priorities 2 and 3 in 58 percent of potential futures. However, the modeling results in 2027-2039 for the Representative Preferred Alternative displayed in **Figure TA 17-3**, above, are not necessarily the anticipated impacts in 2027-2028 under the Preferred Alternative for Arizona Priorities 2 and 3 based on the May 1 proposal by Lower Division States, which represents the best available information at the time of publication. This proposal would distribute shortage according to the LB Priority approach. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results are heavily influenced by shortages in 2029-2039, which are distributed according to the Priority distribution. See **Chapter 2** and **Appendix C**, **Table C-1** for additional information. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage).

Figure TA 17-4, below, presents potential shortage impacts on domestic water deliveries to Arizona PPR.

Across the first decade of the modeling period (2027–2039), greater than 80 percent of normal domestic water delivery to Arizona PPR occurs in 100 percent of potential futures under all alternatives, excluding the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives. Under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, greater than 80 percent delivery to Arizona PPR occurs in no potential futures. However, greater than 60 percent of normal delivery occurs in 100 percent of potential futures under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives. This is because the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives apply a pro rata distribution, thus shortage is distributed evenly across entitlement holders regardless of the seniority of water entitlements. Under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives (the least robust alternatives for these users), shortages would be higher, and domestic deliveries would not be consistent with annual normal delivery. Under the No Action, Basic Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives and the CCS Comparative Baseline, greater than 80 percent of normal delivery to Arizona PPR occurs in 100 percent of futures. There would be no impacts on shortage for Arizona PPR, except under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives. Therefore, the No Action, Basic Coordination, Maximum Operational Flexibility, and Supply Driven (LB Priority approach) Alternatives and the CCS Comparative Baseline would result in similar impacts on shortage for Arizona PPR. However, if dead pool–related reductions, which may impact these users, are considered, the Maximum Operational

Flexibility Alternative is the most robust compared with the CCS Comparative Baseline and the No Action Alternative (as well as all the action alternatives).

Figure TA 17-4
Arizona Present Perfected Rights: Robustness
Percentage of futures in which annual delivery is the percentage of normal domestic delivery specified in each row in at least 90 percent of years

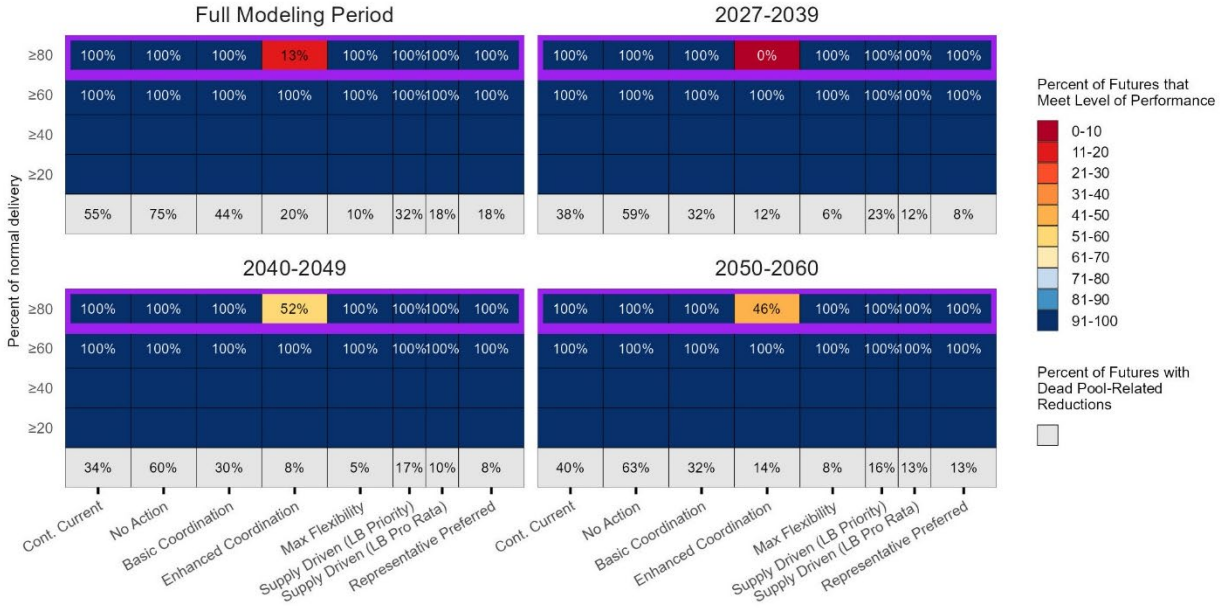


Across the first decade of the modeling period (2027–2039), greater than 80 percent of normal domestic water is delivered to Arizona PPR priority holders in 100 percent of potential futures under the Representative Preferred Alternative. Under this alternative, modeled shortages occur less frequently, and domestic deliveries remain consistent with annual normal delivery for these users.

However, the modeling results in 2027-2039 for the Representative Preferred Alternative displayed in **Figure TA 17-4**, above, are not necessarily the anticipated impacts in 2027–2028 under the Preferred Alternative for Arizona PPR based on the May 1 proposal by Lower Division States, which represents the best available information at the time of publication. This proposal would distribute shortage according to the LB Priority approach. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results are heavily influenced by shortages in 2029-2039, which are distributed according to the Priority distribution. See **Chapter 2** and **Appendix C**, **Table C-1** for additional information. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage).

Figure TA 17-5, below, presents potential shortage impacts on domestic water deliveries to California Priority 4.

Figure TA 17-5
California Priority 4: Robustness
Percentage of futures in which annual delivery is the percentage of normal domestic delivery specified in each row in at least 90 percent of years



Across the first decade of the modeling period (2027–2039), greater than 80 percent of normal domestic water is delivered to California Priority 4 under the No Action, Basic Coordination, and Supply Driven (LB Pro Rata approach) Alternatives. Under the CCS Comparative Baseline, greater than 80 percent delivery to California Priority 4 occurs in 12 percent of potential futures. Under the Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives, greater than 80 percent delivery to California Priority 4 occurs in zero percent of potential futures. When compared with the No Action Alternative and the CCS Comparative Baseline, the Supply Driven (LB Pro Rata approach) and Basic Coordination Alternatives are the most robust action alternatives. However, an additional alternative is robust when looking at the next row of normal water delivery: greater than 60 percent of normal delivery. When considering this next level of performance, the No Action, Basic Coordination, Enhanced Coordination, and Supply Driven (LB Pro Rata approach) Alternatives would result in similar impacts on shortage for California Priority 4, with greater than 60 percent of normal domestic water delivery occurring 100 percent of futures across the first decade of the modeling period. However, it is important to note that under the No Action Alternative, there are 59 percent of futures with dead pool–related reductions across the first decade of the modeling period. In contrast, there are 32 percent, 12 percent, and 12 percent of futures with dead pool–related reductions under the Basic Coordination, Enhanced Coordination, and Supply Driven (LB Pro Rata approach) Alternatives across the first decade of the modeling period. When considering dead pool–related reductions, which may impact these users, the Supply Driven Alternative (LB Pro Rata approach) is the most robust, followed by the Basic Coordination Alternative, compared with the CCS Comparative Baseline and the No Action Alternative (as well as all action alternatives).

Across the first decade of the modeling period (2027–2039), there are no potential futures in which there is any percentage of normal domestic water delivery to California Priority 4 under the Representative Preferred Alternative. Under this alternative, modeled shortages occur more frequently, and domestic deliveries would not be consistent with normal annual delivery for these users. However, the modeling results in 2027-2039 for the Representative Preferred Alternative displayed in **Figure TA 17-5,** above are not necessarily the expected impacts in 2027–2028 under the Preferred Alternative for California Priority 4 based on the May 1 proposal by Lower Division States, which represents the best available information at the time of publication. This proposal would distribute shortage according to the LB Priority approach. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results are heavily influenced by shortages in 2029-2039, which are distributed according to the Priority distribution. See **Chapter 2** and **Appendix C**, **Table C-1** for additional information. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage).

Figure TA 17-6, below, presents potential shortage impacts on domestic water deliveries to California PPR.

Figure TA 17-6
California Present Perfected Rights: Robustness
Percentage of futures in which annual delivery is the percentage of normal domestic delivery specified in each row in at least 90 percent of years

Across the first decade of the modeling period (2027–2039), greater than 80 percent of normal domestic water is delivered to California PPR in 100 percent of potential futures under all alternatives, excluding the Enhanced Coordination Alternative. While there are no potential futures in which greater than 80 percent delivery to California PPR occurs under the Enhanced Coordination Alternative, greater than 60 percent delivery to California PPR occurs in 100 percent

of potential futures under this alternative. Again, this is because the Enhanced Coordination Alternative uses a pro rata distribution, thus shortage is distributed evenly across entitlement holders regardless of the seniority of water entitlements. Because the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives and the CCS Comparative Baseline meet the preferred minimum performance in 100 percent of futures, there is no domestic shortage to California PPR, except under the Enhanced Coordination Alternative. While the all alternatives, excluding the Enhanced Coordination Alternative, would result in similar impacts on shortage, if dead pool–related reductions, which may impact these users, are considered, the Maximum Operational Flexibility Alternative followed by the Representative Preferred Alternative, are the most robust alternatives compared with the CCS Comparative Baseline and the No Action Alternative (as well as all action alternatives).

Across the first decade of the modeling period (2027–2039), greater than 80 percent of normal domestic water is delivered to California PPR priority holders in 100 percent of potential futures under the Representative Preferred Alternative. Under this alternative, modeled shortages occur less frequently, and domestic deliveries remain consistent with annual normal delivery for these users. However, the modeling results in 2027-2039 for the Representative Preferred Alternative displayed in **Figure TA 17-6**, above are not necessarily the expected impacts in 2027–2028 under the Preferred Alternative for California PPR based on the May 1 proposal by Lower Division States, which represents the best available information at the time of publication. This proposal would distribute shortage according to the LB Priority approach. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results are heavily influenced by shortages in 2029-2039, which are distributed according to the Priority distribution. See **Chapter 2** and **Appendix C**, **Table C-1** for additional information. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage).

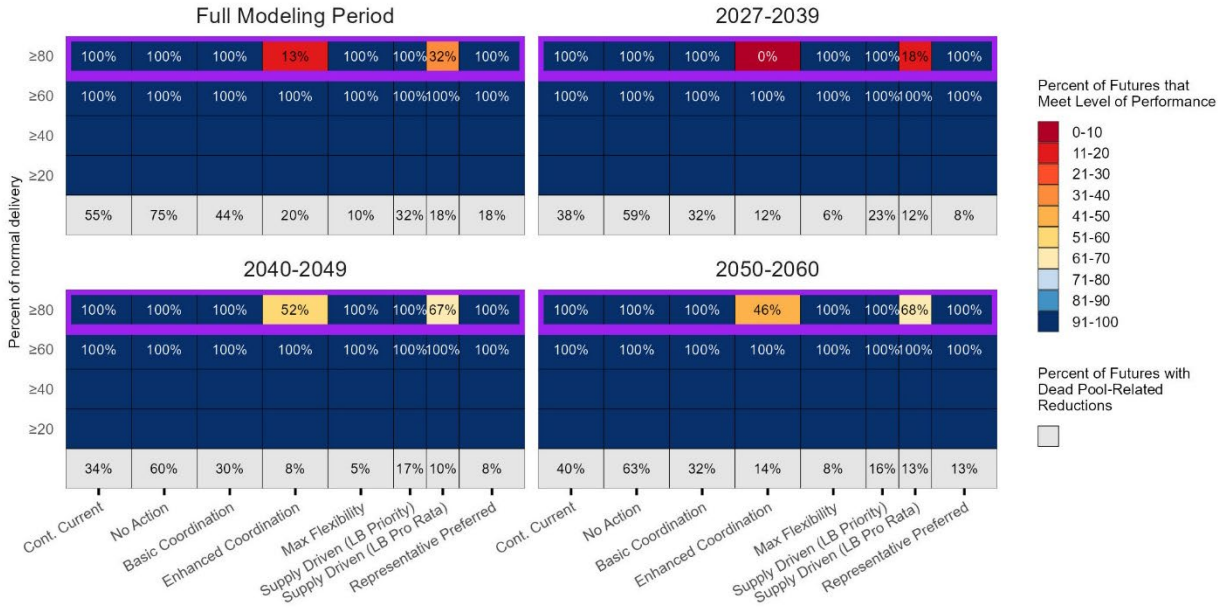


Figure TA 17-7, below, presents potential shortage impacts on domestic water deliveries to Nevada Priorities 1-7.

Across the first decade of the modeling period (2027–2039), greater than 80 percent of normal delivery to Nevada Priorities 1-7 occurs in 100 percent of potential futures under all alternatives, excluding the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives. Under the Enhanced Coordination and Supply Driven (LB Priority approach) Alternatives, greater than 80 percent delivery to Nevada Priorities 1-7 occurs in 0percent and 18 percent of potential futures, respectively. This makes sense because the Enhanced Coordination and Supply Driven (LB Priority approach) Alternatives apply a pro rata distribution, where shortage is distributed evenly across all entitlements regardless of the seniority of water entitlements. Under all alternatives, greater than 60 percent of normal delivery occurs in 100 percent of futures.

Across the first decade of the modeling period (2027–2039), greater than 80 percent delivery occurs in 100 percent of potential futures under the CCS Comparative Baseline and the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives. Therefore, there would be no impacts on shortage to Nevada

Priorities 1-7, except under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives. While the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives would result in similar impacts on shortage, if dead pool–related reductions, which may impact these users, are considered, the Maximum Operational Flexibility Alternative followed by the Representative Preferred Alternative, are the most robust alternatives compared with the CCS Comparative Baseline and the No Action Alternative (as well as all action alternatives).

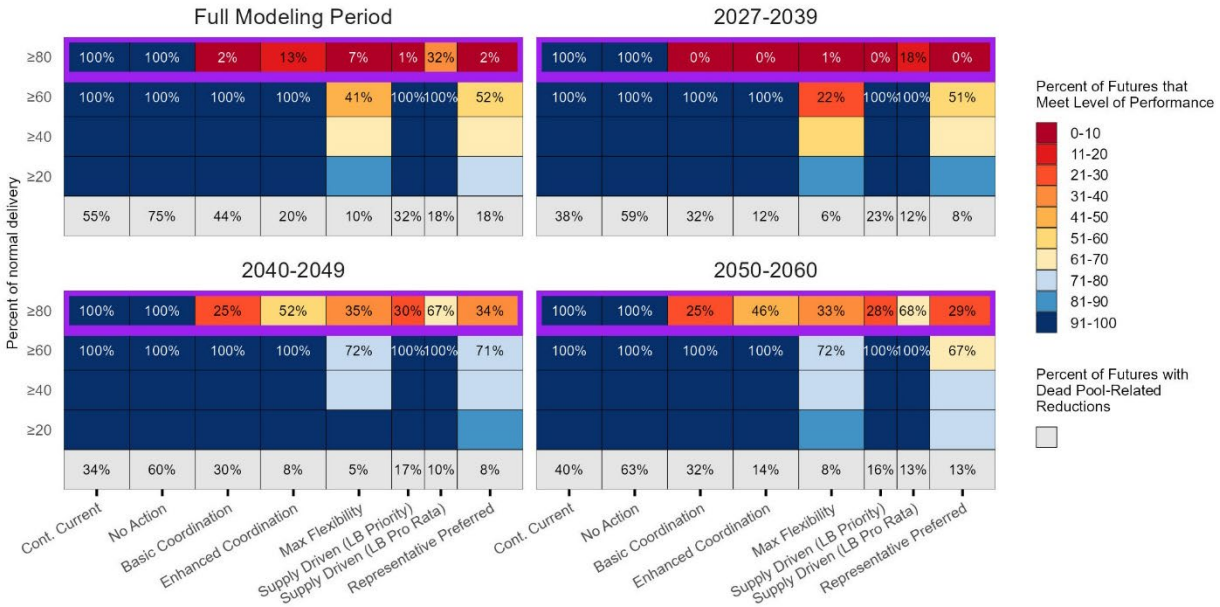

Figure TA 17-7
Nevada Priorities 1-7: Robustness
Percentage of futures in which annual delivery is the percentage of normal domestic delivery specified in each row in at least 90 percent of years

Across the first decade of the modeling period (2027–2039), greater than 80 percent of normal domestic water is delivered to Nevada Priorities 1-7 in 100 percent of potential futures under the Representative Preferred Alternative. Under this alternative, modeled shortages occur less frequently, and domestic deliveries remain consistent with annual normal delivery for these users. However, the modeling results in 2027-2039 for the Representative Preferred Alternative displayed in **Figure TA 17-7**, above are not necessarily the expected impacts in 2027–2028 under the Preferred Alternative for Nevada Priorities 1-7 based on the May 1 proposal by Lower Division States, which represents the best available information at the time of publication. This proposal would distribute shortage according to the LB Priority approach. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results are heavily influenced by shortages in 2029-2039, which are distributed according to the Priority distribution. See **Chapter 2** and **Appendix C**, **Table C-1** for additional information. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage).

Figure TA 17-8, below, presents potential shortage impacts on domestic water deliveries to Nevada Priority 8.

Figure TA 17-8
Nevada Priority 8 (Including Balance and Surplus): Robustness
Percentage of futures in which annual delivery is the percentage of normal domestic delivery specified in each row in at least 90 percent of years

Across the first decade of the modeling period (2027–2039), greater than 80 percent delivery to Nevada Priority 8 (including Balance and Surplus) occurs in 100 percent of futures under the CCS Comparative Baseline and the No Action Alternative. For all other alternatives, the percentage of potential futures in which greater than 80 percent of normal delivery occurs varies. Under both the Basic Coordination, Enhanced Coordination, Supply Driven (LB Priority approach), and Representative Preferred Alternatives greater than 80 percent of normal delivery occurs in no potential futures. Under the Maximum Operational Flexibility and Supply Driven (LB Pro Rata approach) Alternatives, greater than 80 percent delivery to Nevada Priority 8 occurs in 1 percent and 18 percent of potential futures, respectively. Generally, deeper shortages do not occur for the CCS Comparative Baseline and the No Action and Basic Coordination Alternatives. For the CCS Comparative Baseline and the No Action Alternative, this is because the shortages do not extend far into Nevada's apportionment. However, it is important to note that for the CCS Comparative Baseline and the No Action Alternative, the percentage of futures with dead pool–related reductions are 38 percent and 59 percent, respectively, across the first decade of the modeling period.

The next level below the preferred minimum performance is greater than 60 percent of normal domestic water delivery to Nevada Priority 8. Across the first decade of the modeling period, greater than 60 percent of normal delivery occurs in 100 percent of futures for all alternatives except the Maximum Operational Flexibility and Representative Preferred Alternatives. The Maximum Operational Flexibility Alternative, followed by the Representative Preferred Alternative, are the

least robust compared with the other alternatives, because Maximum Operational Flexibility and Representative Preferred Alternatives apply a priority-based distribution with higher maximum shortage volumes. When considering this next level (greater than 60 percent delivery), and considering dead pool–related reductions, the Basic Coordination, Enhanced Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are the most robust compared with the other alternatives, with greater than 60 percent of normal domestic water delivery occurring in 100 percent of futures across the first decade of the modeling period. Additionally, when considering dead pool–related reductions, which may impact these users, dead pool–related reductions would be lowest under the Enhanced Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives. Overall, the Enhanced Coordination, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would result in similar impacts on shortage. However, when considering dead pool–related reductions, which may impact these users, the Supply Driven Alternative (LB Pro Rata approach) and the Enhanced Coordination Alternative would be the most robust compared with the CCS Comparative Baseline and the No Action Alternative (as well as all action alternatives). Under these alternatives, modeled shortages occur less frequently, and domestic deliveries remain consistent with normal annual delivery for these users.

Across the first decade of the modeling period (2027–2039), there are no potential futures in which greater than 80 percent of normal domestic water is delivered to Nevada Priority 8 under the Representative Preferred Alternative. Greater than 60 percent of normal domestic water is delivered to Nevada Priority 8 in 51 percent of potential futures. Under this alternative, modeled shortages occur more frequently, and domestic deliveries would not be consistent with normal annual delivery for these users. However, the modeling results in 2027-2039 for the Representative Preferred Alternative displayed in **Figure TA 17-8**, above are not necessarily the expected impacts in 2027–2028 under the Preferred Alternative for California Priority 4 based on the May 1 proposal by Lower Division States, which represents the best available information at the time of publication. This proposal would distribute shortage according to the LB Priority approach. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results are heavily influenced by shortages in 2029-2039, which are distributed according to the Priority distribution. See **Chapter 2** and **Appendix C**, **Table C-1** for additional information. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage).

TA 17.2.3 DMDU Analysis Summary

The DMDU analysis allows for comparison of the alternatives in terms of potential shortage impacts on domestic entitlements. When comparing the domestic water impacts, it is important to note that a more robust alternative results in a higher percentage of potential futures where domestic water delivery remains consistent with normal conditions and shortages occur less frequently. Conversely, a less robust alternative yields fewer futures with normal domestic water delivery and a higher frequency of shortages.

The SAMs used to inform the DMDU analysis do not incorporate water management measures such as conservation programs or demand-reduction strategies. These measures do not change entitlement amounts or shortages; however, as described in the affected environment section,

conservation programs and other management strategies can influence domestic water demand and help mitigate the operational pressures associated with shortage, uncertain supply, and population growth. Therefore, while the model results presented here do not capture these measures, the potential impacts of shortages on domestic water supply for the Lower Basin would also depend in part on existing and future conservation and management actions implemented by states, local water providers, and individual users. Potential impacts would also depend on other external factors such as environmental and economic conditions.

Communities and municipal providers may respond to shortages through a range of adaptation measures, which could include increased conservation and demand management, use of existing storage or water banking arrangements where available, investments in infrastructure (for example, treatment upgrades, reuse, interconnections), operational changes, or pursuit of alternative supplies and agreements. The feasibility, timing, and effectiveness of these measures would vary by location and provider, and may be constrained by physical and geographic availability of replacement water, jurisdictional and legal limitations (including state-law and contractual considerations), the time required for planning, permitting, financing, and construction, and constraints related to existing infrastructure configurations and prior investments. Adaptation measures may also involve direct and indirect economic costs to providers and ratepayers and may require trade-offs among objectives under different future conditions. Consistent with the DMDU framework, these uncertainties and constraints should be considered when interpreting robustness results and evaluating the extent to which an alternative can reduce both direct delivery impacts and potential secondary effects on development patterns and land use. **Table TA 17-17**, Summary of Potential Effects on Domestic Water by Alternative, below, provides an overview of impacts on domestic water by alternative based on the DMDU figures discussed in detail above. The table demonstrates how the different alternatives perform in terms of percentage of normal delivery in potential futures. **Table TA 17-17** includes two performance indicators: greater than 80 percent of normal delivery and greater than 60 percent of normal delivery in 90 percent of potential futures, across the first decade of the modeling period. The table displays how each alternative performs for these two performance indicators, by priority group. The performance indicators illustrate how each alternative performs in maintaining domestic water deliveries under a wide range of uncertain future conditions. The alternatives that would achieve greater than 80 percent of normal delivery in 90 percent of years demonstrate strong robustness, indicating that domestic deliveries would remain near normal levels across most modeled futures. These alternatives would result in fewer and less severe shortages, which would provide greater reliability for domestic water users. This performance indicator is difficult to achieve under many alternatives. To show further variation across the alternatives, **Table TA 17-17** includes greater than 60 percent of normal delivery in 90 percent of years. The alternatives that only meet the greater than 60 percent of normal delivery in 90 percent of years threshold demonstrate lower robustness. Under these conditions, more frequent domestic delivery reductions or shortages could occur in modeled futures, particularly for junior priority groups. Such outcomes could increase the likelihood of secondary socioeconomic impacts, including constraints on growth or secondary changes in land development patterns.

As shown in **Table TA 17-17**, for the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives, which apply a priority-based distribution of shortage, under most modeled futures, water users with senior

entitlements would likely continue to experience relatively consistent domestic water deliveries, as these entitlements are contractually prioritized during periods of reduced supply. However, junior entitlements could face greater reductions in water deliveries during Shortage Conditions. Consequently, while senior entitlement holders may maintain service levels closer to normal, junior entitlement holders could experience more frequent or severe delivery constraints.

As shown in **Table TA 17-17**, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, which apply pro rata distribution of shortage, under most modeled futures, would generally allow a larger number of priority groups to receive domestic water deliveries closer to normal conditions. While a pro rata approach would change the distribution of water across all users during shortages, this section solely focuses on the distribution of water to domestic users. This approach would deviate from the priority-based distribution, resulting in some modeled reductions to domestic deliveries for some senior entitlement holders who would otherwise maintain normal domestic delivery under the existing priority system. In contrast, more domestic junior priority water entitlement holders continue to receive some level of water supply under this approach. In general, the pro rata method would result in more existing users receiving moderate water deliveries during shortages through a redistribution of water from senior entitlements.

As described in **Section TA 17.1**, Affected Environment, peer-reviewed studies document that domestic water availability significantly influences population dynamics and land use. To provide a high-level overview of potential impacts on domestic water and the associated impacts on population and land-use patterns, key summaries are also provided below for Arizona, California, and Nevada.

Table TA 17-17
Summary of Potential Effects on Domestic Water by Alternative

Impact Category	Performance Indicator	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority approach)	Supply Driven Alternative (LB Pro Rata approach)	Representative Preferred Alternative
Priority Group: Arizona CAP NIA-A and NIA-B	Percentage of potential futures in which greater than 80 percent of normal domestic delivery occurs 90 percent of the time, across the first decade of the modeling period. The higher the percentage, the more robust an alternative is with respect to achieving normal domestic deliveries.[1]	**0 percent** of modeled futures meet the performance definition.	**0 percent** of modeled futures meet the performance definition.	**0 percent** of modeled futures meet the performance definition.	**0 percent** of modeled futures meet the performance definition.	**0 percent** of modeled futures meet the performance definition.	**0 percent** of modeled futures meet the performance definition.	**0 percent** of modeled futures meet the performance definition.

Impact Category	Performance Indicator	Impacts Summary						
		No Action Alternative	**Basic Coordination Alternative**	**Enhanced Coordination Alternative**	**Maximum Operational Flexibility Alternative**	**Supply Driven Alternative (LB Priority approach)**	**Supply Driven Alternative (LB Pro Rata approach)**	**Representative Preferred Alternative**
How would operational changes affect irrigated agricultural land-use patterns?	Acres of irrigated agricultural land within the corridor and potential for changes based on agricultural water availability.	Frequent and severe shortages for junior priority irrigation users likely lead to fallowing, crop switching, and long-term land retirement in Arizona CAP counties; Imperial Valley remains protected.	Capped shortages reduce extreme outcomes but concentrated impacts in Arizona still drive significant agricultural land-use changes; California remains insulated.	Pro rata distribution mitigates concentrated impacts but introduces broader reductions, increasing risk of widespread crop switching and fallowing in both Arizona and California.	Large shortage volumes and reliance on conservation participation create high uncertainty; potential for extensive land retirement if participation is low.	Concentrates impacts on junior users, preserving senior districts but accelerating land-use change in Arizona CAP counties.	Distributes shortages broadly, increasing exposure for California and potentially leading to widespread fallowing and crop switching across the Basin.	The representative preferred alternative for 2027-2028 would result in shortages, with impacts concentrated on junior users. In the longer term (2029-2060) modeled outcomes indicate potential for additional fallowing land and crop switching, with impacts concentrated on junior users. However, the distribution of shortage under any specific operating guidelines adopted under the Preferred Alternative decision framework may differ from the priority distribution method reflected here for the Representative Preferred Alternative, as a result, the potential for fallowing, crop switching, and other associated long term land - use patterns in any given area may vary and impacts may be mitigated in part by specific operational guidelines.

Arizona: Figure TA 17-1 through **Figure TA 17-4** display potential impacts on domestic water deliveries for Arizona priority groups**.** Across the first decade of the modeling period, the No Action, Basic Coordination, and Supply Driven (LB Priority approach) Alternatives would result in similar impacts on water supply for more senior entitlements (Arizona Priorities 2 and 3 and Arizona PPR), with greater than 80 percent of normal delivery occurring in 100 percent of potential futures. In other words, there would be no domestic shortage impacts for Arizona PPR and Priorities 2 and 3 under these alternatives. However, potential impacts do vary under the other action alternative for these two priority groups. Under all alternatives, excluding the Enhanced Coordination Alternative, 100 percent of normal delivery to Arizona PPR occurs in 100 percent of potential futures. Under the Maximum Operational Flexibility and Representative Preferred Alternatives, greater than 80 percent of normal delivery to Arizona Priorities 2 and 3 occurs in 26 percent and 54 percent of potential futures, respectively. Compared with the No Action, Basic Coordination, and Supply Driven (LB Priority approach) Alternatives, the Maximum Operational Flexibility and Representative Preferred Alternatives are more robust with respect to achieving normal domestic deliveries to Arizona PPR and less robust with respect to achieving normal domestic deliveries to Arizona Priorities 2 and 3. When considering dead pool–related reductions, which may impact these users, the Supply Driven Alternative (LB Priority approach) is the most robust of the alternatives, followed by the Basic Coordination Alternative, with respect to achieving normal domestic deliveries to more senior entitlements (Arizona Priorities 2 and 3 and PPR). Under these alternatives, there is a higher percentage of potential futures where domestic water delivery to Arizona PPR, Priority 2, and Priority 3 remains consistent with normal conditions. A higher percentage of potential futures with greater than 80 percent of normal delivery could support existing communities, future population growth, water demand, and development in areas serviced by these priority groups. Because the Basic Coordination and Supply Driven (LB Priority approach) Alternatives have greater robustness for Arizona PPR, Priority 2, and Priority 3, there could be fewer potential indirect impacts on population and land-use-related outcomes for existing communities and on future population growth and land development.

In contrast, the CCS Comparative Baseline, and the Basic Coordination, Maximum Operational Flexibility Supply Driven (LB Priority approach), and Representative Preferred Alternatives would result in similar impacts on shortage for more junior entitlements (Arizona CAP NIA-A, CAP NIA-B, CAP Indian, M&I, and 4(i)), with greater than 80 percent delivery occurring between 0 and 1 percent of potential futures. Further, under the Basic Coordination, Enhanced Coordination, and Representative Preferred Alternatives, there are no potential futures in which Arizona CAP NIA-A, CAP NIA-B, CAP Indian, M&I, and 4(i)) priority groups receive any percentage of normal domestic water delivery. Under these alternatives, there is a higher frequency of shortage and no potential futures in which normal domestic delivery to these priorities occurs. Shortages could manifest as reduced water allocations, delivery restrictions, or the need for additional conservation measures, limiting the capacity to meet domestic water demand. A higher frequency of shortages and fewer potential futures with normal domestic delivery to these junior priorities could result in potential impacts on municipalities and communities that rely on domestic water delivery under these entitlements. Under the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives, Arizona CAP NIA-A, CAP NIA-B, CAP Indian, M&I, and 4(i)) could experience less reliable water delivery for existing populations and future population growth, secondary impacts on land use and development

patterns, and decreased capacity to respond to water demands. As described in **TA 4**, Water Deliveries, maximum shortage to junior entitlements is highest under the Maximum Operational Flexibility Alternative. Should shortages result in a reduction or elimination of legal access to municipal water, widespread impacts on social and economic conditions may also be possible. Further, the shortage distributions applied under these alternatives could result in the complete loss of domestic water for these users. Some third-party studies evaluate potential socioeconomic impacts under specific scenarios and assumptions. For example, a 2026 report describes categories of potential economic impacts that could occur under reduced CAP deliveries (WestWater 2026)[2]. While the WestWater 2026 report is scenario-specific, it is cited here to provide examples of the nature and types of potential impacts and pathways that may occur under reduced CAP deliveries (that is, direct, indirect, and induced economic impacts affecting employment, population, and housing). In some scenarios, municipalities may find the need to pursue adaptation measures including alternative water sources, or hauled water if available, as an alternative to support continued services. However, adaptation measures (for example, new supplies, infrastructure, treatment, interconnections, and related financing) can require substantial time and resources and may not be available on the same schedule for all communities. While these specific local project decisions would occur outside the scope of this Final EIS, it is important to note the potential for impacts. In addition, indirect social costs may occur as a result of a reduction in ecosystem services, or benefits to people provided by the environment. For example, trees in urban areas have been shown to provide high levels of benefits to people in the form of shade, which mitigates impacts of urban heat (that is, heat-related illness),[3] local air quality improvements, and enhancement of the visual setting. Should a reduction in domestic water supply result in die-offs of urban and suburban area trees, this could represent a loss of value that would take decades to recapture, due to the growth time required for trees (see, for example, Bloome et al. 2016).

The DMDU figures do not capture individual years within the modeling period, however, they are modeled. The modeling assumptions for the Representative Preferred Alternative in the first two years (2027–2028) are described in **Chapter 2** and the shortages up to 1.5 maf are distributed via LB Priority. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage). **TA 4**, Water Deliveries, shows analysis of the Representative Preferred Alternative for 2027 and 2028 at the state distribution level. The potential 2027 and 2028 operating guidelines modeling is compared to the Representative Preferred Alternative in **Appendix T,** Preliminary Description and Analysis of Anticipated Operating Guidelines for 2027 and 2028. The results for the Representative Preferred Alternative in 2029–2036, in which the Priority distribution is applied, would result in more shortage impacts on Arizona junior entitlements. Impacts beyond 2028 under the Preferred Alternative may be different from what is shown in the DMDU figures for the Representative Preferred Alternative, as this

[2] Because this study is scenario-specific and not directly comparable to the Draft EIS modeling framework, the Final EIS does not adopt quantified estimates from this study.

[3] Sudeep Sinha et al., Variation in Estimates of Heat-Related Mortality Reduction Due to Tree Cover in U.S. Cities, 301 J. Envtl. Mgmt. 113751 (2022); Darin J. Jenerette et al., Micro-Scale Urban Surface Temperatures Are Related to Land-Cover Features and Residential Heat-Related Health Impacts in Phoenix, AZ (USA), 31 Landscape Ecology 745-60 (2016); Peder Ibsen et al., Urban Tree Cover Provides Consistent Mitigation of Extreme Heat in Arid but Not Humid Cities, 113 Sustainable Cities & Soc'y 105677 (2024).

alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**.

When considering all Arizona priority groups, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives generally demonstrate the most robust performance for domestic water entitlements, based on maintaining greater than 60 percent of normal delivery in at least 90 percent of years across the first decade of the modeling period, for the greatest number of users. Compared with the CCS Comparative Baseline and the No Action Alternative, under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, 60 percent or more of normal domestic water delivery occurs across the largest percentage of potential futures and for the greatest number of priority groups. While this approach maximizes delivery reliability for more users overall, it involves a trade-off: senior entitlements would experience delivery reductions that would not occur under a priority distribution, whereas more junior entitlements may continue to receive near-normal deliveries, across the modeled futures. This allocation reflects a balance between broad delivery coverage and the reallocation of shortage risk across the priority groups.

California: Figure TA 17-5 through **Figure TA 17-6** display potential impacts on domestic water deliveries for California priority groups**.** Under the No Action, Basic Coordination, and Supply Driven (LB Pro Rata approach) Alternatives, greater than 80 percent of normal delivery occurs in 100 percent of potential futures for California PPR and Priority 4. In other words, there would be no impacts on domestic shortage for California PPR and Priority 4, under these alternatives. However, potential impacts do vary under the other action alternative for these two priority groups. Under all alternatives, excluding the Enhanced Coordination Alternative, 100 percent of normal delivery to California PPR occurs in 100 percent of potential futures. Under all alternatives, excluding the Enhanced Coordination Alternative, there would be no shortage to California PPR across modeled futures. When considering dead pool–related reductions, which may impact California PPR, the Maximum Operational Flexibility and the Representative Preferred Alternatives are the most robust compared with other alternatives, with the lowest percent of potential futures with dead pool–related reductions (6 percent and 8 percent across the first decade of the modeling period, respectively). Therefore, with the greatest frequency of normal domestic water delivery, these alternatives would result in the least potential impacts on domestic water for California PPR. However, for California Priority 4, deliveries greater than 80 percent of normal delivery occurs in no potential futures under the Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives. Therefore, under these alternatives modeled delivery reductions could result in impacts to existing residents, economic sectors, and essential services reliant on domestic deliveries. Communities could experience increased constraints on existing and new residential and commercial development, need for additional adaptation measures, and greater pressure to accelerate development of replacement supplies. When evaluating both California priority groups together, the Supply Driven Alternative (LB Pro Rata approach) is the most robust compared with the No Action Alternative and all other action alternatives. It provides 100 percent of normal delivery to California PPR and California Priority 4 in 90 percent of years across 100 percent of potential futures. Additionally, considering the dead pool–related reductions, which could affect these users, the Supply Driven Alternative (LB Pro Rata approach) has the third lowest percentage of futures with constrained releases (12 percent) across the first decade of the modeling period, compared with all other alternatives. Reliable domestic water deliveries under the Supply

Driven Alternative (LB Pro Rata approach) would support existing communities, continued population growth, and land development in areas served by California PPR and Priority 4. Maintaining near-normal deliveries across modeled futures supports the capacity for planned and new development, housing availability, and municipal services that rely on water supply. In contrast, the alternatives with lower reliability or greater exposure to dead pool–related reductions could limit opportunities for residential and commercial growth, particularly areas experiencing high population growth, intensive development, or elevated municipal water demand, and could influence land-use patterns or delay new construction. Ensuring robust water delivery across multiple futures is therefore an important factor supporting existing communities, sustainable population growth, and land-use planning in California.

The DMDU figures do not capture individual years within the modeling period, however, they are modeled. The modeling assumptions for the Representative Preferred Alternative in the first two years (2027–2028) are described in **Chapter 2** and the shortages up to 1.5 maf are distributed via LB priority. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage). **TA 4**, Water Deliveries, shows analysis of the Representative Preferred Alternative for 2027 and 2028 at the state distribution level. The potential 2027 and 2028 operating guidelines modeling is compared to the Representative Preferred Alternative in **Appendix T,** Preliminary Description and Analysis of Anticipated Operating Guidelines for 2027 and 2028. The results for the Representative Preferred Alternative in 2029–2036, in which Priority distribution is applied, would result in more shortage impacts on Arizona junior entitlements. Impacts beyond 2028 under the Preferred Alternative may be different from what is shown in the DMDU figures for the Representative Preferred Alternative, as this alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**. Nevada: Figure TA 17-7 and **Figure TA 17-8,** display potential impacts on domestic water deliveries for Nevada priority groups**.** Under all alternatives, except the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, 100 percent of normal delivery to Nevada Priorities 1–7 occurs in 90 percent of years across 100 percent of potential futures. Under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, deliveries greater than 80 percent of normal to both priority groups occurs in only 13 percent and 32 percent of potential futures, respectively.

The CCS Comparative Baseline and No Action Alternative result in similar outcomes for both Nevada priority groups—Priorities 1–7 and Priority 8—with 100 percent of normal delivery to each group occurring in 90 percent of years across 100 percent of potential futures. However, it is important to note that for the No Action Alternative and the CCS Comparative Baseline, across the first decade of the modeling period the percentage of futures with dead pool–related reductions are 38 percent and 59 percent, respectively.

For Nevada Priorities 1–7 specifically, the Maximum Operational Flexibility Alternative is the most robust, followed by the Representative Preferred Alternative, compared with the No Action Alternative and the other action alternatives. In contrast, for Nevada Priority 8, these same alternatives are some of the least robust, with deliveries greater than 80 percent of normal occurring in only 1 percent of potential futures (Maximum Operational Flexibility Alternative) and no potential futures (Representative Preferred Alternative).

When considering both Nevada priority groups together, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives provides the most robust performance. These alternatives deliver greater than 60 percent of normal domestic water across the largest percentage of potential futures and for the greatest number of priority groups. Robust domestic water deliveries are critical to supporting existing communities and population growth and land development in Nevada. The alternatives that maintain more reliable deliveries across modeled futures for both priority groups support the capacity for existing and new housing, commercial development, and essential municipal services that depend on water supply. Conversely, alternatives with lower reliability, particularly for Nevada Priority 8, could result in impacts to the capacity to support existing residents, economic sectors, and essential services reliant on domestic deliveries. Communities could experience increased constraints on existing and new residential and commercial development, impacts on the capacity of communities to expand, and effects on land-use patterns or delays to new construction projects. Modeled delivery reductions could result in the need for additional adaptation measures, and greater pressure to accelerate development of replacement supplies. By sustaining domestic water availability across a broad range of potential futures, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives may help support existing residents, economies, and essential services; stable population growth; and more predictable land-use planning across the state, where modeled deliveries remain reliable.

The DMDU figures do not capture individual years within the modeling period, however, they are modeled. The modeling assumptions for the Representative Preferred Alternative in the first two years (2027–2028) are described in **Chapter 2** and the shortages up to 1.5 maf are distributed via LB Priority. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage). **TA 4**, Water Deliveries, shows analysis of the Representative Preferred Alternative for 2027 and 2028 at the state distribution level. The potential 2027 and 2028 operating guidelines modeling is compared to the Representative Preferred Alternative in **Appendix T**, Preliminary Description and Analysis of Anticipated Operating Guidelines for 2027 and 2028. The results for the Representative Preferred Alternative in 2029–2036, in which Priority distribution is applied, would result in more shortage impacts on Arizona junior entitlements. Impacts beyond 2028 under the Preferred Alternative may be different from what is shown in the DMDU figures for the Representative Preferred Alternative, as this alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**.

TA 17.2.4 Issue 2: How would operational changes affect irrigated agricultural land-use patterns?

This issue examines how different operational strategies may influence land-use patterns associated with irrigated agriculture, and the potential for long-term changes to these land uses based on Colorado River water availability for this use. While agricultural producers may pursue adaptive responses such as crop switching in response to reduced water availability, the feasibility of these responses may be constrained by local conditions and may involve additional costs or risks. Additional discussion of the economic implications of agricultural responses, including fallowing, is provided in the **TA 16,** Socioeconomics.

Estimated water shortages for Lower Basin agricultural users are shown in **Table TA 17-18**, by modeling approach and alternative. Additional details related to the shortage allocation model estimates are included in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation. An overview of state levels shortages for all uses is included in **TA 4**, Water Deliveries. Potential broader market responses (for example, production shifts to other regions, imports, and price effects) are uncertain and were not explicitly modeled in this analysis, which focuses on irrigation water availability and potential land-use response in the analysis area.

The analysis of impacts to irrigation water deliveries relies on data outputs from the SAM. Irrigation shortage and subsequent impacts to users is directly correlated to reservoir releases: please see **TA 3** Hydrologic Resources, **Section 3.2.3.**, for a detailed analysis of reservoir releases.

The CCS Comparative Baseline reflects Colorado River operations from recent years, incorporating the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead, the 2019 Drought Contingency Plan, Minute 323 of the 1944 United States-Mexico Water Treaty on Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande, and related agreements. These strategies have supported a mix of voluntary conservation, Intentionally Created Surplus (ICS) banking, and coordinated shortage responses that have helped buffer impacts on land use, particularly in urban and agricultural areas. While shortages still occur under the CCS Comparative Baseline, the framework provides more predictability and flexibility than the No Action Alternative, which reverts to pre-2007 operations. As a result, land-use patterns, including irrigated agriculture and urban development, are more likely to remain stable under the CCS Comparative Baseline, especially in areas with access to ICS or conservation programs. However, long-term viability of water-dependent land uses may still be challenged by declining reservoir elevations and increasing demand pressures.

While the CCS Comparative Baseline framework offers structure and predictability, modeled results illustrate how these outcomes vary between states and across different shortage levels, reflecting the continued vulnerability of certain user groups. Irrigation users in Arizona experience greater reductions under alternatives with pro rata distribution approaches at lower to mid-level system shortage volumes because currently most irrigators hold higher priority entitlements, and allocating reductions proportionally results in larger volumetric impacts than the priority-based framework. Although existing conservation and management measures help moderate impacts, irrigation reductions are still expected and may influence land use decisions such as fallowing or crop switching. Existing literature supports these findings, showing that sustained irrigation reductions in Arizona, particularly among junior priority users, have already led to reduced farm income and localized economic contraction (Arizona Extension 2024). In contrast, California's agricultural users experience relatively greater shortages only under higher system shortage volumes, consistent with the state's senior water rights structure that provides protection under moderate conditions but may require larger contributions during more severe shortages. Studies in California similarly indicate that even modest reductions in irrigation can result in shifts toward drought tolerant crops and eventual land retirement in more vulnerable areas (Prakash 2023). Overall, while the CCS Comparative Baseline provides greater predictability than the No Action Alternative, the long-term viability of irrigated agriculture in Arizona and California may still be challenged by persistent shortages and declining reservoir conditions.

Table TA 17-18
Agricultural Water Shortage by State by Alternative

	Irrigation Shortage Impacts		Total Shortage Volume (acre-feet)									
	Modeling Approach	**EIS Alternative**	**600,000**	**1,000,000**	**1,500,000**	**1,800,000**	**2,000,000**	**2,100,000**	**2,300,000**	**3,000,000**	**3,600,000**	**4,000,000**

Note: The highlighting shows the values from the smallest (in white or no highlighting) to the largest (in yellow highlighting). The cells with hash-marks represent the values above shortages; these values are outside of the scope of this analysis. See the Shortage Allocation and Alternative Distribution Models (**Appendix C**) for more information on the shortage values for each entitlement holder type above shortages.

[1] Due to its fixed shortage volumes for the CCS Comparative Baseline, shortages for 600,000 acre-feet and 1 million acre-feet (maf) are actually associated with 613,000 acre-feet and 1.013 maf in the CCS Comparative Baseline. Greater shortages are based on an extension of priority beyond the levels of shortage provided by the pertinent documents.

[2] The maximum shortage for the Basic Coordination Alternative is 1.48 maf, however, the table above shows the maximum shortage as 1.5 maf for ease of comparison across the alternatives.

[3] The distribution of shortages up to 1.5 maf in 2027-2028 in the Representative Preferred Alternative reflects the May 1 proposal by the Lower Division States. Although not specified in their proposal, the Representative Preferred assumes shortages and their distribution above 1.5 maf in 2028 as necessary to avoid critically low elevations in Lake Mead. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative and their representation in the Representative Preferred Alternative).

[4] Expected impacts from 2029–2060 under the Preferred Alternative may be different from what is shown for the Representative Preferred (2029–2060) Alternative, as this alternative provides a framework that allows for shortage distributions to be negotiated in different ways, consistent with sideboards described in **Chapter 2**.

Without conservation mechanisms or coordinated flexibility, agricultural users face more severe impacts. Conservation mechanisms can support water deliveries by increasing usable system supply and providing operational buffers, without altering the delivery priority hierarchy unless an alternative explicitly modifies it. Water banking and groundwater savings facilities allow participating entities to reduce immediate diversion, store conserved water in reservoir accounts, and recover water later when needed, helping to maintain deliveries during shortage periods. Under the No Action Alternative, no new conservation mechanisms are introduced, and shortages are distributed by priority. Agricultural users with junior entitlements (i.e. Priority 4(i) users in La Paz, Mohave, and Yuma Counites in Arizona, see **Appendix C**, Shortage Allocation Model and Alternative Distribution Model, for additional details) would likely experience frequent and severe reductions in water deliveries because they rely heavily or entirely on surface water, may also face increased fallowing. The lack of flexibility in water management due to the absence of operational or conservation mechanisms could exacerbate long-term declines in irrigated acreage, especially in counties already showing downward trends in harvested cropland (USDA 2025). Analysis of water productivity across the Colorado River Basin (Basin) shows that Lower Basin counties, particularly in Arizona and California, generate higher crop revenue per acre-foot of water applied than Upper Colorado River Basin regions. This suggests that reductions in agricultural water deliveries in these areas could have disproportionately high economic impacts, reinforcing the need for more adaptive water management strategies (Bickel et al. 2024). Under the No Action Alternative, Lake Mead is projected to fall below dead pool in 75 percent of modeled futures, which could constrain releases to downstream users. These constraints may result in reduced water availability for urban and agricultural land uses, potentially leading to fallowing, development delays, or infrastructure abandonment in affected counties (see **TA 4**, Water Deliveries). The No Action Alternative offers slight improvement in predictability due to capped shortages, but not necessarily meaningful change in agricultural water reliability or land-use outcomes.

These modeled outcomes are further supported by additional analyses that examine how physical and policy-based delivery constraints under deteriorating hydrologic conditions would exacerbate agricultural vulnerabilities. Under the No Action Alternative, modeled capacity constraints occur frequently enough that irrigation users in Arizona and California would face reductions that exceed existing policy-level shortage mechanisms. Without continuation of current shortage-sharing and conservation mechanisms, this alternative exposes Arizona and California to heightened risks of physical delivery constraints as reservoir elevations decline. Literature from USGS, 2019 and Prakash, 2023 indicates that when water availability is constrained by infrastructure or operational limits, agricultural users often experience abrupt and severe reductions in supply, leading to land retirement, fallowing, and associated economic disruption. In Arizona, such outcomes could accelerate land-use changes in Yuma, Mohave, and La Paz counties, while in California, even senior priority districts may be affected if physical shortages become the limiting factor in water supply. These findings highlight the increased vulnerability of irrigated agriculture under conditions of limited operational flexibility and deteriorating hydrologic reliability.

The Basic Coordination Alternative introduces a capped shortage mechanism, offering modest improvements in predictability but few new tools for agricultural resilience. This alternative retains the priority-based shortage distribution of the No Action Alternative but introduces a capped shortage volume of 1.48 maf. While this cap is intended to ensure that an assumed minimum flow is

available for infrastructure protection and delivery for municipal use by CAP users and other Fourth Priority mainstem entitlement holders in Arizona when mainstream shortage is distributed by priority, it does not establish new agricultural conservation mechanisms to offset reductions through stored or deferred diversions. As a result, agricultural users in Arizona and California, especially those with junior entitlements, continue to face significant reductions in water deliveries.

The increase in capped volume may reduce the frequency of extreme shortages compared with the No Action Alternative, but the absence of conservation pools means agricultural land use remains highly vulnerable. In Arizona, La Paz, Mohave, and Yuma Counties may see increased fallowing and economic stress in farming communities. California's Imperial Valley would not experience shortages, but other regions could experience similar pressures. The capped shortage volume provides marginal improvement in predictability, but agricultural water reliability and land-use outcomes remain largely unchanged from the No Action Alternative.

Detailed modeling results reinforce this outcome, showing that although the capped shortage slightly moderates total reductions, its benefits remain distributed by priority across states and users. The Basic Coordination Alternative irrigation shortages follow a pattern similar to the No Action Alternative but are capped at a system-wide reduction up to the policy-level cap of 1.48 maf. Within this range, Arizona bears all modeled irrigation shortages, while California experiences none, consistent with the continuation of existing priority structures. Because this alternative maintains the current priority framework and does not change delivery priorities, shortages follow existing priority rules. As a result, junior priority users, including both irrigation and domestic users within Arizona Priority 4, continue to bear the largest reductions. The resulting reductions increase the likelihood of fallowing, crop switching, and economic stress in affected agricultural communities, potentially leading to long-term land-use changes such as farmland retirement (Presson and Eden 2023).

By comparison, the Enhanced Coordination Alternative incorporates conservation pools and reductions that distribute shortages across more users and increase operational flexibility. This alternative introduces coordinated reservoir operations and conservation pools in Lake Powell (2 maf) and Lake Mead (5 maf), with shortages distributed pro rata across Lower Basin water users. This represents a departure from the No Action Alternative's priority-based approach.

Agricultural users in Arizona benefit from a broader distribution of shortages, reducing the likelihood of concentrated fallowing impacts among junior users. Arizona counties (Yuma, Mohave, and La Paz) and California's Imperial Valley see enhanced stability relative to the No Action Alternative due to conservation pool access. The pro rata distribution method ensures that agricultural users across states share reductions more evenly, mitigating the concentrated impacts seen under the No Action Alternative for juniors.

This alternative supports the continuation of some irrigated agriculture across the Basin, with the potential to sustain a measure of productivity across all priorities. Compared with the No Action Alternative, it provides a more resilient framework for some level of irrigated agriculture under a range of hydrologic conditions. Studies suggest that pro rata reductions tend to spread fallowing and crop switching more broadly, whereas priority-based approaches protect senior-rights districts but concentrate impacts on lower-priority users (Lee et al. 2020; Prakash 2023; USDA ERS 2021).

The quantitative results under the Enhanced Coordination Alternative mirror these operational changes, demonstrating how pro rata allocation redistributes impacts across states. Irrigation shortages in Arizona are generally larger than those under the No Action and Basic Coordination Alternatives when total shortage volumes are low. However, when total shortage volumes are above 3.5 maf, irrigation shortages are smaller than under those alternatives because of the coordinated, pro rata shortage allocation across Lower Basin water users. This approach reduces the concentration of impacts on Arizona's junior priority irrigation users but results in a broader distribution of shortages across states, meaning California's agricultural users, typically protected under priority-based operations, would experience increased reductions. Literature suggests that such shared reductions may lessen localized land-use impacts but increase regional exposure. Prakash (2023) found that more equitable shortage sharing often encourages widespread adoption of efficient irrigation practices and crop switching, particularly in regions such as the Imperial Valley and Yuma County. While these adjustments may enhance long-term resilience, the higher overall shortage volumes modeled under this alternative could still contribute to land retirement and economic stress in water-dependent regions (USGS 2019; Arizona Extension 2024).

While the Enhanced Coordination Alternative emphasizes shared reductions, the Maximum Operational Flexibility Alternative expands management tools even further, allowing for the largest potential shortages (up to 4 maf) and includes a Conservation Reserve (up to 8 maf) shared across basins. While this introduces flexibility not included in the No Action Alternative, it also increases exposure to extreme shortage scenarios. Agricultural users in Yuma, La Paz and Mohave Counites may face high risk of fallowing unless conservation participation is robust. The Conservation Reserve allows users to store water in either Lake Powell or Lake Mead and convert it to system water when needed, offering a buffer against extreme shortages. California's agricultural regions benefit from similar flexibility, though effectiveness depends on participation and reservoir conditions. Compared with the No Action Alternative, this alternative introduces tools for adaptation and resilience, but agricultural outcomes depend heavily on conservation engagement and interbasin cooperation.

Modeling results under this framework underscore the same theme: flexibility can help smooth impacts under moderate conditions but cannot fully offset risks to agricultural viability under prolonged shortages. The Maximum Operational Flexibility Alternative modeled irrigation shortages in Arizona are similar to those under the Supply Driven Alternative (LB Priority approach). This alternative incorporates operational flexibility based on hydrologic conditions and system storage, which helps moderate shortages during less severe periods. California experiences smaller but more consistent irrigation reductions through the middle range of system shortages, though less than under the alternatives using pro rata distribution. Overall, this approach maintains a priority-based structure while introducing adaptive mechanisms that influence the timing and distribution of irrigation impacts across the Colorado River Basin. Literature indicates that the flexibility introduced under this alternative may help buffer irrigation impacts during less severe hydrologic periods, though its effectiveness depends on conservation participation. Conservation programs have helped stabilize water availability, but long-term reductions still pose risks. USDA ERS (2021) notes that irrigated agriculture increasingly relies on adaptive strategies such as deficit irrigation and crop switching to maintain productivity. In both Arizona and California, these adjustments may lead to

shifts in land use toward fallowing or land retirement and may reduce the economic viability of certain crops.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) decouples Lake Powell and Lake Mead operations and analyzes both priority-based and pro rata shortage distribution schemes. This dual-path approach allows for more nuanced control than the No Action Alternative, which relies solely on priority-based allocation.

Under priority-based allocation, agricultural users with junior entitlements, particularly in Arizona, would face impacts similar to those under the No Action Alternative. However, under pro rata distribution, impacts are more evenly spread, reducing impacts on Arizona counties and increasing impacts on senior priorities, primarily in California. The conservation pools in Lake Powell (3 maf) and Lake Mead (8 maf) offer conservation mechanisms, and the phased conversion of existing ICS may add further flexibility.

Compared with the No Action Alternative, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has the potential to improve agricultural outcomes, particularly under the Supply Driven Alternative (LB Pro Rata approach). However, its effectiveness depends on implementation details, stakeholder agreements, and conservation participation. It offers a more tailored approach that distributes shortages across a broader set of users, changing how agricultural water deliveries are managed compared with the other alternatives.

Further detail from the two modeled approaches of the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) clarifies how different allocation schemes affect the scale and distribution of irrigation shortages, revealing important trade-offs between distribution of reductions, magnitude of reductions, and overall agricultural outcomes. Under the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), modeled irrigation shortages reach the policy-level cap at 2.1 maf. Under the Supply Driven Alternative (LB Priority approach), Arizona and California are modeled as splitting the irrigation reductions unevenly. In contrast, under the Supply Driven Alternative (LB Pro Rata approach), the reductions would be distributed more evenly and more heavily on California as the modeled shortage increases. While this approach reduces concentrated impacts in Arizona, it introduces greater irrigation reductions for California's agricultural users than under the other alternatives. Overall, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) reflects a trade-off between distribution and magnitude of impact, with broader distribution of shortages but higher total volumes of shortage to irrigators. Literature indicates that pro rata reductions are more likely to result in widespread fallowing and crop switching, while priority-based approaches preserve senior-rights districts but concentrate impacts (Lee et al. 2020; Prakash 2023; USDA ERS 2021). In both cases, sustained irrigation reductions are expected to influence land-use decisions and economic outcomes across the Basin. (Prakash 2023; USDA ERS 2021).

The Preferred Alternative provides additional flexibility to develop operational guidelines based on conditions. Up to 1.5 maf, the Representative Preferred (2027-2028) Alternative would result in shortages similar to those under the Maximum Flexibility and the Supply Driven (LB Priority approach) Alternatives, with impacts concentrated on junior users.

In the longer term (2029-2060) modeled outcomes for the Representative Preferred Alternative follow the priority approach for distribution, indicate potential for fallowing of land as noted under the Basic Coordination Alternative, with impacts concentrated on junior users. Unlike the Basic Coordination Alternative, the Representative Preferred (2029-2060) Alternative policy-level shortage caps are not applied until 3.6 maf, therefore there is the potential for higher levels of shortage with increased potential for fallowing and land use changes. However, the distribution of shortage under any specific operating guidelines adopted under the Preferred Alternative decision framework may differ from the priority distribution method reflected here for the Representative Preferred Alternative, as a result, the potential for fallowing, crop switching, and other associated long term land -use patterns in any given area may vary and impacts may be mitigated in part by specific operational guidelines.

TA 17.2.5 Summary Comparison of Alternatives

Population and Developed Land Use – The alternatives vary in how they distribute domestic shortages and, in their potential, to impact domestic water deliveries and, in turn, indirectly impact population dynamics and land use within the analysis area.

As shown in **Table TA 17-17**, for the No Action, Basic Coordination, Maximum Operational Flexibility, and Supply Driven (LB Priority approach), and Representative Preferred Alternatives, which apply a priority-based distribution of shortage, under most modeled futures, water users with senior entitlements would likely continue to experience relatively consistent domestic water deliveries. This is because these entitlements are contractually prioritized during periods of reduced supply. However, junior entitlements could face greater reductions in water deliveries during Shortage Conditions. Consequently, while senior entitlement holders may maintain service levels closer to normal, junior entitlement holders could experience more frequent or severe delivery constraints.

Under the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives, greater than 80 percent of normal domestic delivery to most senior entitlements occurs in all potential futures. The specific Arizona, California, and Nevada senior entitlements vary by alternative (see **Table TA 17-17**). Because these alternatives have greater robustness for senior priority groups there could be fewer potential indirect impacts on existing communities as well as population growth and land development. A higher percentage of potential futures with greater than 80 percent of normal delivery could support future population growth, water demand, and development in areas serviced by these priority groups.

Under the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives, for junior entitlements there are fewer potential futures, and in some cases no potential futures, in which there is any percentage of normal delivery across the first decade of the modeling period. The specific Arizona, California, and Nevada junior entitlements vary by alternative (see **Table TA 17-17**). Under the Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives, greater than 80 percent of normal domestic delivery to all junior entitlements occurs in no potential futures, across the first decade of the modeling period. Domestic shortages could manifest as reduced water allocations, delivery restrictions, or the need for additional adaptation and conservation measures, which could

in turn limit the capacity to meet domestic water demand. Reduced capacity to meet domestic water demand could impact existing residents and essential services, constrain planned and future development, and create conveyance or treatment system challenges. The extent of these effects would vary by community based on local water portfolios, infrastructure, regulatory context, conservation achievements, financing capacity, hydrologic conditions, and adaptation feasibility. Further, the shortage distributions applied under these alternatives could result in the complete loss of domestic water for these users. Should shortages result in a reduction or elimination of legal access to municipal water, widespread impacts on social and economic conditions could also be possible. For example, in some scenarios, municipalities could even find the need to pursue alternative water sources, or hauled water if available, as an alternative to support continued services. However, adaptation measures (for example, new supplies, infrastructure, treatment, interconnections, and related financing) can require substantial time and resources and may not be available on the same schedule for all communities. While these specific local project decisions would occur outside the scope of this Final EIS, it is important to note the potential for impacts.

In addition, indirect social costs could occur as a result of a reduction in ecosystem services; also, indirect social costs could occur from reduction of benefits to people provided by the environment. For example, trees in urban areas have been shown to provide high levels of benefits to people in the form of shade, which mitigates urban heat impacts (that is, heat-related illness), local air quality improvements, and enhancement of the visual setting. Should a reduction in domestic water supply result in die-offs of urban and suburban area trees, this could represent a loss of value that would take decades to recapture, due to the growth time required for trees (see, for example, Bloome et al. 2016).

As shown in **Table TA 17-17**, for the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, which apply pro rata distribution of shortage, under most modeled futures, would generally allow a larger number of priority groups to receive domestic water deliveries closer to normal conditions. While a pro rata approach would change the distribution of water across all users during shortages, this approach would deviate from the priority-based distribution, resulting in some modeled reductions to domestic deliveries for senior entitlement holders who would otherwise maintain normal domestic delivery under the existing priority system. In contrast, more domestic junior priority water entitlement holders would continue to receive some level of water supply under this approach. In general, the pro rata method would result in more users receiving moderate water deliveries during shortages through a redistribution of water from senior entitlements.

Agricultural Land Use: The alternatives vary in how they distribute irrigation shortages and therefore in their potential to influence long-term land-use patterns. The No Action and Basic Coordination Alternatives rely on priority-based distribution and result in concentrated impacts on junior priority users in Arizona (primarily in Yuma, La Paz and Mohave Counites), with limited mitigation tools. These conditions increase the likelihood of fallowing, crop switching, and economic stress in affected communities. The Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives distribute shortages more broadly across the states and users, reducing concentrated impacts on junior priority holders but introducing greater reductions in California, which could lead to more widespread land-use changes. The Maximum Operational Flexibility and Supply Driven (LB Priority approach) Alternatives incorporate adaptive tools and conservation

reserves, offering potential buffers against extreme shortages; however, their effectiveness depends on stakeholder participation and hydrologic conditions. The Preferred Alternative provides additional flexibility to develop operational guidelines based on conditions. Up to 1.5 maf, the Representative Preferred Alternative for 2027-2028 would result in shortages similar to that under the Maximum Flexibility and the Supply Driven (LB Priority approach) Alternatives, with impacts concentrated on junior users. In the longer term (2029-2060) modeled outcomes under the Representative Preferred Alternative indicate potential for the greatest level of shortage to junior priority users of any alternative. However, based on by the potential 2027-2028 agreements among Lower Division States at the time of publication, the distribution of shortage under any specific operating guidelines adopted under the Preferred Alternative decision framework may differ from the priority distribution method reflected here for the Representative Preferred Alternative; as a result, the potential for fallowing, crop switching, and other associated long term land -use patterns in any given area may vary and impacts may be mitigated in part by agreements that may arise during the development of specific operating guidelines under the Preferred Alternative.

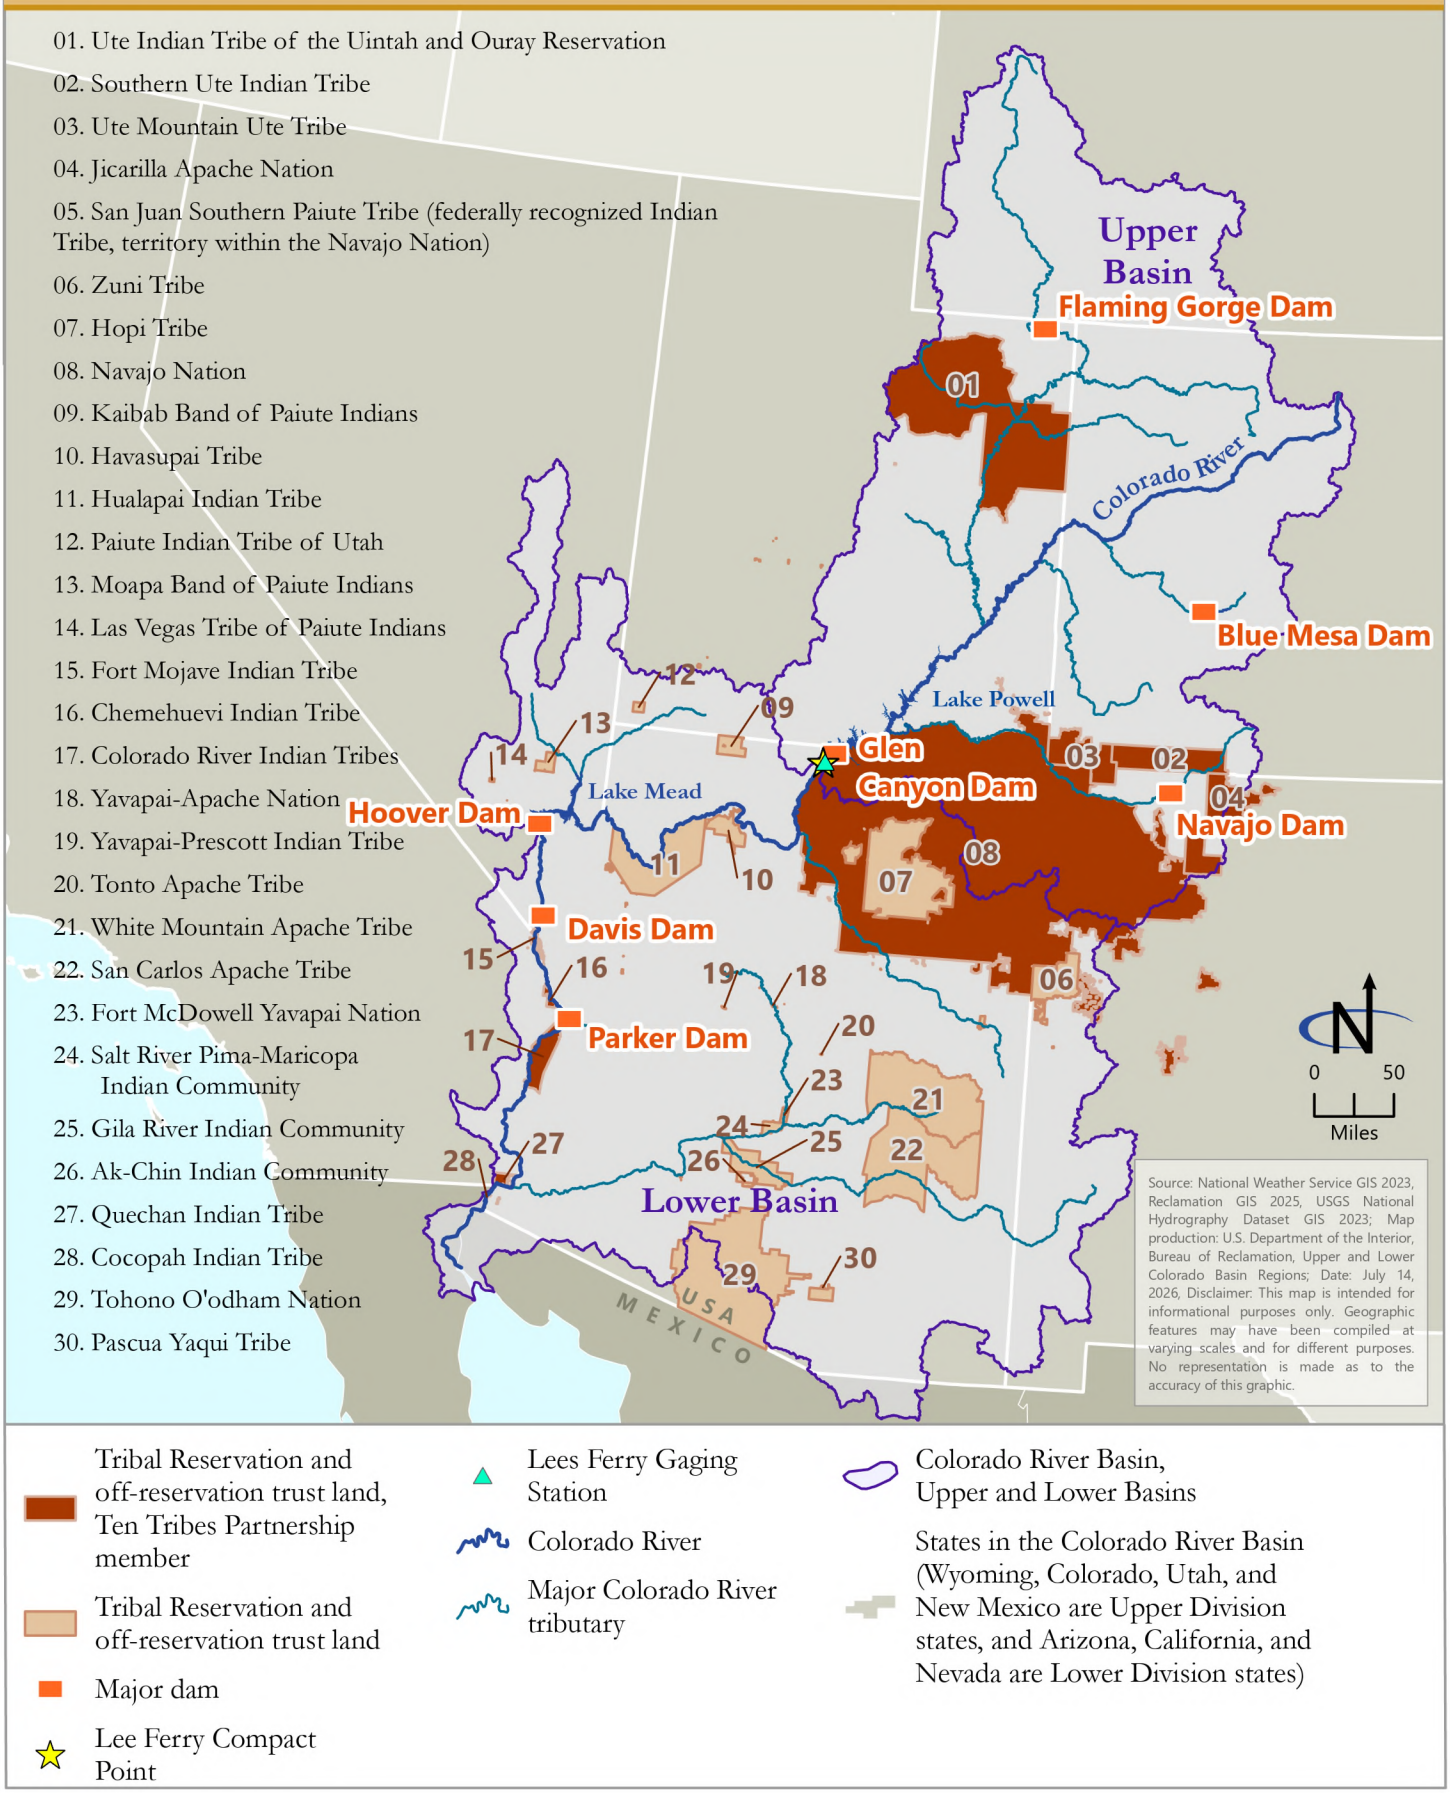
TA 18. Indian Trust Assets

TA 18.1 Affected Environment

The United States (U.S.) has a trust responsibility to tribes as defined by statutes, court decrees, treaties, or other applicable law.[1] Indian trust assets (ITAs) are legal interests in assets held in trust by the federal government for the benefit of federally recognized Native American tribes or individual Native Americans (Reclamation 1994). ITAs can be located on or off established reservation lands and can consist of land or water entitlements[2]; natural resources; monies, such as trust funds; mineral rights; hunting, fishing, trapping, and gathering rights; and other assets. Beneficiaries of the Indian trust relationship are tribes and individual Native Americans; the U.S. is the trustee. ITAs are generally restricted against alienation (that is, they cannot be sold, transferred, abandoned, or lost without approval from the Secretary of the Interior). With federal authority and approval, ITAs may be leased to generate income for tribes or individual Native Americans (Department 2025).

It is the general policy of the Department of the Interior to carry out activities in a manner that protects ITAs and avoids adverse effects whenever possible (Reclamation 1993). In accordance with Bureau of Reclamation (Reclamation) ITA policy and guidance (Reclamation 1994), tribal consultation addressing trust assets should be initiated with appropriate tribal groups and the Bureau of Indian Affairs, and the presence or absence of ITAs should be addressed explicitly in all National Environmental Policy Act documents. Reclamation has consulted with tribes regarding the proposed Post-2026 Operational Guidelines and Strategies for Lake Powell and Lake Mead Environmental Impact Statement (EIS).

TA 18.1.1 Trust Lands



Indian trust lands are lands that the U.S. holds in trust for the benefit of a tribe (tribal trust land) or for an individual Native American (individual trust land). Trust lands may be located on or off a reservation. While reservations are not always synonymous with trust lands, the exterior boundaries of reservations are used to define the trust land assets for purposes of this National Environmental Policy Act analysis, to be inclusive. There are 30 federally recognized tribes in the Colorado River Basin; of these, 29 have established reservations (**Map TA 18-1**). The San Juan Southern Paiute Tribe does not have its own reservation. Tribal land uses include, but are not limited to, communal and spiritual uses, domestic use, and agriculture and economic development.

[1] Nothing in this technical appendix is intended to modify, abrogate, or create ITAs. Any particular ITA remains defined by and subject to applicable authority.

[2] Rights and entitlements may be used interchangeably in this technical appendix for simplicity, and no legal change to any ITA is intended.

— BUREAU OF —
RECLAMATION

Map TA 18-1
Tribes and Reservations within the Colorado River Basin

Native American reservations in the U.S. were created and modified through a complex history of statutes, treaties, executive orders, agreements, and federal policies (BIA 2025a). The Indian Removal Act of 1830 resulted in the forced removal of tribes from their ancestral lands east of the Mississippi River into the Western U.S. Lands inhabited by these relocated groups came to be known as "Indian territory", which served as the precursor to federal reservations (BIA 2025a). The Indian Appropriations Act of 1851 resulted in further confinement of Native Americans to areas called "reservations" (Elliott 2025). The General Allotment Act (also known as the Dawes Act) of 1887 divided communal reservation lands into trust land allotted to individual Native Americans and their families (BIA 2025a). It also opened non-allotted land to non-tribal ownership, resulting in significant fractionalization and loss of tribal-controlled land (BIA 2025a). In the twentieth and twenty-first centuries, federal policies have attempted to help restore the self-determination of Native American tribes and reduce the effects of reservation fractionalization (BIA 2025a, 2025b). See the Tribal Treaties Database (OSU 2025) for detailed information on treaties, agreements, and executive orders.

Upper Basin

From approximately Northeast to Southeast, the Upper Colorado River Basin (Upper Basin) reservations include those associated with the Ute Indian Tribe of the Uintah and Ouray Reservation (Utah), the Southern Ute Indian Tribe (Colorado), the Ute Mountain Ute Tribe (Colorado, New Mexico, Utah), the Jicarilla Apache Nation (New Mexico), and the Navajo Nation (Arizona, New Mexico, Utah).

Lower Basin

From approximately Northeast to Southeast, Lower Colorado River Basin (Lower Basin) reservations include those associated with the Zuni Tribe (Arizona, New Mexico), the Navajo Nation (Arizona, New Mexico, Utah), the Hopi Tribe (Arizona), the Kaibab Band of Paiute Indians (Arizona), the Havasupai Tribe (Arizona), the Hualapai Indian Tribe (Arizona), the Shivwits Band of Paiute Indian Tribe (Utah), the Moapa Band of Paiute Indians (Nevada), the Las Vegas Tribe of Paiute Indians (Nevada), the Fort Mojave Indian Tribe (Arizona, California, Nevada), the Chemehuevi Indian Tribe (California), the Colorado Indian River Tribes (Arizona, California),[3] the Yavapai-Apache Nation (Arizona), the Yavapai-Prescott Indian Tribe (Arizona), the Tonto Apache Tribe (Arizona), the White Mountain Apache Tribe (Arizona), the San Carlos Apache Tribe (Arizona), the Fort McDowell Yavapai Nation (Arizona), the Salt River Pima-Maricopa Indian Community (Arizona), the Gila River Indian Community (Arizona), the Ak-Chin Indian Community (Arizona), the Fort Yuma Quechan Indian Tribe (Arizona, California), the Cocopah Indian Tribe (Arizona), the Tohono O'odham Nation (Arizona), and the Pascua Yaqui Tribe (Arizona).

In addition, trust land includes the Fort Mojave off-reservation trust land in San Bernardino County, California. No other off-reservation trust land along the mainstream Colorado River has been identified.

[3] Colorado River Indian Tribes is comprised of members of four distinct tribes: the Mohave, Chemehuevi, Hopi, and Navajo.

TA 18.1.2 Water Entitlements, Water Deliveries, and Storage and Conservation Options

The management and operation of the Colorado River and delivery of its waters to various users is governed by a complex set of treaties, statutes, Supreme Court decrees, and other settlements and agreements collectively known as the "Law of the River". In general terms, the Law of the River establishes a priority system for the distribution of available water. Higher priority (senior) water entitlements are filled first, and lower priority (junior) entitlements are filled next. Some tribal water entitlements have higher priorities and others are lower priorities. **Appendix C,** Shortage Allocation Model and Alternative Distribution Model Documentation, provides more detail on the priority of each tribal water entitlement in the Lower Basin.

TA 4, Water Deliveries, provides more detail on the Law of the River. This appendix includes tables of tribal mainstream Colorado River water entitlements and Central Arizona Project (CAP) contracts.[4] The entitlements included in this analysis are consistent with those in the Shortage Allocation Models (SAMs) and Alternative Distribution Models (ADMs; see **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation) and other sections of the Final EIS.[5]

Upper Basin

Water Entitlements

The five Upper Basin Tribes draw from various tributaries to the Colorado River (**Table TA 18-1**).

Table TA 18-1
Upper Basin Native American Water Rights

Tribe or Reservation	Basin	Diversion Right (Acre-feet per year [afy])	Depletion Right (afy)
Jicarilla Apache Nation	San Juan River	45,683	34,195
Navajo Nation	San Juan River	633,531	336,979
Navajo Nation	State of Utah		81,500
Southern Ute Indian Tribe	San Juan, Piedra, Pine, Florida, Animas, La Plata, and Mancos	137,090	74,138
Ute Indian Tribe of the Uintah and Ouray Reservation	Duchesne, Lake Fork, Yellowstone, Uinta, Whiterocks, White, and Green Rivers; Bitter, Sweet Water, Willow, and Hill Creeks	480,594	258,943
Ute Mountain Ute Tribe	San Juan, Animas, La Plata, Mancos, McElmo, and Dolores Rivers	88,358	51,081

Source: Reclamation 2012

[4] While some entitlements are not ITAs, they are included for reference in this Appendix.
[5] Tribes may have other sources of water, including groundwater and other surface water, which are not part of this analysis.

Lower Basin

Water Entitlements

Lower Basin Tribes have mainstream Colorado River water entitlements as determined and quantified under the 2006 Consolidated Decree, and water entitlements and settlements, including CAP water.

Water Entitlements Determined under Arizona v. California

The Consolidated Decree determined and quantified mainstream Colorado River water rights for five tribes— Chemehuevi Indian Tribe (Chemehuevi Indian Reservation of California), Colorado River Indian Tribes (Colorado River Indian Reservation of Arizona and California), Fort Mojave Indian Tribe (Fort Mojave Indian Reservation of Arizona, California, and Nevada), Fort Yuma Quechan Indian Tribe (Fort Yuma Indian Reservation of Arizona and California), and Cocopah Indian Tribe (Cocopah Indian Reservation of Arizona) water entitlements.

Table TA 18-2 summarizes water entitlements along the Colorado mainstream in the Lower Basin.

Table TA 18-2
Colorado River Mainstream Native American Water Entitlements

Tribe/Reservation	State	Entitlement (afy of Diversion)	Present Perfected Right (PPR) Number	Priority within State	Priority Date

[+] Indicates that the entitlement is not an ITA.

Notes: Arizona (AZ); California (CA); Nevada (NV)

Notes: The diversionary entitlements, including equivalents, are listed for comparative analysis purposes, which is not intended to modify the entitlement as defined by the applicable establishing authority.

Central Arizona Project

Several tribes in Arizona hold CAP water entitlements, which may be held in trust in accordance with the applicable settlement. These tribal entitlements to CAP water or Colorado River water delivered through the CAP in central Arizona are administered pursuant to settlements and water delivery contracts between tribes and the Secretary of the Interior (**Table TA 18-3**).

Table TA 18-3
CAP Water Delivery Entitlements

Tribe or Reservation	Contract Delivery Volume (afy)	Arizona Priority	CAP Priority
Ak-Chin Community	50,000	3	N/A
Ak-Chin Community	58,300	4	Indian

[6] The U.S. delivers between 72,000 to 85,000 afy to the Ak-Chin Indian Community in accordance with the terms of its settlement, even though Ak-Chin's total entitlement is greater than this amount. The San Carlos Apache Tribe is entitled to the CAP Indian Priority water not required for delivery to the Ak-Chin Indian Community, consistent with the terms of its settlement.

[7] Other supplies are not listed in this appendix.

[8] In addition, the San Carlos Apache Tribe is entitled to the Ak-Chin Community's CAP Indian Priority water not required for delivery to the Ak-Chin Indian Community, consistent with the terms of its settlement.

Tribe or Reservation	Contract Delivery Volume (afy)	Arizona Priority	CAP Priority
White Mountain Apache Tribe	1,218	4	Indian
White Mountain Apache Tribe subtotal	*25,000*	*N/A*	*N/A*
Yavapai-Apache Nation[+]	1,200	4	Indian

Source: Reclamation 2012; CAP 2025

[+] Indicates that the entitlement is not an ITA.

Unquantified and Undeveloped Water Rights

In the context of tribal water, unquantified water rights refer to federally reserved water rights that have not yet been determined and quantified through an adjudication or settlement. While recognizing this important issue, the water deliveries analysis only considers quantified tribal water rights. This analysis should not be construed to, in any way, preclude or limit any ongoing or future quantification of tribal water rights.

In the context of tribal water, undeveloped water rights refer to quantified rights that are not being fully utilized. Undeveloped water may be due to a lack of the infrastructure needed to divert, transport, and/or use water (Water and Tribes Initiative 2025). While recognizing this important issue, this analysis does not distinguish between developed and undeveloped rights in the water deliveries analysis. This analysis should not be construed to, in any way, preclude or limit any ongoing or future tribal development of water rights.

TA 18.1.3 Other Indian Trust Assets

ITAs can also include hunting, fishing, trapping, and gathering rights; mineral rights; and cultural, biological, and other resources. Whether or not specific rights or resources legally qualify as an ITA is complicated and depends on multiple factors, such as land status (Reclamation 1994). Reclamation consulted with tribes and the Bureau of Indian Affairs to identify ITAs. To date, potential changes in water deliveries and activities affected by potential changes in water deliveries (e.g., irrigated agriculture) have been the primary concerns related to ITAs.

Reclamation acknowledges that the 30 Basin Tribes depend on the Colorado River and its tributaries for a variety of purposes, including cultural and spiritual activities, wildlife, instream flows, recreation, and other purposes. See **TA 13**, Tribal Resources, and **TA 11**, Cultural Resources, for analysis of tribal and cultural resources, respectively. In general, those analyses apply to tribal and cultural resources that qualify as ITAs.

Although income derived from ITAs is not an ITA, Reclamation notes that income derived from ITAs such as agricultural products, water leases, and fees charged for outdoor recreation on tribal land can be an important source of income for tribes.

TA 18.2 Environmental Consequences

Following Reclamation ITA policy (Reclamation 1994), the following analysis discusses actions that affect the value, use, or enjoyment of ITAs.

TA 18.2.1 Methodology

The methodology varies for each type of ITA. Quantitative metrics are analyzed where possible; otherwise, qualitative discussion is provided.

- For trust lands, potential changes in irrigated acreage due to fluctuating water deliveries are a primary concern. The amount of tribal agricultural land (in acres) estimated to be fallowed under each alternative is presented.
- For water entitlements, the analysis focuses on changes in the quantity of water (in acre-feet) estimated to be delivered to tribes under each alternative. Changes in options to conserve and store water are also discussed.
- For other ITAs, analysis is qualitative.

Impact Analysis Area

The impact analysis area includes land within the boundaries of reservations and off-reservation trust land within the Colorado River Basin (29 reservations listed in **TA 18.1**[9]).

Assumptions

- Trust land includes land within the borders of established reservations and off-reservation trust land.
- For the water deliveries analysis, the assumptions of Colorado River Simulation System modeling (**Appendix A**, CRSS Model Documentation) and SAM modeling (**Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation) apply.
- For potential impacts on agricultural land, the assumptions of the agricultural modeling apply (see **TA 16**, Socioeconomics, for more details).

Impact Indicators

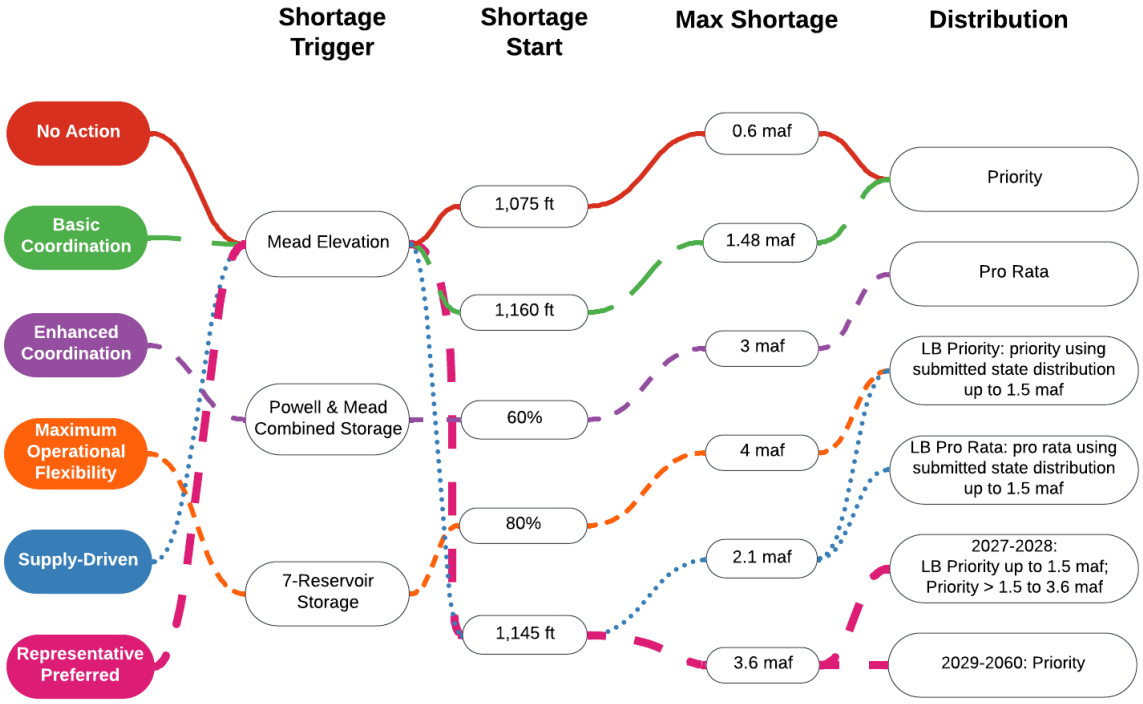
- Percent of normal water entitlement delivered to Upper and Lower Basin Tribes.
- Changes in acres of irrigated tribal agricultural land.

TA 18.2.2 Issue 1: How Will Changes in Dam Operations Affect Tribal Water Entitlements, Water Deliveries, and Water Storage and Conservation Options?

The approaches to distributing shortages incorporated in all alternatives are designed to explore a wide range of potential concepts and impacts; they do not reflect an intention by Reclamation to alter apportionments or water entitlements. However, because the concepts would affect a range of

[9] As discussed in **Section TA 18.1**, one of the 30 Basin Tribes does not have an established reservation; therefore, there are 29 reservations.

users, impacts on deliveries to different entities are analyzed, and addressed in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation.



With respect to potential tribal water deliveries, the alternatives can be distinguished based on the following characteristics:

- The maximum shortage, which affects the relative frequency and severity of Lower Basin water shortages, including potential dead pool–related reductions (that is, releases reduced by low Lake Mead levels or outlet limits).
- The approach used to distribute Lower Basin water under shortages[10].
    - The Priority distribution approach distributes shortages based on existing statutory, case law, and contractual provisions. It is used in the Continued Current Strategies (CCS) Comparative Baseline, the No Action Alternative, and the Basic Coordination Alternative. It is also used in the Preferred Alternative when no consensus distribution agreements exist that would alter the approach. Note that Reclamation and stakeholders would remain able to adopt consensus shortage distributions during the term of the Preferred Alternative.
    - The Pro Rata distribution approach distributes shortages pro rata (that is, in a determined proportion) across water users. It is used in the Enhanced Coordination Alternative.
    - The Lower Basin Priority (LB Priority) distribution approach follows specified state-specific distributions for the first 1.5 million acre-feet (maf) of shortage and then follows priority for larger shortages. It is used in the Maximum Operational Flexibility and the Supply Driven (LB Priority approach) Alternatives.
    - The Lower Basin Pro Rata (LB Pro Rata) approach follows specified state-specific distributions for the first 1.5 maf of shortage and then follows pro rata for larger shortages. It is used in the Supply Driven Alternative (LB Pro Rata approach).
- Options for tribes and other water users to conserve and store water in Lake Powell or Lake Mead.

Figure TA 18-1 and **Table TA 18-4** summarize the alternatives based on these characteristics. **Figure TA 18-1** provides summary information on the shortage triggering metric, when shortages start relative to that metric, maximum operational shortage volume, and modeled distribution method. **Table TA 18-4** provides information on the maximum shortage volume, distribution method, and water storage and conservation options. **Table TA 18-4** includes the CCS Comparative Baseline for comparison. See **Chapter 2**, Description of Alternatives, and **Appendix S**, Additional Description of Alternatives, for a more detailed discussion of the alternatives.

[10] See **Appendix C,** Shortage Allocation Model and Alternative Distribution Model Documentation, for more information on the distribution methods.

Figure TA 18-1
Lower Basin Shortage Guidelines

Notes: Additional restrictions in water deliveries will occur when Lake Mead is near dead pool, resulting in large reductions (referred to as "dead pool-related reductions"). These are not considered an operational element of the alternatives. The "Representative Preferred Alternative" is a set of modeling assumptions designed around the Preferred Alternative sideboards. The specific operating guidelines for each operating interval during the term of the Preferred Alternative may differ. Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Table TA 18-4
Comparison of Key Factors Affecting Tribal Water Deliveries among Alternatives and the CCS Comparative Baseline

Scenario	Maximum Shortage (maf)[b]	Distribution Method	Water Storage and Conservation Options
CCS Comparative Baseline	1.375[a]	Priority	Continued intentionally created surplus (ICS). No new mechanisms.
No Action Alternative	0.6	Priority	Water conserved under previous mechanisms that remains in Lake Mead in 2027 would be delivered in accordance with existing agreements. No new mechanisms.

Scenario	Maximum Shortage (maf)[b]	Distribution Method	Water Storage and Conservation Options
Preferred Alternative (Including Representation of Operational Elements)	3.6	In 2027-2028, shortages up to 1.5 maf are distributed based on LB Priority and shortages exceeding 1.5 maf are distributed based on priority. After 2028, shortages are distributed based on priority.	Yes, three new mechanisms in place of ICS (one conservation pool in Lake Powell and two in Lake Mead)
Basic Coordination Alternative	1.48	Priority	Water conserved under previous mechanisms that remains in Lake Mead in 2027 would be delivered in accordance with existing agreements. No new mechanisms.
Enhanced Coordination Alternative	3.0	Pro rata	Yes, three new mechanisms in place of ICS (one conservation pool in Lake Powell and two in Lake Mead)
Maximum Operational Flexibility Alternative	4.0	LB Priority	Yes, one new mechanism in place of ICS (a combined Lake Powell and Lake Mead conservation pool)
Supply Driven Alternative (LB Priority approach)	2.1	LB Priority	Yes, two new mechanisms in place of ICS (one conservation pool in Lake Powell and one in Lake Mead)
Supply Driven Alternative (LB Pro Rata approach)	2.1	LB Pro Rata	Yes, two new mechanisms in place of ICS (one conservation pool in Lake Powell and one in Lake Mead)

[a] Includes the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead, Minute 323 Bi-national Water Scarcity Contingency Plan, and Drought Contingency Plans.

[b] Shortage distributions include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Upper Basin

Water Deliveries

None of the alternatives would directly or indirectly affect Upper Basin tribal water entitlements. As discussed below, water storage and conservation mechanisms under some alternatives could indirectly affect the amount of stored conservation water available to Upper Basin Tribes.

Storage and Conservation Options

The No Action and Basic Coordination Alternatives have no new water storage mechanisms and would not affect water storage and conservation by Upper Basin Tribes. The other four alternatives do have new storage and conservation mechanisms, which are summarized below. See **Chapter 2** for a full description of these mechanisms and how they would operate. Note that in all cases, stored water would be available for water transactions with other Upper Basin water users, both within and across Upper Division States.

- Under the Preferred Alternative, up to 3.0 maf of water conserved by Upper Basin water users could be stored in Lake Powell. Upper Basin Tribes would receive credit for the contribution of conserved consumptive use stored in the pool. Under certain conditions, water in the pool could be released.
- Under the Enhanced Coordination Alternative, up to 2.0 maf of water conserved by Upper Basin water users could be stored in Lake Powell. Under certain conditions, the stored water would be made available to offset portions of Lower Basin shortages, thereby reducing the amount of stored water available to Upper Basin Tribes that have participated in the mechanism.
- Under the Maximum Operational Flexibility Alternative, up to 3.0 maf of water conserved by Upper Basin water users could be stored in a combined pool managed across both Lake Powell and Lake Mead. Under certain conditions, stored water could be converted to system water, thereby reducing the amount of stored water available to Upper Basin Tribes that have participated in the mechanism.
- Under the Supply Driven Alternative, Upper Basin water users could contribute up to 3.0 maf of water to a storage pool in Lake Powell. Water in the pool could be released if needed to meet the determined water-year volume, thereby reducing the amount of stored water available to Upper Basin Tribes that have participated in the mechanism.

In general, the four alternatives above that include new mechanisms for storage and conservation of water would provide additional options to Upper Basin Tribes. Assuming these methods could be implemented with appropriate authority, first, the mechanisms would allow tribes to store water as insurance against potential future changes in water demand or supply. Second, the mechanisms would create a new way for tribes to lease or transfer water from or to other Upper Basin water users.

Lower Basin

Water Deliveries

Some alternatives impact Lower Basin tribal entitlements by altering the shortage distribution methodologies. The alternatives also impact water deliveries to some degree. Reclamation modeled water deliveries in the Lower Basin using the SAM and ADM. There are three unique SAMs and five ADMs to capture the nuances of the alternatives and sensitivity analyses, which are further explained in **Appendix S**, Additional Description of Alternatives.

In this analysis, three main factors combine to determine potential Lower Basin tribal water deliveries in any given year:[11]

1. The severity of potential shortages
2. The distribution method used to allocate water under shortages
3. The frequency of dead pool–related reductions[12]

This analysis focuses on the first two factors. The third factor, dead pool–related reductions, is not a focus of this analysis.[13] In general, Reclamation anticipates acting to minimize dead pool–related reductions. However, the methods for doing so and the methods for allocating water under a dead pool–related release are unknown and too speculative to be included in this Final EIS.

Figure TA 18-2 illustrates how the percentage of water delivery changes as shortages become more severe. There are four tables in **Figure TA 18-2**, one for each of the different distribution methods included in the alternatives. For the purposes of this analysis, tribes are aggregated into four groups based on entitlement priorities, which are contained in the rows of **Figure TA 18-2**:[14] Shortage impacts for specific entities are contained in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation.

- The "AZ CAP NIA" group are the most junior entitlements and includes tribes with Arizona CAP non-Indian agriculture (NIA)-A and NIA-B priorities. This group consists of four tribes with contracts totaling approximately 177,000 acre-feet per year (afy).
- The "AZ CAP Indian, CAP municipal and industrial (M&I), AZ 4i" group includes tribes with Arizona CAP Indian, CAP Municipal & Industrial, and Arizona 4i priorities. This group consists of 13 tribes and 16 individual entitlements (including mainstream water reserved for future settlement and unallocated) totaling approximately 374,000 afy.
- The "AZ 3" includes one tribe with Arizona 3rd priority, totaling 50,000 afy.
- The present perfected right (PPR) group are the most senior entitlements; this group includes five tribes in all three Lower Division States. Five tribes with 15 discretely quantified entitlements totaling approximately 503,000 afy are included in this group.

The columns in **Figure TA 18-2** represent different total Lower Basin shortage levels. The cells in **Figure TA 18-2** show the percentage delivery of water entitlements for each group. Note that the cells in **Figure TA 18-2** are combined results for each group, not for any single tribe within a group; therefore, the data for individual tribes within a group may differ from the group's data. Similar information on potential deliveries for individual tribes is presented in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation.

[11] The phrase "potential water deliveries" is intended to recognize that some tribal entitlements are not fully developed and/or utilized. For simplicity, this analysis assumes that water deliveries and entitlements refer to the same quantities of water.
[12] Conditions that might cause a dead pool–related release are described in **TA 4**, Water Deliveries.
[13] Modeling results related to the potential frequency of dead pool–related releases are discussed further below.
[14] The number of tribes, water entitlements, and amounts listed below come from the SAM (see **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation, for modeling assumptions and descriptions of priority nomenclature).

Figure TA 18-2
Comparison of Water Deliveries by Distribution Method, Tribal Priority Group, and Shortage Amount

Percent Delivery by Total Shortage Volume (maf) under the Priority Distribution Method (Used in No Action, Basic Coordination, and Representative Preferred [2029-2060] Alternatives)

Tribal Priority Group	0.0	0.2	0.4	0.6	0.8	1.0	1.5	3.0	4.0	5.0	6.0	7.0

Source: SAMs and ADMs.

It is important to note that the shortages depicted in **Figure TA 18-2** extend beyond the maximum shortages specified in the alternatives, which range from 0.6 maf to 4.0 maf (**Table TA 18-4**). The inclusion of larger shortages in **Figure TA 18-2** should not be taken to imply that these specific distributions would, in fact, apply to shortages higher than the maximum shortages (such as might happen during a dead pool–related release); rather, it is intended to better illustrate the implications of the different distribution methods. Please refer to the maximum shortages in **Table TA 18-4** when interpreting the information in **Figure TA 18-2**.

In **Figure TA 18-2**, the different influences that the priority and pro rata distribution methods (the first two tables) have on the percentage delivery of water are readily apparent. Under the priority distribution system, less water is delivered to groups with more junior water entitlements, and more water is delivered to groups with more senior water entitlements. The differences in the percentage of water delivered increase as the shortage volume increases. In contrast, the percentage of water delivered under the pro rata distribution method is the same across the groups for all levels of shortages.

The third table shows the LB Priority distribution approach (that is, state-specific percentages up to 1.5 maf of shortage, then the priority distribution method for larger shortages). It results in similar deliveries as the priority distribution for all priority groups except the AZ CAP Indian, CAP M&I, AZ4 group. This group receives more water under shortages up to 1.5 maf than the straight priority distribution method.

The fourth table shows the LB Pro Rata distribution approach (that is, state-specific percentages up to 1.5 maf, then the pro rata distribution method for larger shortages). It has a similar pattern to the pro rata distribution (the second table) but has differences in the specific numbers in each cell. Like the pro rata distribution, the LB Pro Rata distribution approach delivers more water to junior water entitlements holders and less water to senior water entitlements holders, compared to the priority distribution methods.

Decision Making under Deep Uncertainty (DMDU) is an approach used to expand on the quantitative analysis. It is a non-probabilistic evaluation framework that compares alternatives based on their ability to meet specific performance criteria in many potential future conditions and analyzes how the alternatives respond to specific hydrologic conditions. Additional background and technical details about the DMDU framework are provided in **Appendix E**, DMDU Overview and Approach.

DMDU analysis expands the above analysis by integrating information on the percentage of futures in which different amounts of shortages are estimated to occur under the different alternatives. For tribal water deliveries, deliveries of 20 percent, 40 percent, 60 percent, and 80 percent of normal deliveries are modeled. As explained further below, the results show the percentage of futures in which these thresholds are met in 90 percent or more of the years within each modeled future.

The DMDU figures are presented in **Figure TA 18-3** through **Figure TA 18-11**. The rows contain different percentages of normal water deliveries, where "normal" means under non-Shortage Conditions. The top row contains the highest modeled level of water delivery (80 percent of normal

deliveries), which is the hardest threshold to achieve. The columns contain the CCS Comparative Baseline, the No Action Alternative, and the action alternatives.

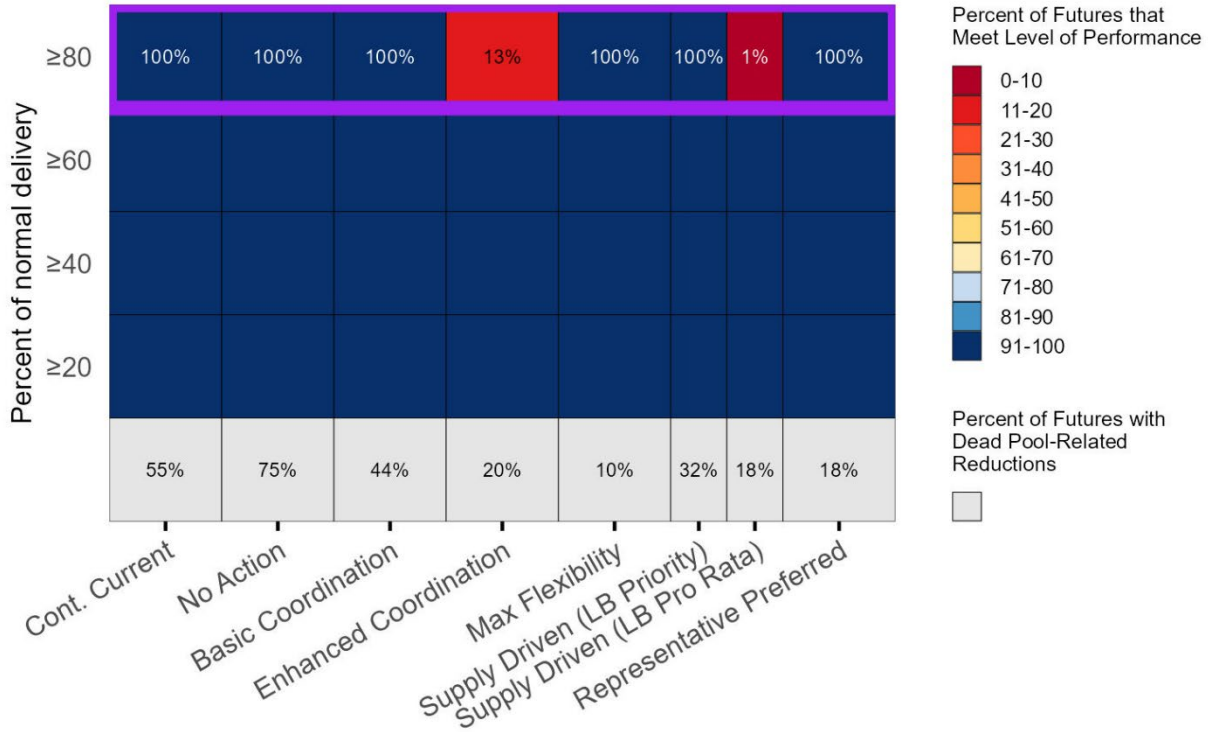
Cells are color-coded to indicate the percentage of modeled futures in which water deliveries exceed the thresholds in the row headers in at least 90 percent of the years of a future. The row indicating water deliveries of at least 80 percent of normal deliveries (the top row) has a purple border. Solely for the purposes of considering vulnerability within the DMDU modeling framework, a "preferred minimum performance" outcome is defined as a future trace in which at least 80 percent of normal water deliveries is estimated to be delivered in at least 90 percent of the years in a modeled future. In contrast, an "undesirable performance" future means that the preferred minimum performance criteria are not met. The 80 percent threshold was chosen as the "preferred minimum performance" because it is the model outcome with the largest quantity of water delivered.[15] Within the purple-bordered row, the percentage of futures that meet the preferred criteria is presented.

Note that the non-gray cells (that is, those except the bottom row) in the DMDU figures present the percentage of futures associated with shortages only. A shortage is prescribed by each alternative. Another type of reduction in water delivery results from a dead pool–related release, which occurs when conditions do not support unconstrained releases.[16] Different shortage volumes under the different alternatives affect the frequency of dead pool–related reductions.[17] The percentage of futures in which dead pool–related reductions occur under each alternative is presented in the gray cells at the bottom of the DMDU figures.

The DMDU figures are discussed below, in order of the priority groups with the most senior water entitlements to the group with the most junior entitlements. Note that the DMDU analysis is summarized at the end of this section. The following points are helpful when interpreting DMDU results for the Representative Preferred Alternative:

- There is an important distinction between the Preferred Alternative and the *Representative* Preferred Alternative. As discussed in **Chapter 2**, the Preferred Alternative is a multi-year decision framework that establishes the process and criteria that would govern development and adoption of operating guidelines through 2036. The decision framework is anticipated to be implemented in two-year operating intervals. Unlike other alternatives, the operating guidelines for each interval are not specified in this Final EIS. The sideboards provide a basis for assumptions included in the Representative Preferred Alternative which captures the range of operating guidelines that may be adopted during each interval, but exact operations would be subject to the guidelines in place during each interval.

- The Preferred Alternative has a defined implementation timeframe of 10 years; however, the Representative Preferred Alternative is compared to the other alternatives for the entire modeling horizon of 34 years to enable comparison of potential long-term impacts.



[15] In this context, "preferred minimum performance" and "undesirable performance" are terms selected to understand a modeling analysis, and they do not imply any policy, legal, or other conclusions about the analysis or ITAs.
[16] See **TA 4**, Water Deliveries for more information.
[17] In general, more frequent dead pool–related reductions are associated with lower maximum shortages, and vice-versa.

- A key assumption affecting tribal water deliveries is the shortage distribution method that would be used under Lower Basin shortage conditions. To capture the May 1, 2026 proposal by the Lower Division States for distributing up to 1.5 maf of shortage, the best available information at time of publication, the Representative Preferred Alternative uses the LB Priority distribution method to distribute the first 1.5 maf or shortage for 2027-2028. While the Representative Preferred Alternative models shortages above 1.5 maf in 2028, consistent with the sideboards, under the Preferred Alternative, Reclamation would consult with stakeholders if Lake Mead elevation is projected below 1,000 feet. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative). For 2029-2060, the Representative Preferred Alternative uses the Priority distribution method.

- The DMDU figures do not capture individual years within the modeling period, however, they are modeled. The modeling assumptions for the Representative Preferred Alternative in the first two years (2027–2028) are described in **Chapter 2** and the shortages up to 1.5 maf are distributed via LB priority. Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage). **TA 4**, Water Deliveries, shows analysis of the Representative Preferred Alternative for 2027 and 2028 at the state distribution level. The potential 2027 and 2028 operating guidelines modeling is compared to the Representative Preferred Alternative in **Appendix T**, Preliminary Description and Analysis of Anticipated Operating Guidelines for 2027 and 2028. The results for the Representative Preferred Alternative in 2029–2036, in which the Priority distribution is applied, would result in more shortage impacts on Arizona junior entitlements. Impacts beyond 2028 under the Preferred Alternative may be different from what is shown in the DMDU figures for the Representative Preferred Alternative, as this alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**.

Figure TA 18-3 contains the DMDU full analysis period modeling results for the PPR group. The PPR group contains the most senior water entitlements in the Lower Basin. As shown in the purple-bordered row (the top row), in the CCS Comparative Baseline and all alternatives other than the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, 100 percent of futures meet the assumed preferred minimum performance criteria, meaning that at least 80 percent of the normal water delivery is delivered in 90 percent of the years of a modeled future. This occurs because these are the most senior water entitlements in the Lower Basin, and all alternatives that have 100 percent in the purple-bordered row use a variation of the priority system. Because at least 80 percent of water is delivered in 100 percent of futures for these alternatives, the rows below the purple-bordered row for those alternatives (which indicate lower quantities of delivered water) are also 100 percent and thus are classified into the 91-100 percent category.

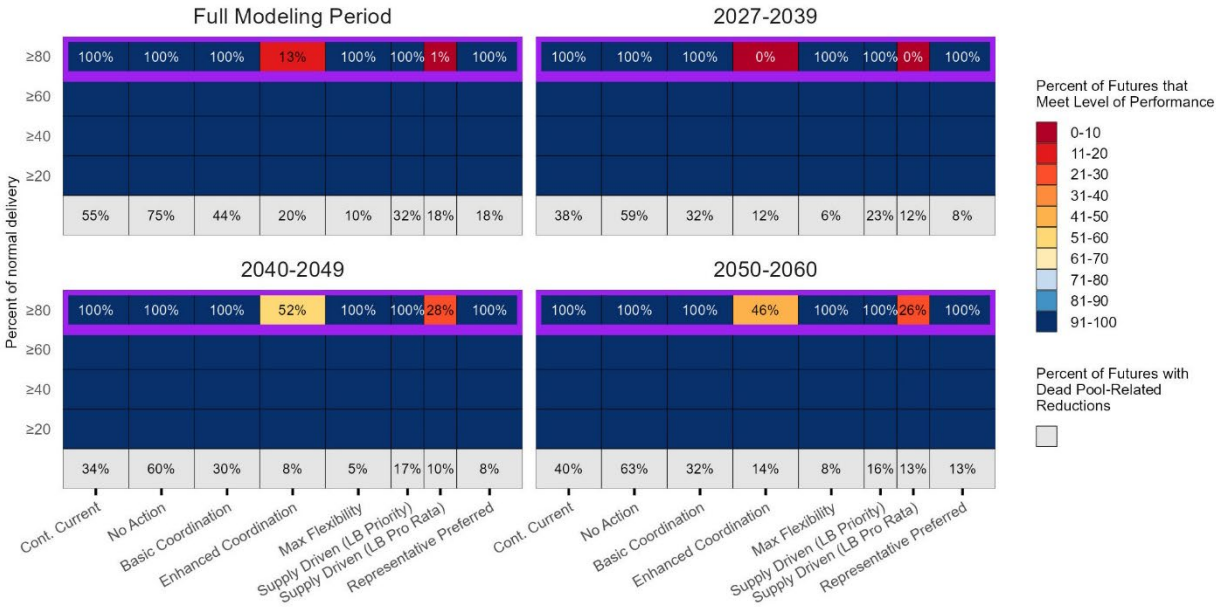
Figure TA 18-3
Present Perfected Rights: Robustness (Full Period).
Percent of futures in which annual delivery is the percent of normal delivery specified in each row in 90 percent of years

For the Enhanced Coordination Alternative, the preferred minimum performance criteria (at least 80 percent of normal water delivery in 90 percent of the years of a future) is met in 13 percent of modeled futures. For the Supply Driven Alternative (LB Pro Rata approach), 1 percent of futures meet the preferred minimum performance criteria. The lower result for these two alternatives is likely due, in part, to these alternatives using a variation of the pro rata distribution, which fulfills these senior water entitlements as though they were equal in priority to other Lower Basin entitlements. While 80 percent of normal water deliveries in 90 percent of years of a future occur in 13 percent of modeled futures under the Enhanced Coordination Alternative, at least 60 percent of water deliveries in all years of a future occur in 91-100 percent of modeled futures. Similarly, at least 60 percent of normal water deliveries would occur in 91-100 percent of modeled futures for the Supply Driven Alternative (LB Pro Rata approach).

Importantly, the analysis does not conclude that all alternatives that meet the preferred minimum performance criteria (the purple-bordered row) in 100 percent of modeled futures perform equally in terms of water deliveries to the PPR priority group. This is because the alternatives have different frequencies of modeled futures in which there is a dead pool–related release, as shown in the gray row at the bottom of the table. Less frequent dead pool–related reductions are better in terms of water deliveries because it means that there are more consistent water deliveries, all else equal. Therefore, among options that meet the preferred minimum performance criteria in 100 percent of

futures, the Maximum Operational Flexibility Alternative would be the most robust (as it minimizes dead pool–related releases) and the No Action Alternative would be the least robust (as it maximizes dead pool–related releases). The Representative Preferred Alternative is the second best performing alternative for this priority group, behind the Maximum Operational Flexibility Alternative. Because the Representative Preferred Alternative assumes a version of the priority distribution method, it performs relatively well for this priority group, which has some of the most senior tribal water entitlements.

The DMDU modeling results for the PPR priority group by subperiod (**Figure TA 18-4**) indicate generally similar relative performance of the CCS Comparative Baseline and the alternatives as those for the full period. As with the full period, in all but the Enhanced Coordination and the Supply Driven (LB Pro Rata approach) Alternatives, at least 80 percent of normal water deliveries in 90 percent of years is estimated to occur in 100 percent of modeled futures. The breakdown by subperiod provides some additional insight into the Enhanced Coordination Alternative. In the 2027-2039 subperiod, 0 percent of futures meet the preferred minimum performance criteria. However, 52 percent and 46 percent of futures meet the preferred minimum performance criteria in the 2040-2049 and 2050-2060 subperiods, respectively. A similar pattern occurs for the Supply Driven Alternative (LB Pro Rata approach), with 0 percent, 28 percent, and 26 percent of futures meeting the preferred minimum performance criteria in the three subperiods, respectively. The lower result for the first subperiod for these two alternatives occurs because the modeled futures start at low reservoir conditions, making it more difficult to deliver full water deliveries under variations of the pro rata distribution method during the 2027-2039 subperiod.



It is important to focus on the first decadal period (2027-2039), as this contains the implementation period of the Preferred Alternative. During this period, the Maximum Operational Flexibility Alternative performs the best, as it meets the preferred minimum performance criteria in 100 percent of modeled futures and has the lowest percent of futures with a dead pool–related release (6 percent). The Representative Preferred Alternative performs nearly as well for this priority group, meeting the preferred performance criteria in 100 percent of modeled futures and having the second-lowest percent of futures with a dead pool-related reduction (8 percent).

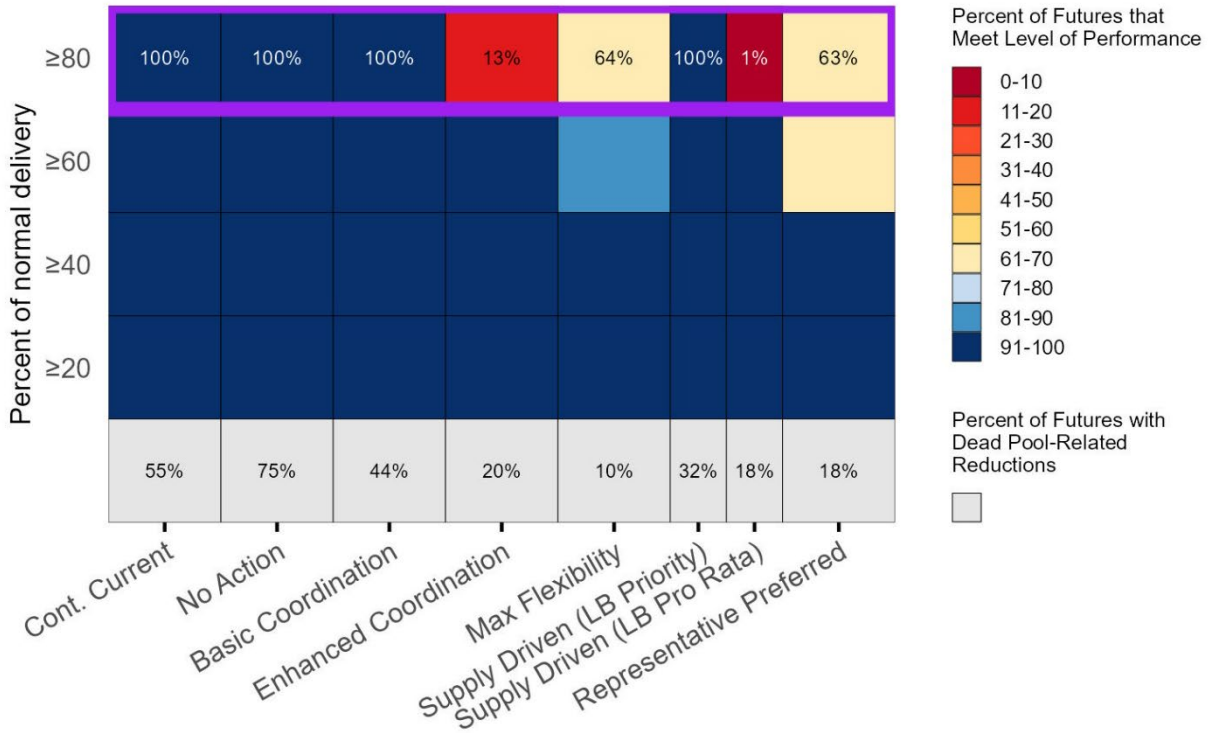
The Preferred Alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**, which could yield different impacts than the distribution methods assumed for the Representative Preferred Alternative. The DMDU figures do not capture individual years within the modeling period, however, they are modeled. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results in the full modeling period and the first modeling period are heavily influenced by the Priority distribution method, which is modeled 2029-2060. Entity-specific shortage impacts under each shortage distribution method that was modeled for this EIS are presented in **Appendix C,** Shortage Allocation Model and Alternative Distribution Model Documentation.

Several alternatives meet the preferred minimum performance criteria less frequently in the first subperiod (2027-2039) compared to the later two subperiods (2040-2049 and 2050-2060). This

occurs because the first subperiod follows low flow conditions, reducing operational flexibility and making Lower Basin shortages more common during that time frame.

Figure TA 18-4
Present Perfected Rights: Robustness (by Subperiod).
Percent of futures in which annual delivery is the percent of normal delivery specified in each row in 90 percent of years

The full period DMDU results for the Arizona Priority 3 group (**Figure TA 18-5**) are the same as for the PPR group except for the Maximum Operational Flexibility Representative Preferred Alternatives. For the Maximum Operational Flexibility Alternative, the preferred minimum performance criteria (at least 80 percent of normal water deliveries in 90 percent of years of a future) is estimated to be met in 64 percent of modeled futures, a decrease in its robustness relative to the PPR group.



Note that the percentage of futures with a dead pool–related release is independent of the priority group and is therefore the same as in the PPR group results. Similar considerations as described for the PPR group apply.

No alternative is clearly more robust than the others for the Arizona Priority 3 group. Depending on whether one considers the percentage of futures that meet preferred minimum performance criteria or the percentage of futures in which dead pool–related reductions are avoided as more important, the most robust would be either the Supply Driven Alternative (LB Priority Approach; which delivers more water considering only shortages) or the Maximum Operational Flexibility Alternative (which minimizes the frequency of dead pool–related reductions).

The results for the Arizona Priority 3 group by subperiod (**Figure TA 18-6**) do not change the conclusions above concerning the relative robustness of the alternatives; the most robust alternative is either the Supply Driven Alternative (LB Pro Rata) or the Maximum Operational Flexibility

Alternative, depending on whether one prioritizes deliveries considering shortages only or the frequency of dead pool-related reductions.

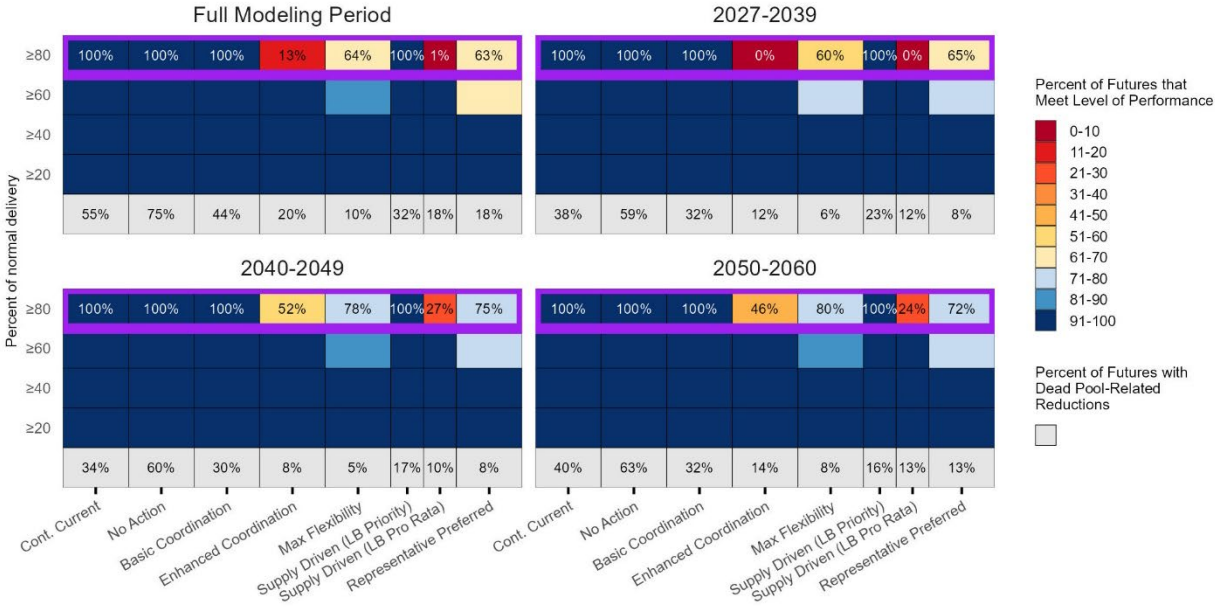


Figure TA 18-5
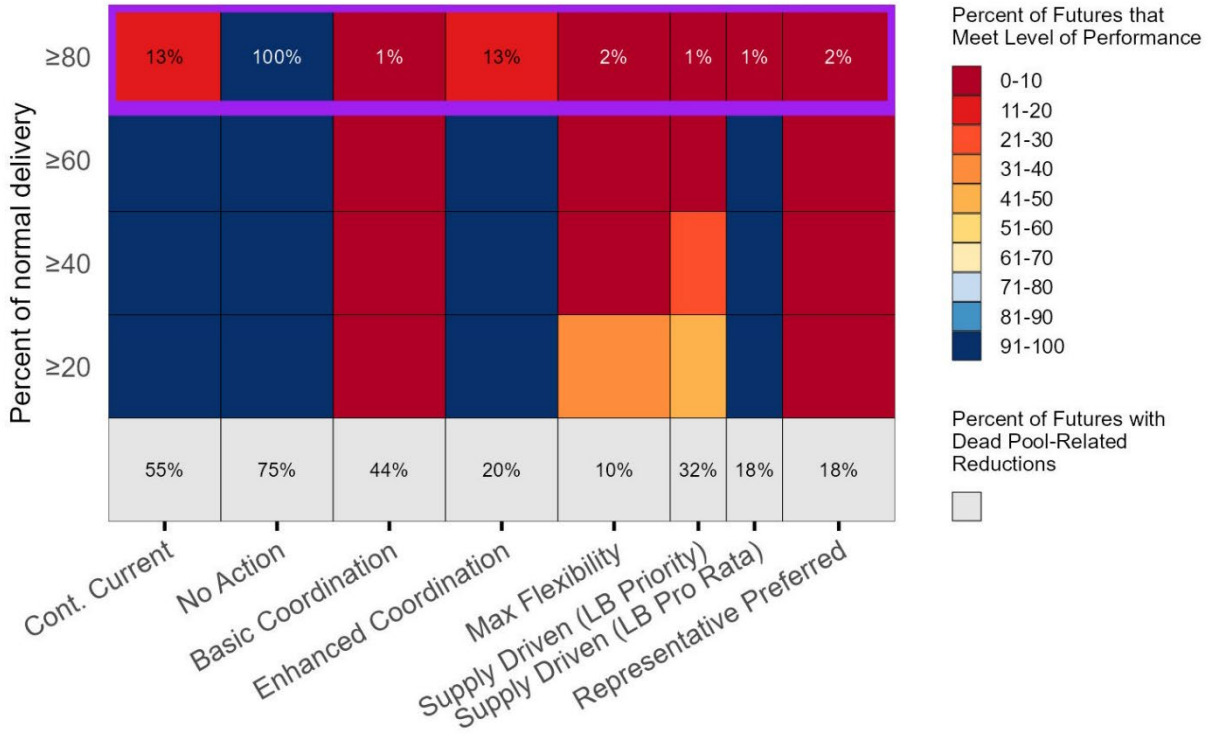
Arizona Priority 3: Robustness (Full Period).
Percent of futures in which annual delivery is the percent of normal delivery specified in each row in 90 percent of years

For the first decadal period (2027-2039), which contains the implementation period of the Preferred Alternative, the Representative Preferred Alternative performs second-to-last among the alternatives for deliveries, meeting the preferred performance criteria in 65 percent of modeled futures; however, it has the second-lowest percent of futures with a dead pool-related reduction (8 percent).

The full period DMDU modeling results for the Arizona CAP Indian, CAP M&I, and Arizona Priority 4i group (**Figure TA 18-7**) are very different than the results for the PPR and Arizona Priority 3 groups. Under CCS Comparative Baseline, the preferred minimum performance criteria (at least 80 percent of water is delivered in 90 percent of years of a future) is met in only 13 percent of futures. The No Action Alternative meets the preferred minimum performance criteria in 100 percent of futures. However, as previously noted, this considers only shortages. The No Action Alternative has dead pool–related reductions in 75 percent of futures, implying that full water delivery is unlikely under the No Action Alternative. The Enhanced Coordination Alternative also meets the preferred minimum performance criteria in 13 percent of modeled futures. All other alternatives meet the preferred minimum performance criteria in less than 5 percent of modeled futures.

Figure TA 18-6
Arizona Priority 3: Robustness (by Subperiod).
Percent of futures in which annual delivery is the percent of normal delivery specified in each row in 90 percent of years



Dropping down to the next highest water delivery threshold (60 percent), the CCS Comparative Baseline and three alternatives (No Action Alternative, Enhanced Coordination Alternative, and Supply Driven Alternative [LB Pro Rata approach]) provide at least 60 percent of normal deliveries in 90 percent of years of a future in 91-100 percent of futures. Of these, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives have a lower percentage of futures with dead pool–related releases, which occur in 20 and 18 percent of futures, respectively.

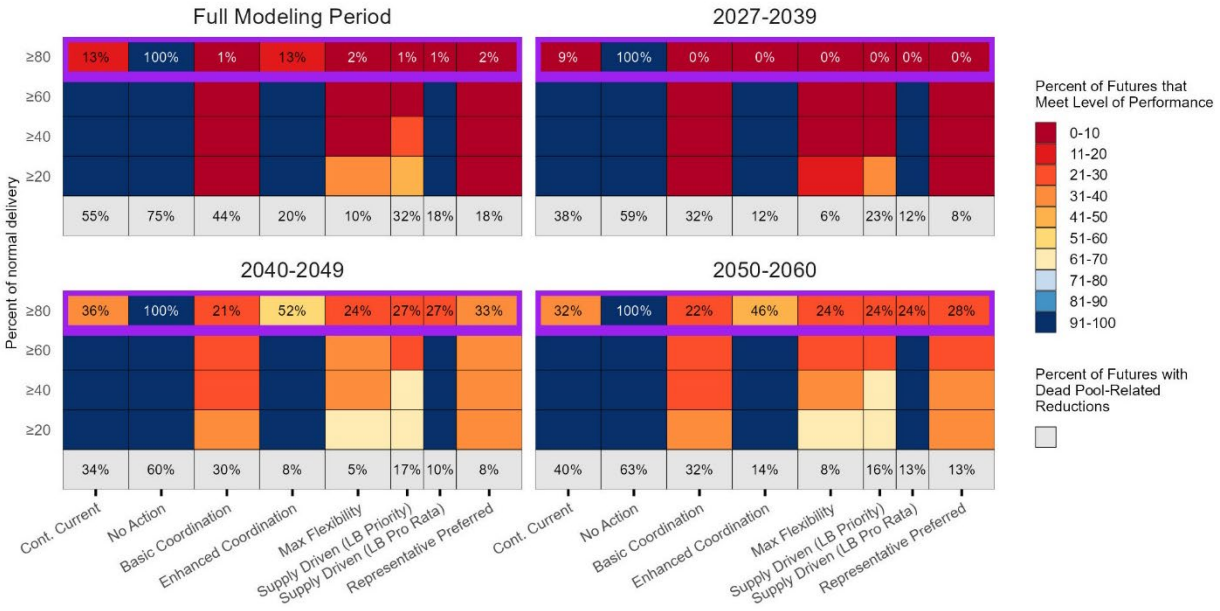
The Representative Preferred Alternative is not robust for this priority group, meeting the preferred performance criteria in only 2 percent of modeled futures over the full modeling period, and 0 percent of modeled futures over the first decadal period (2027-2039), which contains the implementation period of the Preferred Alternative. In addition, the lowest amount of water delivery modeled (at least 20 percent of normal water delivery) occurs in only 1-10 percent of modeled futures. This is because the Representative Preferred Alternative assumes a version of the priority distribution method and this priority group has relatively junior water entitlements. However, the Representative Preferred Alternative still performs second best with respect to dead pool-related reductions.

No alternative is clearly the most robust for this priority group. Depending on whether one considers the percentage of futures that meet preferred minimum performance criteria or the percentage of futures in which dead pool–related releases are avoided as more important, the more robust alternative would be either the No Action Alternative (more water is delivered, considering only shortages) or the Enhanced Coordination Alternative (which meets the preferred performance criteria substantially less often but has a substantially lower frequency of dead pool–related reductions).

Figure TA 18-7
Arizona CAP Indian, CAP M&I, and Priority 4i: Robustness (Full Period).
Percent of futures in which annual delivery is the percent of normal delivery specified in each row in 90 percent of years

Considering the DMDU modeling for the AZ CAP Indian, CAP M&I, and AZ 4i group results by subperiod (**Figure TA 18-8**), the same high-level performance rankings as the full period hold; the best performing alternatives are the No Action and the Enhanced Coordination Alternatives. However, the Enhanced Coordination Alternative appears more robust by subperiod than when considering only the full period, as it is estimated to be more robust in the two later subperiods compared to the first subperiod and the full period. While the Basic Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives would also be more robust in the later two subperiods compared to the first subperiod and full period, the Enhanced Coordination Alternative continues to be more robust than the other action alternatives for this priority group.

Figure TA 18-8
Arizona CAP Indian, CAP M&I, and Priority 4i: Robustness (by Subperiod).
Percent of futures in which annual delivery is the percent of normal delivery specified in each row in 90 percent of years



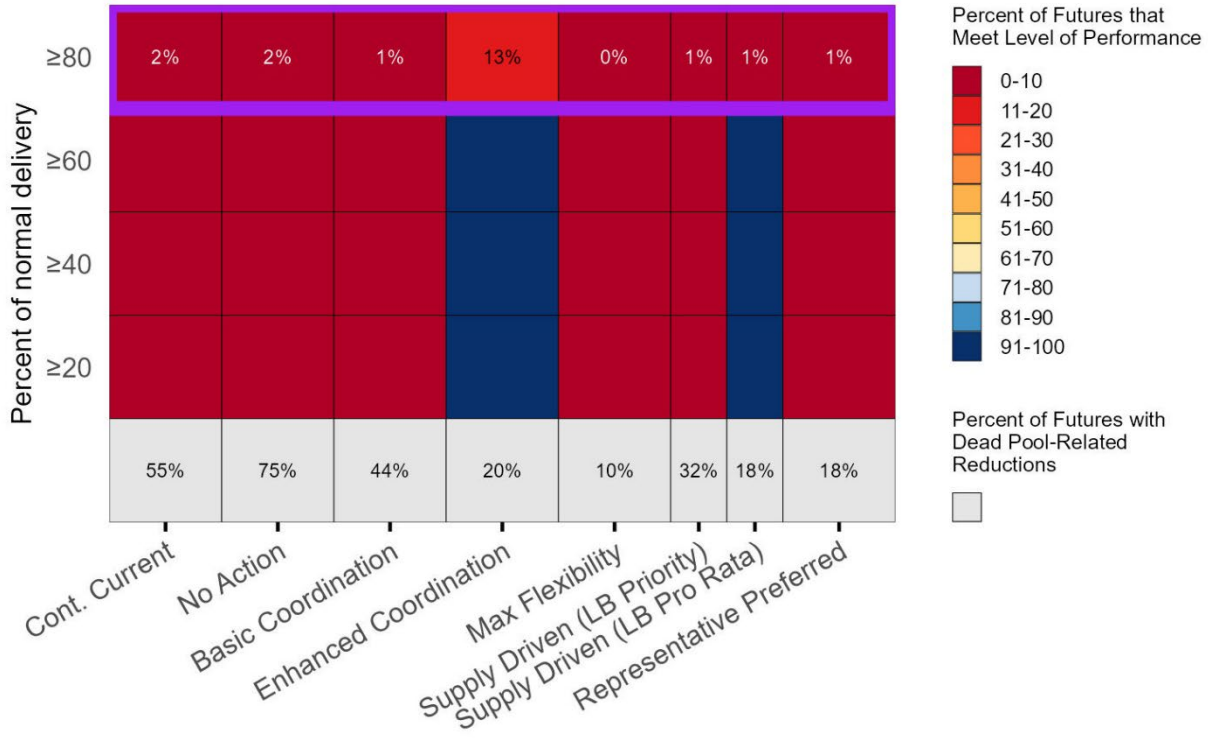


Figure TA 18-9 presents DMDU full period modeling results for the CAP Indian NIA group. These contracts are some of the most junior tribal entitlements in the Lower Basin. As such, it should be expected that deliveries will often be lower during Shortage Conditions compared to other priority groups. With one exception (the Enhanced Coordination Alternative), the CCS Comparative Baseline and the alternatives meet the preferred minimum performance criteria in less than 5 percent of modeled futures. The Enhanced Coordination Alternative meets the preferred minimum performance criteria in 13 percent of modeled futures.

The only two alternatives that consistently deliver water to this priority group are the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, which deliver at least 60 percent of normal water deliveries in 90 percent of years of a future in 91-100 percent of futures. This is likely due to their use of variations of the pro rata distribution method, which delivers more water to junior entitlements as shortages increase compared to the priority distribution, some variation of which is used by CCS Comparative Baseline and the other alternatives. Combined with its relatively low percentage of futures with a dead pool–related release (16 percent), the Enhanced Coordination Alternative is clearly the most robust alternative for this priority group.

As with the Arizona CAP Indian, CAP M&I, and Arizona Priority 4i group, the Representative Preferred Alternative is not robust for the CAP Indian NIA group, meeting the preferred performance criteria in only 1 percent of modeled futures for the full modeling period and delivering at least 20 percent of normal water deliveries in only 1-10 percent of modeled futures. For the first decadal period (2027-2039), which includes the implementation period for the Preferred Alternative, the Representative Preferred Alternative does not meet the preferred performance criteria in any

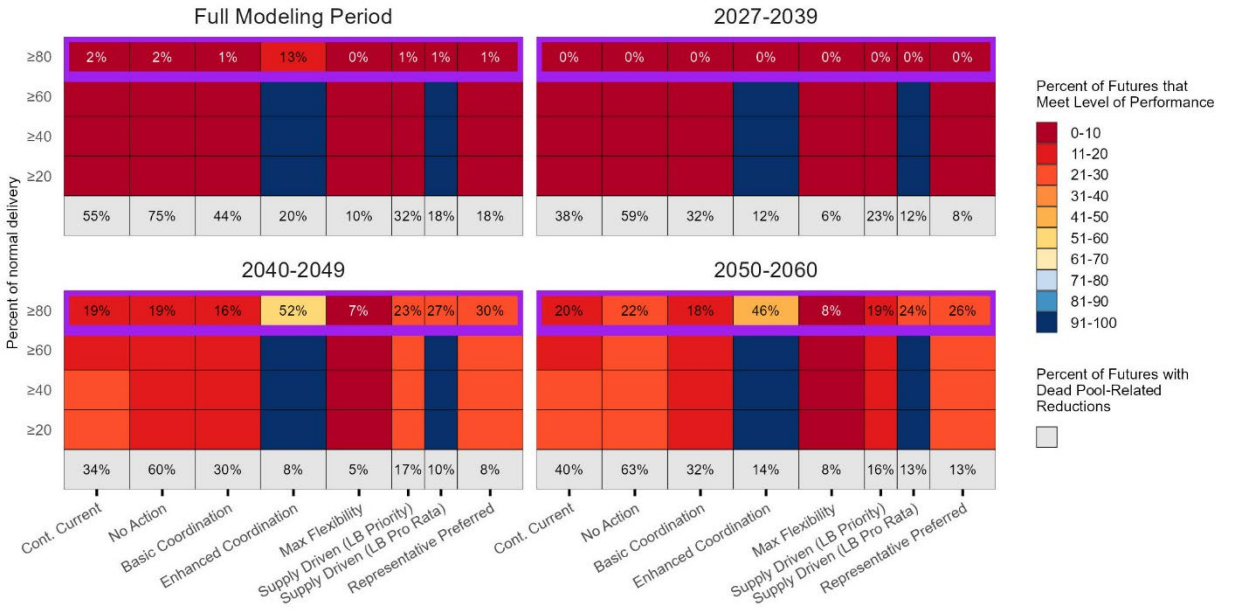
modeled futures. This is because the Representative Preferred Alternative assumes a version of the priority distribution method and this priority group has relatively junior water entitlements. However, for dead pool-related reduction, the Representative Preferred Alternative still performs second-best.

Figure TA 18-9
Arizona CAP Non-Indian Agriculture Priority: Robustness (Full Period). Percent of futures in which annual delivery is the percent of normal delivery specified in each row in 90 percent of years

The Preferred Alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**, which could yield different impacts than the distribution methods assumed for the Representative Preferred Alternative. The DMDU figures do not capture individual years within the modeling period, however, they are modeled. While the Representative Preferred Alternative does model shortages up to 1.5 maf using the LB Priority approach in 2027 and 2028, the results in the full modeling period and the first modeling period are heavily influenced by the Priority distribution method, which is modeled 2029-2060. Entity-specific shortage impacts under each shortage distribution method that was modeled for this EIS are presented in **Appendix C**.

The subperiod DMDU modeling results for the CAP Non-Indian Agriculture priority group (**Figure TA 18-10**) show similarities to the subperiod results for other priority groups, specifically that several alternatives are more robust in the later two subperiods compared to the first subperiod and the full period. For this priority group, the rank of the alternatives is not affected by the subperiods; the Enhanced Coordination Alternative continues to be the most robust for this priority group.

Figure TA 18-10
Arizona CAP Non-Indian Agriculture Priority: Robustness (by Subperiod).
Percent of futures in which annual delivery is the percent of normal delivery specified in each row in 90 percent of years



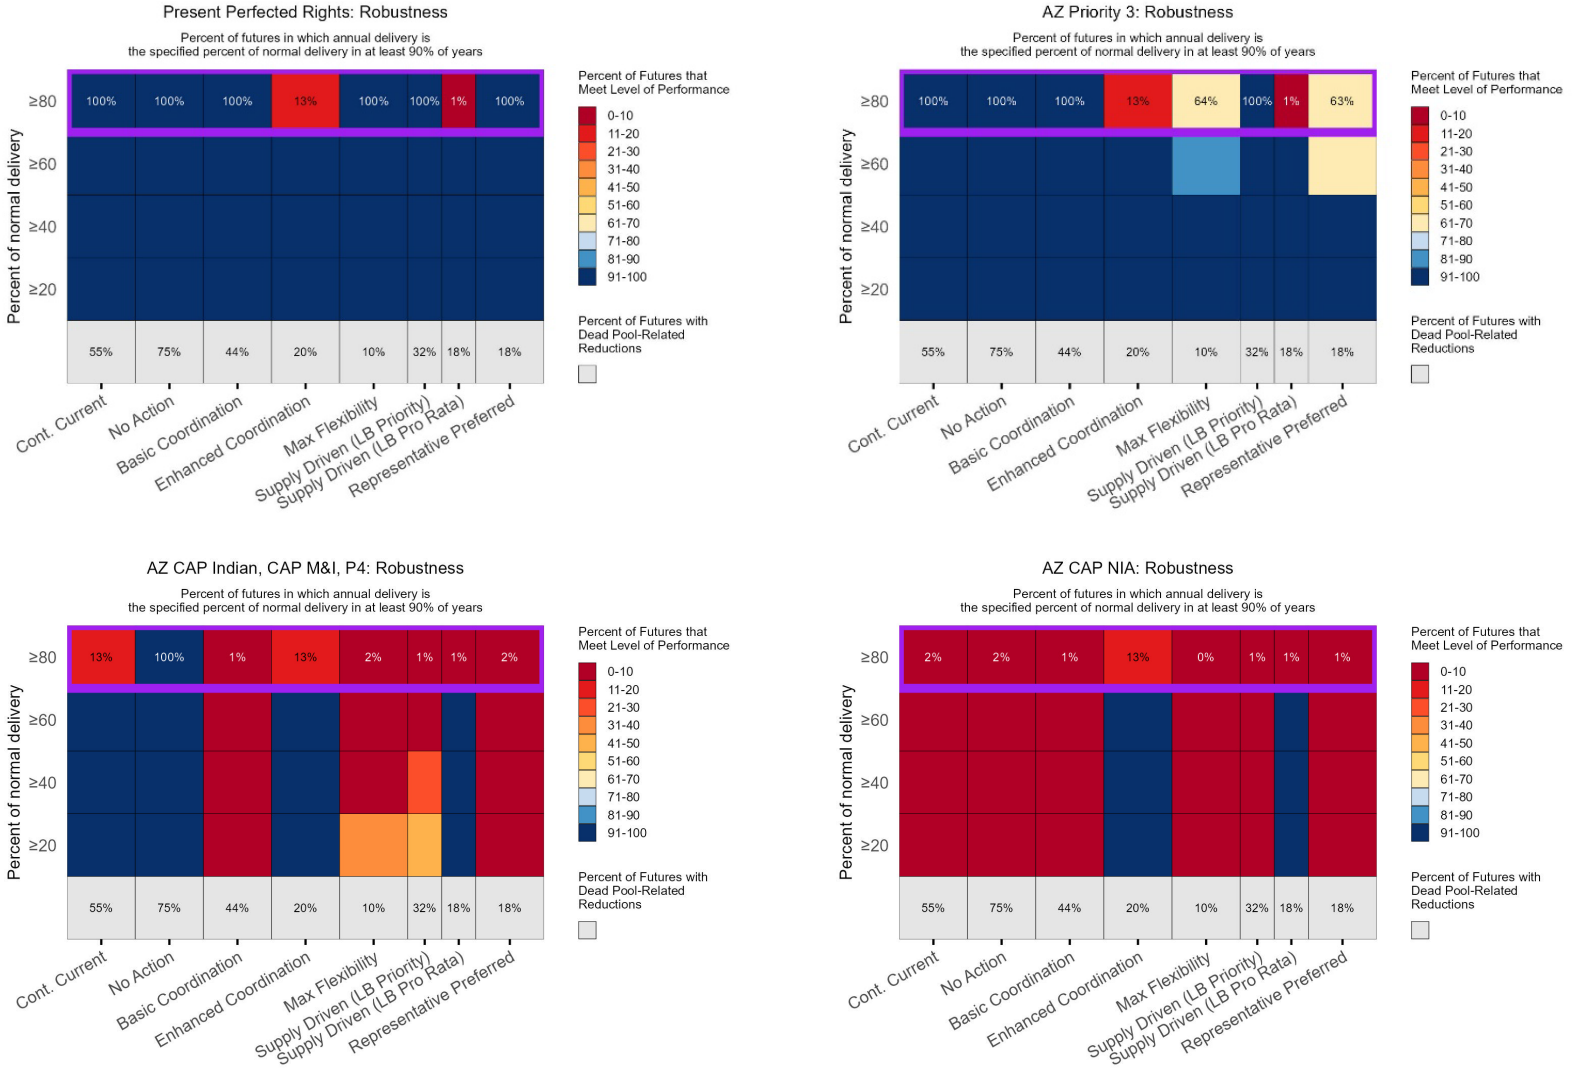


Figure TA 18-11 shows the full-period DMDU modeling results for all priority groups. Key findings differentiating the alternatives in terms of tribal water deliveries across the priority groups based on the full-period DMDU heat maps include the following:[18, 19]

- There is no alternative that is the most robust across the priority groups in terms of maximizing water deliveries to all tribes. The alternatives perform differently for the priority groups and, for some priority groups, depend on the importance placed on results considering only shortages relative to the frequency of futures with dead pool-related releases.

[18] Other key metrics are evaluated and discussed elsewhere in the EIS.
[19] The Preferred Alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**, which could yield different impacts than the distribution methods assumed for the Representative Preferred Alternative.

Figure TA 18-11
Robustness Comparison for All Priority Groups (Full Period)

- For the most senior water entitlements (the PPR group), the Maximum Operational Flexibility Alternative is the most robust. It meets the preferred minimum performance criteria in 100 percent of modeled futures and has the lowest percentage of futures with dead pool–related reductions. The Representative Preferred Alternative is the second best performing alternative for this priority group.
- For the next most senior water entitlements priority group (the Arizona Priority 3 group), a case could be made for either the Maximum Operational Flexibility or Supply Driven (LB Priority approach) Alternatives. Which is more robust depends on how this group trades off water delivery, considering only shortages (which favors the Supply Driven Alternative [LB Priority approach]) or minimizing the percentage of futures with a dead pool–related release (which favors the Maximum Operational Flexibility Alternative). The Representative Preferred Alternative is not one of the two top performing alternatives for this priority group.
- For the next most senior water entitlements priority group (the AZ CAP Indian, M&I, AZ 4i group), a case could be made for either the No Action or Enhanced Coordination Alternatives. Which is more robust depends on how this group trades off water delivery, considering only shortages (which favors the No Action Alternative) or minimizing the percentage of futures with a dead pool–related release (which favors the Enhanced Coordination Alternative). The Representative Preferred Alternative is not robust for this priority group.
- For the most junior water entitlements priority group (the AZ CAP NIA group), the Enhanced Coordination Alternative is the most robust. The Representative Preferred Alternative is not robust for this priority group.
- Considering shortages only (that is, not considering dead pool–related reductions), the No Action Alternative is estimated to meet the preferred minimum performance criteria in 100 percent of normal water deliveries to all priority groups except the AZ CAP NIA group. This result is likely due to a lower maximum shortage than other alternatives (**Figure TA 18-1** and **Table TA 18-4**). However, the No Action Alternative has the highest potential for dead pool–related releases of any alternative, with 75 percent of futures estimated to have a dead pool–related release. Therefore, water delivery would be unlikely under the No Action Alternative.
- The CCS Comparative Baseline is similar to the No Action Alternative, except 13 percent of futures meet preferred minimum performance criteria for the CAP Indian, CAP M&I, and AZ 4i priority group, and 2 percent of futures meet the preferred minimum performance criteria for the CAP NIA group. Dead pool–related reductions are estimated to occur in 55 percent of modeled futures, which is less frequent than the No Action Alternative.
- The Representative Preferred Alternative is the second best performer for the PPR priority group. It is not among the most robust alternatives for any other priority group.
- The Basic Coordination Alternative is not among the most robust alternatives for any priority group.
- The Enhanced Coordination Alternative has a more complicated pattern of robustness.
    - 13 percent of futures meet the preferred minimum performance criteria for all priority groups, fewer than some other alternatives. This is likely due to the fact that shortages

start relatively early compared to other alternatives, and there is a high maximum shortage (see **Figure TA 18-1** and **Table TA 18-4**).
    - However, it performs very well in terms of delivering at least 60 percent of normal water, as it does so in 91-100 percent of modeled futures for all priority groups. This result is likely due, in part, to its use of the pro rata distribution method.
    - Finally, it has 20 percent of futures with dead pool–related releases, among the fewest of the options modeled.
- Considering only shortages, the Maximum Operational Flexibility Alternative is more robust than the Enhanced Coordination Alternative for the two more senior water entitlements groups (PPR, Arizona Priority 3) and less robust than the Enhanced Coordination Alternative for the two less senior water entitlements groups (AZ CAP Indian, M&I, and 4i; CAP NIA). It has the lowest percentage of futures with a dead pool–related release (10 percent) of all the options modeled.
- The Supply Driven Alternative (LB Priority approach) generally is more robust than the Maximum Operational Flexibility Alternative with respect to shortages, but has a higher percentage of futures with a dead pool–related release (32 percent).
- The Supply Driven Alternative (LB Pro Rata approach) is closest to the Enhanced Coordination Alternative but does not meet the preferred minimum performance criteria as often and therefore is less robust.

It is important to consider the first subperiod, as the Preferred Alternative is a 10-year decision framework. The conclusions above all hold for the first decadal subperiod with the one exception: for the Arizona Priority 3 group, a case could be made that either the Maximum Operational Flexibility, Supply Driven (LB Priority approach), or Representative Preferred Alternatives are the best performing.[20] These three alternatives have various trade-offs between water deliveries considering only shortages and the percentage of futures with a dead pool-related reduction.

Storage and Conservation Options

The No Action and Basic Coordination Alternatives have no water storage mechanisms that would affect Lower Basin Tribes or the quantities of water available to them. Under both alternatives, water conserved under previous mechanisms that remains in Lake Mead in 2027 would be delivered in accordance with existing agreements. The other four alternatives do contain new water storage and conservation mechanisms, which are summarized below. See **Chapter 2** and **Appendix S** for a full description of these mechanisms and how they would operate. Note that in all cases, stored water would be available for water transactions with other Lower Basin water users, both within and across Lower Division States.

- Under the Preferred Alterative, Lower Basin water users would be able to store up to 7.0 maf in conservation pool in Lake Mead, including the storage of pre-2027 intentionally created surplus (ICS). There would also be a Federally Managed Water Resources Pool. This

[20] In the full period results, the Maximum Operational Flexibility Alternative performs better than the Representative Preferred Alternative.

pool could potentially be filled by, among other mechanisms, compensated Lower Basin tribal water (conserved consumptive use).

- Under the Enhanced Coordination Alternative, water conserved by Lower Basin water users could be stored in a Lake Mead conservation pool. There would also be a Reclamation-controlled Federal Lake Mead conservation pool. Water for the Federally Managed Water Resources Pool could be voluntarily acquired by compensation for conserved water, among other mechanisms. Previously stored ICS water would be transferred into the non-Federal Lake Mead conservation pool and would be subject to the new provisions regarding the release of that water.
- Under the Maximum Operational Flexibility Alternative, water conserved by Lower Basin water users could be stored in a combined pool managed across both Lake Powell and Lake Mead. Previously stored ICS water would be transferred into this pool, and the new provisions regarding the release of that water would apply.
- Under the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), Lower Basin water users could contribute to a storage pool in Lake Mead. Previously stored ICS water would be converted into this conservation pool over 10 years, and then the new provisions regarding the release of that water would apply.

All else equal, the four alternatives that include new mechanisms for storage and conservation of water could provide additional options to Lower Basin Tribes. First, the mechanisms allow tribes to conserve water and participate in storage programs. Second, the mechanisms allow transactions with other Lower Basin water users. Third, tribes that participate could receive compensation for conserved consumptive use. However, whether these new mechanisms are better for any specific tribe compared to the current ICS mechanism is outside the scope of this analysis.

TA 18.2.3 Issue 2: How Will Changes in Dam Operations Affect Indian Trust Lands?

Changes in dam operations under the different alternatives would not affect the borders of established reservations or the definitions of any trust lands. Trust land will remain trust land. Future potential acquisitions of land into trust are not limited by the operations. Further, in addition to (uncontrollable) drought conditions in any given year, the different alternatives of various distributions of the available water could add an incremental impact to the use of trust lands. An important aspect of the use of trust lands involves agricultural land, as fluctuations in water levels are estimated to result in some tribal agricultural lands being fallowed. Other changes in the use of tribal land and resources are discussed in **TA 13**, Tribal Resources. The considerations therein generally apply to Trust and non-Trust resources.

Agricultural Land

The potential impacts of changes in dam operations on agricultural land are assumed to be inversely dependent on water deliveries, meaning agricultural impacts are estimated to increase as water deliveries decrease.

Upper Basin

As noted in the Upper Basin water deliveries section above, none of the alternatives would affect water deliveries to Upper Basin Tribes. However, changes in storage and conservation options under some

alternatives could provide opportunities for tribal participation. All else equal, the new mechanisms for conserving and storing water for Upper Basin Tribes (contained in the Preferred, Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven [both LB Priority and LB Pro Rata approaches] Alternatives) would provide additional options for tribes in the Upper Basin.

Lower Basin

TA 16, Socioeconomics, discusses the potential impacts of changes in dam operations and resulting changes in water deliveries on tribal and non-tribal agricultural economies in the Lower Basin. Estimates are presented for several socioeconomic metrics: acres of fallowed agricultural land, direct market value, jobs, and economic output. Results are presented at the state level and by priority groups for Arizona, California, and Nevada. See **TA 16**, Socioeconomics, for a full discussion of the modeling and results. This section focuses on the acres of fallowed land as an indicator of potential impacts on Trust land.

Table TA 18-5 summarizes the modeling results for estimated changes in fallowed tribal agricultural land. For each state and alternative and the CCS Comparative Baseline, the table shows the estimated acres fallowed under two scenarios: a shortage of 0.6 maf, which is applicable to all alternatives and the CCS Comparative Baseline; and the acres of fallowed land under the maximum shortage, which varies across each alternative and the CCS Comparative Baseline. As discussed for Lower Basin water deliveries above, the results must also be understood in the context of the possibility for dead pool–related reductions. See the Water Deliveries section of this Final EIS for more information on dead pool–related releases. **Table TA 18-5** contains the percentage of dead pool–related releases for each alternative and the CCS Comparative Baseline.

Some key findings from **Table TA 18-5** include:

- Similarly to the Lower Basin water deliveries analysis above, the seniority of water entitlements combined with the distribution method makes a large difference in the results.
- Tribal agriculture in Arizona is estimated to experience the largest impacts in terms of the absolute changes in acres of fallowed land. This is likely because the majority of the reservation land is in Arizona (see **Map TA 18-1**). The Representative Preferred Alternative is modeled to fallow the second-least number of acres in Arizona, relative to the other alternatives.
- No alternative is clearly the most robust for Arizona. The different alternatives and the CCS Comparative Baseline have varying trade-offs between fallowed acreage under shortages and percent of futures with dead pool-related reductions.
- In California and Nevada, impacts are only associated with alternatives that use the pro rata distribution method (the Enhanced Coordination and Supply Driven [LB Pro Rata approach] Alternatives).
- All other alternatives, including the Representative Preferred Alternative, and the CCS Comparative Baseline use some variation of the priority distribution method and estimate no reductions in water deliveries, and therefore no fallowed agricultural land, in these states.
- The Maximum Operational Flexibility Alternative performs the best for California and Nevada, as there are zero fallowed acres and the percentage of futures with dead pool–related reductions is minimized. This would be true for PPRs in Arizona as well.

Table TA 18-5
Estimated Tribal Agricultural Land Fallowed under Lower Basin Water Shortages

State	Alternative (or CCS Comparative Baseline)	Acres Fallowed at Shortage of 0.6 maf	Acres Fallowed at Maximum Shortage	Percent of Futures with Dead pool–related Reductions
Arizona	CCS Comparative Baseline	15,586	22,254	55
Arizona	No Action	12,419	12,419	75
Arizona	Basic Coordination	12,419	49,582	44
Arizona	Enhanced Coordination	8,067	39,200	20
Arizona	Maximum Operational Flexibility	6,535	68,054	10
Arizona	Supply Driven (LB Priority approach)	6,535	53,560	32
Arizona	Supply Driven (LB Pro Rata approach)	15,794	38,605	18
Arizona	Representative Preferred Alternative	6,535	67,375	18
California	CCS Comparative Baseline	0	0	55
California	No Action	0	0	75
California	Basic Coordination	0	0	44
California	Enhanced Coordination	1,298	5,092	20
California	Maximum Operational Flexibility	0	0	10
California	Supply Driven (LB Priority approach)	0	0	32
California	Supply Driven (LB Pro Rata approach)	579	2,803	18
California	Representative Preferred Alternative	0	0	18
Nevada	CCS Comparative Baseline	0	0	55
Nevada	No Action	0	0	75
Nevada	Basic Coordination	0	0	44
Nevada	Enhanced Coordination	131	656	20
Nevada	Maximum Operational Flexibility	0	0	10
Nevada	Supply Driven (LB Priority approach)	0	0	32

State	Alternative (or CCS Comparative Baseline)	Acres Fallowed at Shortage of 0.6 maf	Acres Fallowed at Maximum Shortage	Percent of Futures with Dead pool–related Reductions
Nevada	Supply Driven (LB Pro Rata approach)	131	460	18
Nevada	Representative Preferred Alternative	0	0	18

TA 18.2.4 Issue 3: How Will Changes in Dam Operations Affect Other Indian Trust Assets?

Changes in dam operations would not directly affect the status and corpus of other ITAs. Trust assets will remain trust assets. Future potential acquisitions of assets into trust are not limited by the operations. Further, in addition to (uncontrollable) drought conditions in any given year, changes in dam operations could incrementally affect water levels, vegetation, fish, and wildlife, and therefore could indirectly affect the use of ITAs. General changes in vegetation, fish, and wildlife are discussed in their respective sections of this Final EIS.

As noted in **Section TA 18.1.3**, income is not a trust asset, yet Reclamation recognizes that income derived from ITAs can be important to tribes. Impacts on specific income-generating activities depend on a complex array of legal, contractual, and environmental factors. Because income derived from ITAs varies for each tribe, the effects of changes in water levels and deliveries due to the alternatives will also vary by tribe.

However, several general conclusions can be drawn regarding tribes' ability to generate income from leasing water. All else equal, higher quantities of delivered water means more ability to fulfill existing lease agreements and/or enter into new agreements. From this perspective, the conclusions of the water deliveries analysis generally apply to water leases.

Fees for outdoor recreation and other services on tribal land that generate income could be affected by changes in dam operations that result in changes in access, changes in river flows, changes in water quality, changes in fish and wildlife, and other resources that affect outdoor recreation. **TA 14**, Recreation, discusses the expected impacts of the alternatives on recreation.

TA 18.2.5 Summary Comparison of Alternatives

Issue 1: Tribal Water Entitlements, Deliveries, and Storage and Conservation Options

Water Entitlements

The alternatives would not affect entitlements to any Upper Basin or Lower Basin Tribes. The approaches to distributing Lower Basin shortages incorporated in all alternatives are designed to explore a wide range of potential concepts and impacts; they do not reflect an intention by Reclamation to alter apportionments or water entitlements. However, because the concepts would affect a range of users, impacts on deliveries to different entities are analyzed, and addressed in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation.

Water Deliveries

The alternatives would not affect deliveries to any Upper Basin water users, including tribes.

For water deliveries in the Lower Basin, the most robust alternative in terms of estimated water deliveries depends on the priority group.

- For the most senior water entitlements (the PPR group), the Maximum Operational Flexibility Alternative clearly is the most robust. It meets the preferred minimum performance criteria in 100 percent of modeled futures and has the lowest percentage of

futures with dead pool–related reductions. During the first modeling period, which includes the implementation period for the Preferred Alternative, the Representative Preferred Alternative performs second-best to the Maximum Operational Flexibility Alternative, with nearly the same performance.

- For the next most senior water entitlements priority group (the Arizona Priority 3 group), a case could be made for either the Maximum Operational Flexibility or Supply Driven (LB Priority approach) Alternatives. Which is more robust depends on how this group trades off water delivery, considering only shortages (which favors the Supply Driven [LB Priority approach] Alternative) or minimizing the percentage of futures with a dead pool–related release (which favors the Maximum Operational Flexibility Alternative). For the first decadal period, which contains the implementation period of the Preferred Alternative, the Representative Preferred Alternative performs second-to-last among the alternatives for deliveries, meeting the preferred performance criteria in 65 percent of modeled futures; however, it has the second-lowest percent of futures with a dead pool-related reduction.
- For the next most senior water entitlements priority group (the AZ CAP Indian, M&I, AZ 4i group), a case could be made for either the No Action or Enhanced Coordination Alternatives. Which is more robust depends on how this group trades off water delivery, considering only shortages (which favors the No Action Alternative) or minimizing the percentage of futures with a dead pool–related release (which favors the Enhanced Coordination Alternative). For the first decadal period, which contains the implementation period of the Preferred Alternative, the Representative Preferred Alternative is not robust for deliveries, meeting the preferred performance criteria in 0 percent of modeled futures; however, it has the second-lowest percent of futures with a dead pool-related reduction.
- For the most junior water entitlements priority group (the AZ CAP NIA group), the Enhanced Coordination Alternative is the most robust. For the first decadal period, which contains the implementation period of the Preferred Alternative, the Representative Preferred Alternative is not robust for deliveries, meeting the preferred performance criteria in 0 percent of modeled futures; however, it has the second-lowest percent of futures with a dead pool-related reduction.

Storage and Conservation Options

For Upper Basin Tribes, options for conserving and storing water vary among the alternatives. For the No Action and Basic Coordination Alternatives, there would be no new mechanisms to conserve and store water. However, the Preferred, Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives all have new mechanisms for Upper Basin Tribes to conserve and store water in either or both Lake Powell and Lake Mead.

For Lower Basin Tribes, options for conserving and storing water vary among the alternatives. For the No Action and Basic Coordination Alternatives, there would be no new mechanisms to conserve and store water. Water conserved under previous mechanisms that remains in Lake Mead in 2027 would be delivered in accordance with existing agreements. However, the Preferred, Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives all have new mechanisms for Lower Basin Tribes to

conserve and store water in either or both Lake Powell or Lake Mead. These four alternatives also have provisions for converting previously stored ICS water into the new conservation pools. The Enhanced Coordination and Preferred Alternatives are unique in that they would have both user-controlled and Reclamation-controlled conservation pools in Lake Mead, the latter of which could be filled in part by compensating tribes for voluntarily conserving water.

Issue 2: Indian Trust Lands

None of the alternatives would affect the boundaries of established reservations or Trust lands. However, the alternatives would affect the use of Trust lands. Changes in water deliveries could particularly affect the productivity of agricultural land, an important and valuable land use for tribes (Curtis et al. 2023). It is estimated that agricultural land would be fallowed under some alternatives.

In the Upper Basin, none of the alternatives would directly affect agricultural land. Some alternatives would provide new mechanisms for conserving and storing water for Upper Basin Tribes (the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven [both LB Priority and LB Pro Rata approaches] Alternatives).

The following summarizes state-level conclusions in the Lower Basin:

- There is no clear most robust alternative for Arizona. The different alternatives and the CCS Comparative Baseline have varying trade-offs between fallowed acreage under shortages and percent of futures with dead pool-related reductions. The Representative Preferred Alternative is modeled to fallow the second-least number of acres in Arizona, relative to the other alternatives.
- In California and Nevada, impacts are only associated with alternatives that use a pro rata distribution (the Enhanced Coordination and Supply Driven [LB Pro Rata approach] Alternatives). There are no impacts associated with alternatives, including the Representative Preferred Alternative, that use a variation of a priority distribution.

Issue 3: Other Indian Trust Assets

The alternatives would not generally affect other ITAs, but could affect the use of other ITAs. Because impacts are resource- and tribe-specific, no general comparison of alternatives for other ITAs can be made.

TA 19. Visual Resources

TA 19.1 Affected Environment

Visual resources are the physical features that make up the visible landscape, including land, water, vegetation, topography, and human-made features such as buildings, roads, utilities, and structures. They also include the response of viewers to those features.

Visual resources are important both to visitors to Grand Canyon National Park (GCNP), Glen Canyon National Recreation Area (NRA), and Lake Mead NRA, and to the Basin Tribes who use these lands for subsistence or ceremonial uses. The Grand Canyon Protection Act of 1992 specifically calls for the conservation of visual resources, which are also a key component of federal management of these areas. GCNP, Glen Canyon NRA, and Lake Mead NRA are managed under their general management plans, which identify management directions for visual resources as part of the plans. These plans are described below.

The portion of the Colorado River adjacent to Lake Powell, as well as a portion of the river upstream and downstream of Lake Powell, is managed under the Glen Canyon NRA General Management Plan. Large areas of Glen Canyon NRA, including those adjacent to the Colorado River, are managed as a natural zone, which includes ". . . the recreation area's outstanding scenic resources, relatively undisturbed areas isolated and remote from the activities of man . . ." (NPS 1979, 5).

Farther downstream, the landscapes adjacent to the Colorado River are managed under the GCNP General Management Plan, which also identified the lands adjacent to the river as a natural zone, which is managed to ". . . conserve natural resources and ecological processes and to provide for their use and enjoyment by the public in ways that do not adversely affect these resources and processes" (NPS 1995, 19).

Past GCNP, the portion of the Colorado River adjacent to Lake Mead and downstream to Bullhead City is managed under the Lake Mead NRA General Management Plan. An amended plan from 2018, to address low-water levels, does not specifically address visual resources; however, it does acknowledge that "Lowering lake levels exposes new shoreline, which is susceptible to the spread of weeds and invasive nonnative plants" and "The appearance of mineral deposits, mudflats, denuded shorelines, and abandoned high-grounded facilities detract from the scenery of the lake" (NPS 2018, 5).

TA 19.1.1 Lake Powell and Glen Canyon Dam

Landscape Character

The landscapes of the Lake Powell and Glen Canyon area are characterized by sweeping vistas of red rock towers, buttes, and mesas typical of the Colorado Plateau (Fenneman 1931). Navajo Sandstone and desert varnish dominate the existing landscape character, with the introduction of water, associated with Lake Powell, framing these natural features.

Lake Powell has deposits of calcium carbonate, which become visible as reservoir levels decrease. At lower lake elevations, the colorful sandstone canyon walls show a light-toned band of calcium carbonate deposit between the full reservoir elevation and the lower reservoir elevation, which contrasts with the natural, red-colored sandstone (see **Figure TA 19-1**). At lower lake elevations, motorists view the calcium carbonate ring from Utah State Route 95 (Utah Bicentennial Scenic Byway; near Hite, Utah), boaters view it on Lake Powell, recreationists see it at developed and undeveloped recreation areas (for example, Hite, Bullfrog, Halls Crossing, Antelope Point, and Wahweap), and hikers see it on trails adjacent to Lake Powell.

Figure TA 19-1
Photo of Existing Calcium Carbonate Rings at Lake Powell

Source: USGS 2022

Additionally, sediment deltas have formed near the inflow areas of Lake Powell from sediments carried by the Colorado River, San Juan, Dirty Devil, and Escalante Rivers, resulting in downstream-progressing deltas. These appear as expansive, deep, and eroding mud flats cut by river channels. Similarly, lower reservoir levels also expose a band of exposed sediment along the shoreline, which in some areas may expose trash and other waste adjacent to Lake Powell. Sediment exposed for more than a few months is soon colonized by tamarisk, an invasive shrub. These sediment deltas and exposed shoreline areas are considered a visual distraction, particularly as the reservoir elevation decreases and these features become more visible. The sediment deltas and exposed shoreline areas can be seen from viewing locations, including Utah State Route 95 and scenic overlooks adjacent to these inflow areas; water-based recreationists can also see the deltas and exposed shoreline from Lake Powell.

Attraction Features

The analysis focuses on the following specific attraction features that were selected to focus on visibility of specific geological features and the dams associated with each reservoir. Note that the discussion of potential impacts on recreation sites and other viewing locations is described under Issue Statement 2 with further information described in **TA 14**, Recreation.

- **Rainbow Bridge:** Contained within Rainbow Bridge National Monument, which was established in 1910, Rainbow Bridge was originally only accessible via the rugged Wetherill Trail from Navajo Mountain. Today, no facilities support visitation to Rainbow Bridge National Monument from Lake Powell. All infrastructure (docks and restrooms) was relocated to the main channel in 2021, due to the narrowing of the canyon and a delta that has formed at the back of the canyon. Some small, motorized vessels may be able to access the monument; however, they must beach their boat, and the walk may be through very soft sediment to reach the trail. Based on lower lake elevations, visitors do not see water under or near the Rainbow Bridge. Therefore, while Rainbow Bridge is an important visual resource, the potential impacts on access would be the primary effect on visitors; these impacts are described in **TA 14**, Recreation.
- **Cathedral in the Desert:** Lake Powell's waters inundated this feature as the reservoir filled. This feature is only exposed at lower Lake Powell elevations, and it is completely visible and accessible when reservoir elevations are below 3,550 feet. However, boats may not be able to reach it at reservoir elevations below 3,525 feet. Note that other attraction (geological) features, including Gregory Bridge, La Gorce Arch, and other features inundated by Lake Powell, could also become visible at lower lake elevations.
- **Glen Canyon Dam:** The American Society of Civil Engineers considers this dam one of the finest examples of concrete, thin-arch dams in the United States (U.S.). The dam is visible from the adjacent visitor center and from a designated overlook location approximately 0.5 miles south of the dam. While visibility of the dam as an attraction feature is part of the current visual landscape in this area, as reservoir levels decrease, exposing more of the dam's concrete structure, its effect on the area's landscape character increase and further dominate the area's natural landscape character.

TA 19.1.2 Glen Canyon Dam to Lake Mead

Landscape Character

The landscape character along the Colorado River within GCNP and Glen Canyon NRA, as well as within the Hualapai and Navajo Indian Reservations, is defined by towering cliff faces with banded rock strata containing a variety of colors, including reds, oranges, grays, browns, and white. The Colorado River Management Plan builds on this for the portion of the Colorado River in Grand Canyon, stating that it provides "a unique combination of thrilling whitewater adventure and magnificent vistas of a remarkable geologic landscape including remote and intimate side canyons" (NPS 2006, 2).

Vegetation along the river mostly consists of riparian species, such as native willows; nonnative and invasive tamarisk (salt cedar); and isolated areas of cottonwoods and cattails, bulrushes, and reeds in return-current channels (backwaters), channel margins, and mouths of tributary streams from Glen Canyon Dam downstream to Lake Mead. These tributary streams form numerous side canyons leading away from the Colorado River, with many of these side canyons only accessible from the river. Vegetation farther upslope along rock terraces includes saltbush, arrowweed, rabbitbrush, and other arid-adapted plant species.

Previously planned and implemented high-flow experiments (HFEs) from Glen Canyon Dam, to re-create natural floods common before Glen Canyon Dam's construction, have allowed for the transportation and deposition of sand, resulting in the formation of sandbars along the river. In some areas, these HFEs can strip vegetation along the existing sandbars, including tamarisk (salt cedar), which allows the landscape to appear more similar to its natural character.

This portion of the Colorado River does not include visible calcium carbonate rings, sediment deltas, or exposed shoreline. This is because this portion is not contained within an area of fluctuating reservoir levels associated with Lake Powell and Lake Mead.

Attraction Features

This portion of the river, including GCNP, is heavily visited and has been determined to be an eligible (but not yet designated) wild river segment by the National Park Service associated with the Wild and Scenic Rivers Act (Barnes 2005). It includes world-renowned whitewater rafting and other recreational opportunities along the Colorado River, including boating, kayaking, swimming, and fishing, in addition to viewing this varied, high-quality landscape from along the river and from scenic overlooks above the river. The river is also viewed from proposed wilderness areas adjacent to the river, including superior views from high points in these areas. See **TA 14**, Recreation, and **TA 17**, Population and Land Use, for more information regarding recreational opportunities and special management areas along the Colorado River.

TA 19.1.3 Lake Mead to Hoover Dam

Landscape Character

The landscapes of the Lake Mead and Hoover Dam area are similar to those described for the Lake Powell area, except the adjacent landscapes are more typical of the Basin and Range physiographic

province, characterized by parallel, north–south-oriented mountain ranges surrounded by nearly level, typically undrained basins (Fenneman 1931).

Similar to Lake Powell, Lake Mead also has deposits of calcium carbonate, which become visible as reservoir levels decrease. At lower lake elevations, the steep rock slopes, canyon walls, and islands show a light-toned band of calcium carbonate deposit between the full reservoir elevation and the lower reservoir elevation, which contrasts with the natural rock colors. At lower lake elevations, motorists view the calcium carbonate ring on U.S. Highway 93 (between Boulder City, Nevada, and Hoover Dam), boaters view it on Lake Mead, and hikers see it on trails adjacent to Lake Mead. Sediment deltas have been built up at the confluence of the Virgin River and Muddy River at the upper Overton Arm and at upper Lake Mead (Iceberg Canyon, Pearce Basin, and lower Granite Gorge).

Similarly, lower reservoir levels also expose a band of exposed sediment along the shoreline, which in some areas may expose trash and other waste adjacent to Lake Mead. Sediment exposed for more than a few months is soon colonized by tamarisk, an invasive shrub. Sediment deltas and the exposed shoreline are visible primarily to water-based recreationists. Visitors to Lake Mead NRA at Overton Beach and Pearce Ferry can also view them.

Attraction Features

The analysis focuses on the following specific attraction feature:

- **Hoover Dam:** Hoover Dam is a major destination and national landmark with high levels of visitation. In 1955, the American Society of Civil Engineers selected it as one of the seven engineering wonders in the U.S. Since Hoover Dam is in the narrow, steep-walled Black Canyon, only a small portion of Lake Mead is visible from Hoover Dam and the adjacent visitor facilities. While visibility of the dam as an attraction feature is part of the current visual landscape in this area, as reservoir levels decrease, exposing more of the dam's concrete structure, its effect on the area's landscape character increase and further dominate the area's natural landscape character.

TA 19.1.4 Hoover Dam to Southerly International Boundary

The landscapes from the Hoover Dam area to the Southerly International Boundary are characterized by arid mountain ranges and intervening desert plains associated with the Basin and Range physiographic province (Fenneman 1931). Availability of Colorado River water has resulted in large areas of irrigated landscapes, including agricultural lands in Arizona, California, and Nevada (Lower Division States), which have altered the natural landscapes. This increased water availability has introduced vivid greens into these landscapes, associated with crops and ornamental plantings, which expand the influence of the Colorado River into adjacent arid lands beyond the narrow, natural riparian corridor.

TA 19.2 Environmental Consequences

TA 19.2.1 Methodology

The Bureau of Reclamation (Reclamation) used similar methods to those used in the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and Coordinated Operations for Lake Powell and Lake Mead (2007 Interim Guidelines; Reclamation 2007) and Near-term Colorado River Operations Final Supplemental Environmental Impact Statement (2024 Final SEIS) to analyze potential impacts on visual resources. This analysis assesses the potential effects on attraction features, the extent of the visible calcium carbonate ring, and exposure of sediment deltas at reservoir inflow areas while incorporating the Decision Making under Deep Uncertainty (DMDU) framework for this Final Environmental Impact Statement (EIS). Additionally, this analysis considers the effects of expanded shoreline exposure on the area's landscape character.

The assessment of effects on landscape character adjacent to Lake Powell and Lake Mead used similar methods as identified in the 2007 Final EIS and 2024 Final SEIS. However, using modeling and DMDU concepts, the analysis first focuses on the percentage of time during the planning window that Lake Powell would decrease below elevation 3,550 feet. At that elevation, Cathedral in the Desert (and other attractions [geological] features, including Gregory Bridge, La Gorce Arch, and other features inundated by Lake Powell) would become visible and accessible. Based on historical averages, Lake Powell was below 3,550 feet in approximately 9.9 percent of months between October 2007 and May 2025. The alternatives' comparison focuses on maintaining this lake elevation for at least 10 percent of the months during the planning window. Conversely, this analysis also identifies the percentage of preferred minimum performance of futures in which Lake Powell would be above 3,550 feet, resulting in less of the upstream side of Glen Canyon Dam being visible, because higher reservoir levels obscure the structure.

The potential height of the calcium carbonate ring was calculated by comparing differing reservoir elevations with the full pool elevations of Lake Powell (3,700 feet) and Lake Mead (1,229 feet) under DMDU concepts. The assessment of effects from sediment deltas and shoreline exposure considers these differing reservoir elevations and references the analysis conducted in the 2007 Final EIS.

Reclamation added two new analysis items, similar to the 2024 Final SEIS, to assess impacts on the Colorado River's landscape character and broader landscape character in the Lower Division States. This assessment is based on changes in modeled hydrologic conditions under the No Action Alternative and Continued Current Strategies (CCS) Comparative Baseline, as well as management direction associated with the action alternatives. To assess potential changes to the landscape character along the Colorado River (between Glen Canyon Dam and Lake Mead), this analysis includes a qualitative assessment of effects associated with lower flow rates and the potential inability to conduct HFEs from Glen Canyon Dam. This analysis considers and references the analyses contained in **TA 5**, Geomorphology and Sediment, **TA 9**, Vegetation Including Special Status Species, and **TA 14**, Recreation, which assess the effects of the different flow rates resulting from the alternatives on the prevalence of riparian vegetation, sand bars, and the visibility of river features. Historically, from 1906 to 2007, the average annual natural flow at the Lees Ferry Gaging Station was 14.9 million acre-feet (maf), ranging from 5.4 maf to 24.4 maf. Since the implementation of the Record of Decision for Colorado River Interim Guidelines for Lower Basin Shortages and

the Coordinated Operations for Lake Powell and Lake Mead (2008 to 2022), the annual natural flow at the Lees Ferry Gaging Station has averaged 12.7 maf, ranging from a low of 6.7 maf (2021) to a high of 20.3 maf (2011). For more information on historic flow rates along the Colorado River, refer to **TA 3**, Hydrologic Resources.

The assessment of potential impacts on the broader landscape character in the Lower Division States considered changes in annual Colorado River water supplies available to these states. This assessment identifies the extent of large-scale changes in visual character in irrigated landscapes, including changes associated with agricultural production. This analysis considers and references assessment items contained in **TA 16**, Socioeconomics, including the effect of each alternative's proposed distribution of water on agricultural operations, as well as the potential for Lake Mead to reach dead pool–related shortages as described in **TA 4**, Water Deliveries. The analysis of impacts on the broader landscape character also considers the effect of increased dust generation from aridification of exposed lands, as described in **TA 7**, Air Quality, potentially impacting visibility and views within GCNP and other visually sensitive landscapes.

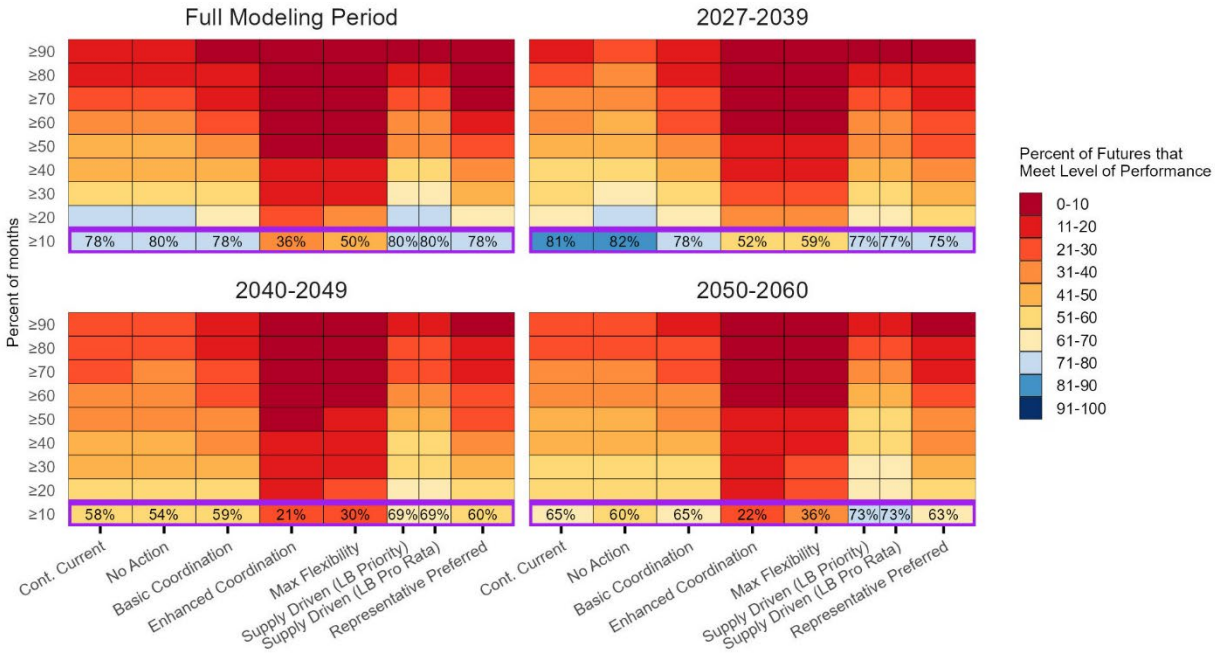
Impact Analysis Area

The visual resources impact analysis area was defined as the area within 5 miles of the Colorado River, from Lake Powell to the Southerly International Boundary, including the full pool elevations of Lake Powell and Lake Mead. While the 2007 Final EIS did not specifically identify an analysis area for visual resources, the 2024 Final SEIS identified the same 5-mile-wide analysis area, based on the typical threshold between the Bureau of Land Management's foreground/middle ground distance zone and background distance zone, where views of the change in management could attract attention in the landscape. Visual effects beyond this geographic area were considered, where appropriate, including the potential effects on the broader landscape character associated with potential decreased water availability for the Lower Division States.

Assumptions

- The analysis methods are consistent with the 2007 Final EIS and 2024 Final SEIS. Attraction features analyzed include Cathedral in the Desert, Glen Canyon Dam, and Hoover Dam. Other attraction features, such as Gregory Bridge, La Gorce Arch, and other features currently inundated by Lake Powell, will be mentioned but not analyzed.
- Decreasing flow rates along the Colorado River and the potential inability to conduct HFEs from Glen Canyon Dam would modify the river corridor's natural, visual character by limiting natural flooding processes.
- This Final EIS references the analysis from the 2007 Final EIS and 2024 Final SEIS regarding impacts associated with expanding sediment deltas.
- Decreasing water availability for the Lower Division States would result in large-scale changes to the visual character of irrigated landscapes, including those associated with agricultural production.

Impact Indicators



- Attraction Features: Qualitative assessment describing the effects from visibility and access to Cathedral in the Desert, as well as more of Glen Canyon Dam and Hoover Dam becoming visible on their upstream side, informed by the Colorado River Simulation System and DMDU analysis. Quantitative analysis showing the percentage of futures that meet the preferred minimum performance level where Lake Powell is below 3,550 feet (and thus Cathedral in the Desert would be visible and accessible) in at least 10 percent of months under each alternative. Conversely, this analysis identifies the percentage of futures that meet the preferred minimum performance level in which Lake Powell is above 3,550 feet, reducing visibility of the dam's upstream face.
- Calcium Carbonate Rings: Comparison of modeled ring height (feet) at Lake Powell and Lake Mead under each alternative, considering the Colorado River Simulation System and DMDU analyses.
- Exposed Shoreline and Sediment Deltas: Qualitative assessment references the 2007 Final EIS and 2024 Final SEIS, considering differing reservoir elevations under each alternative, to assess receding shorelines and formation of sediment deltas resulting from lower reservoir elevations.
- Colorado River Landscape Character: Qualitative description of the effect associated with proposed flow rates and the potential to conduct HFEs from Glen Canyon Dam under each alternative, considering the modeling presented in **TA 9**, Vegetation Including Special Status Species, **TA 5**, Geomorphology and Sediment, **TA 14**, Recreation, and **TA 7**, Air Quality.
- Broader Landscape Character: Qualitative description of the effects associated with potential decreases in water availability for the Lower Division States on the broader landscape character. This includes considering modeling associated with potential changes to crop production resulting from proposed distribution of water, as described in **TA 16**, Socioeconomics, as well as the potential for Lake Mead to reach dead pool–related shortages as described in **TA 4**, Water Deliveries.

TA 19.2.2 Issue 1: How would management of reservoir elevations affect visibility of attraction features?

The assessment of impacts on landscape character associated with the elevations of Lake Powell considers two concepts. The assessment notes that some visitors view visibility and access to Cathedral in the Desert and other attraction features inundated by Lake Powell (below 3,550 feet) as a benefit, while others prefer higher water levels.. Specifically, some recreationists and other users of this landscape, visibility and access to this feature are important and perceived as an improvement to the area's landscape character. Whereas other recreationists and users may prefer a landscape where water levels are higher, minimizing the impacts on landscape character associated with calcium carbonate rings, exposed shoreline, and sediment deltas (see Issue 2). Historically, Lake Powell has been at or below this elevation approximately 10 percent of the months. As shown in **Figure TA 19-2**, the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both Lower Basin Priority [LB Priority] and Lower Basin Pro Rata [LB Pro Rata] approaches) Alternatives would result in the largest percentage of preferable futures where Cathedral in the Desert is visible and accessible at least 10 percent of the months during the planning period (similar to historic frequency, between 78 percent and 80 percent). The Enhanced Coordination and

Maximum Operational Flexibility Alternatives would have fewer preferable futures where Cathedral in the Desert is visible and accessible at least 10 percent of the months during the planning period, 36 percent, and 50 percent, respectively. The positive influence on landscape character associated with the visibility of Cathedral in the Desert would occur in the most futures under the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives. Considering the first 10 years (modeled 2027-2039), the CCS Comparative Baseline, No Action Alternative, and all action alternatives would have similar results as during the full modeling period, except the Enhanced Coordination Alternative, which would perform better with a larger percentage of preferable futures over the first 10 years compared to the full modeling period. The Representative Preferred Alternative exhibits a similar performance as the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives for the first 10 years (modeled 2027-2039 period), with the results being within the range analyzed associated with these alternatives.

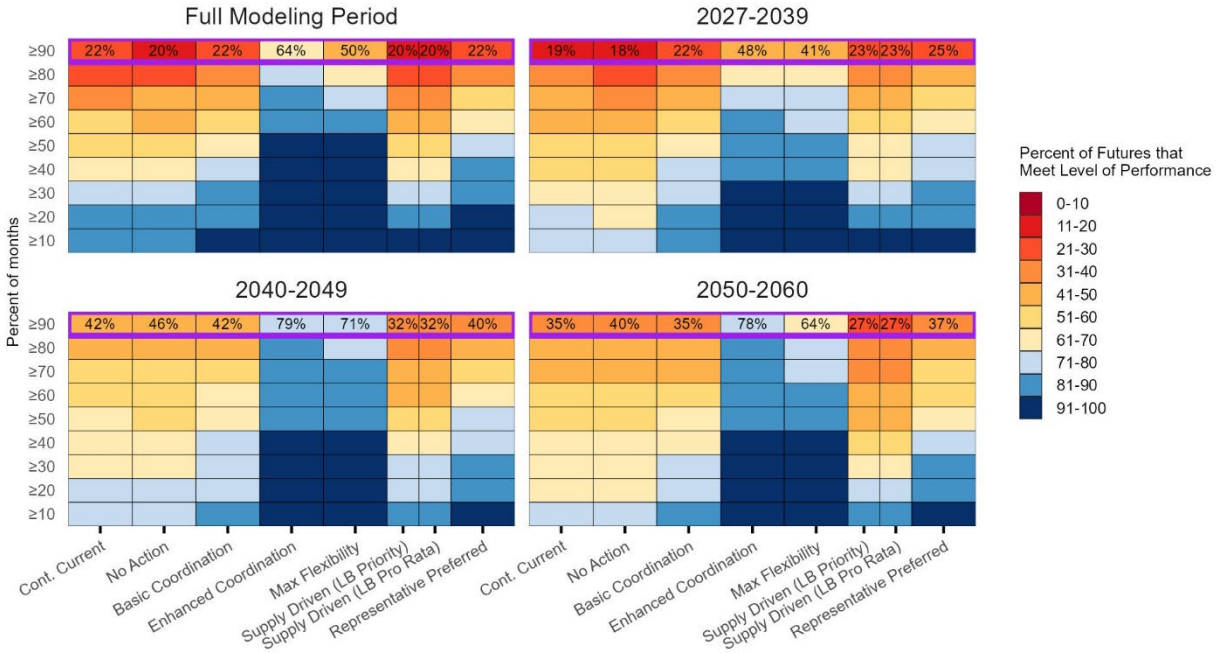


Figure TA 19-2
Visibility and Access to Cathedral in the Desert (and other attraction features inundated by Lake Powell): Robustness.
Percentage of futures in which the elevation of Lake Powell is less than 3,550 feet in the percentage of months specified by each row

The second part of the analysis focuses on keeping the Lake Powell water levels high, which reduces visibility of Glen Canyon Dam, specifically when above 3,550 feet. Therefore, as reservoir levels drop and more of the dam is exposed, its visual prominence increases and can further dominate the surrounding landscape. As shown in **Figure TA 19-3**, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would result in more preferable futures where less of the upstream side of Glen Canyon Dam would be visible, 64 percent and 50 percent, resulting in this

feature being obscured by high water levels. Lower flows could keep Lake Powell at higher elevations under the Enhanced Coordination and Maximum Operational Flexibility Alternatives compared to the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives (between 20 percent and 22 percent). This would result in more preferable outcomes under the Enhanced Coordination and Maximum Operational Flexibility Alternatives, with less of the upstream side of Glen Canyon Dam being visible. Considering the first 10 years (modeled 2027-2039), the CCS Comparative Baseline, No Action Alternative, and all action alternatives would have similar results as during the full modeling period except the Enhanced Coordination Alternative, which would have a smaller percentage of preferable futures over the first 10 years compared to the full modeling period. The Representative Preferred Alternative exhibits a similar performance as the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives for the first 10 years (modeled 2027-2039 period), with the results being within the range analyzed associated with these alternatives.

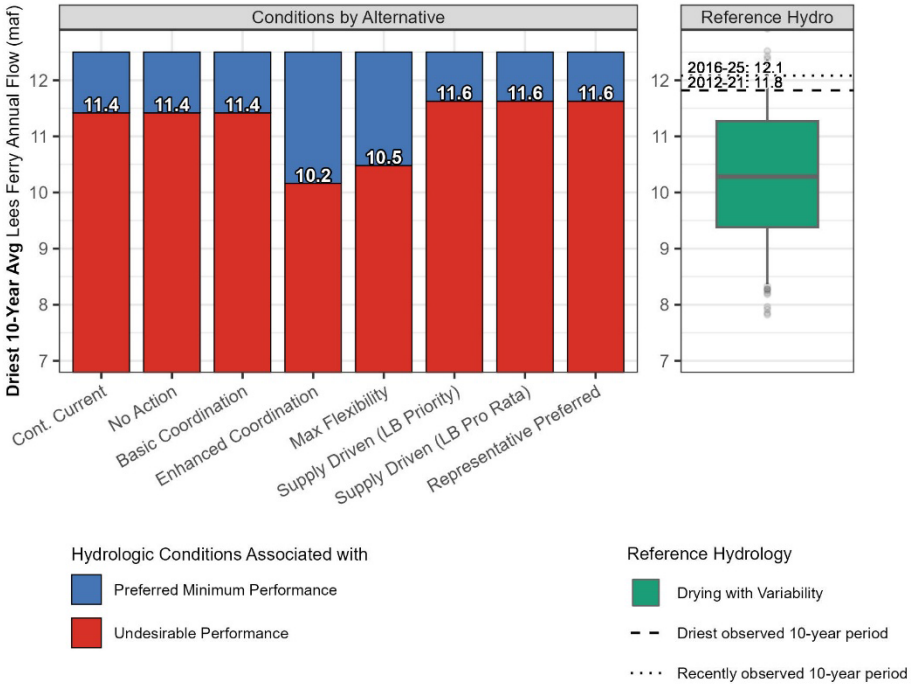

Figure TA 19-3
Limiting the Visibility of Glen Canyon Dam: Robustness.
Percentage of futures in which the elevation of Lake Powell is above 3,550 feet in the percentage of months specified by each row

As shown in **Figure TA 19-4**, comparing DMDU modeling with the driest historic 10-year average Lees Ferry natural flows to identify hydrologic conditions that could cause undesirable performance defined as when Lake Powell is below 3,550 feet for more than 10 percent of the months. The CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would require higher flows to maintain similar elevations, which makes those alternatives more vulnerable to missing the preferred minimum performance

level. Specifically, those alternatives would be more vulnerable than the Enhanced Coordination and Maximum Operational Flexibility Alternatives, with over 75 percent of traces in the reference hydrology exhibiting conditions where Lake Powell could decrease below 3,550 feet for 10 percent or more of months during the planning period. Under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative, based on updated modeling, approximately 50 percent of traces in the reference hydrology exhibit conditions that are expected to result in Lake Powell falling below 3,550 feet for 10 percent or more of the planning period. The Representative Preferred Alternative exhibits a similar performance as the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives within the range analyzed under other alternatives.

Figure TA 19-4
Limiting the Visibility of Glen Canyon Dam: Vulnerability.
Conditions that could cause Lake Powell to fall below 3,550 feet in more than 10 percent of months

Modeling of lake levels within Lake Powell and Lake Mead indicates that, under the CCS Comparative Baseline and the No Action, Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternative, Hoover Dam visibility follows the same pattern described for Glen Canyon Dam. Under the Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, based on managing higher reservoir levels in Lake Mead compared to Lake Powell, less of the upstream side of Hoover Dam would be visible under these alternatives, with comparatively more of the upstream side of Glen Canyon Dam being visible as described above. Therefore, as reservoir levels decrease, exposing more of the dam's concrete structure, its effect on the area's landscape character would increase and further dominate the landscape character.

TA 19.2.3 Issue 2: How would management of reservoir elevations affect landscape character including visibility of calcium carbonate rings, exposed shoreline, and sediment deltas?

The assessment compares how often modeled futures fall into reservoir elevation ranges relative to full pool and relates those ranges to changes in landscape character. This difference in reservoir elevations creates a light-toned band of calcium carbonate deposit, as well as generating larger sediment deltas and exposing more shoreline. The lower the lake levels become, the impacts on landscape character increase including effects from calcium carbonate rings, exposed shoreline with trash and other debris, and sediment deltas. To compare alternatives, the assessment focused on whether calcium carbonate rings, during the planning period, would exceed historic maximums at any time.

For Lake Powell, the tallest calcium carbonate ring was 179 feet tall, which occurred in February 2023. As shown in **Figure TA 19-5**, **Figure TA 19-6**, and **Figure TA 19-7**, based on updated modeling, all alternatives would exceed the historical maximum during the modeling period. In looking at a higher threshold of 200 feet tall, the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would result in more futures where the calcium carbonate rings would exceed the 200-foot maximum height during the modeling period with only 5 percent, 4 percent, 13 percent, and 18 percent of futures under these alternatives resulting in calcium carbonate rings being less than 200 feet tall for all the months of modeling. The Enhanced Coordination and Maximum Operational Flexibility Alternatives increase these values to 74 percent and 86 percent. Considering the first 10 years (modeled 2027-2039), the CCS Comparative Baseline, No Action Alternative, and all action alternatives would have similar results as the full modeling period except all the action alternatives would result in slightly higher percentage of preferable futures over the first 10 years compared to the full modeling period. The Representative Preferred Alternative would potentially exceed the 200-foot maximum height, with 45 percent of futures resulting in calcium carbonate rings being less than 200 feet for all months of modeling for the first 10 years (modeled 2027-2039 period) and 24 percent of futures during the full modeling period, with these results within the range analyzed associated with these alternatives.

Figure TA 19-5
Maximum Height of Lake Powell Calcium Carbonate Ring: Robustness.
Percentage of futures in which the monthly calcium carbonate ring at Lake Powell is always less than the height specified by each row

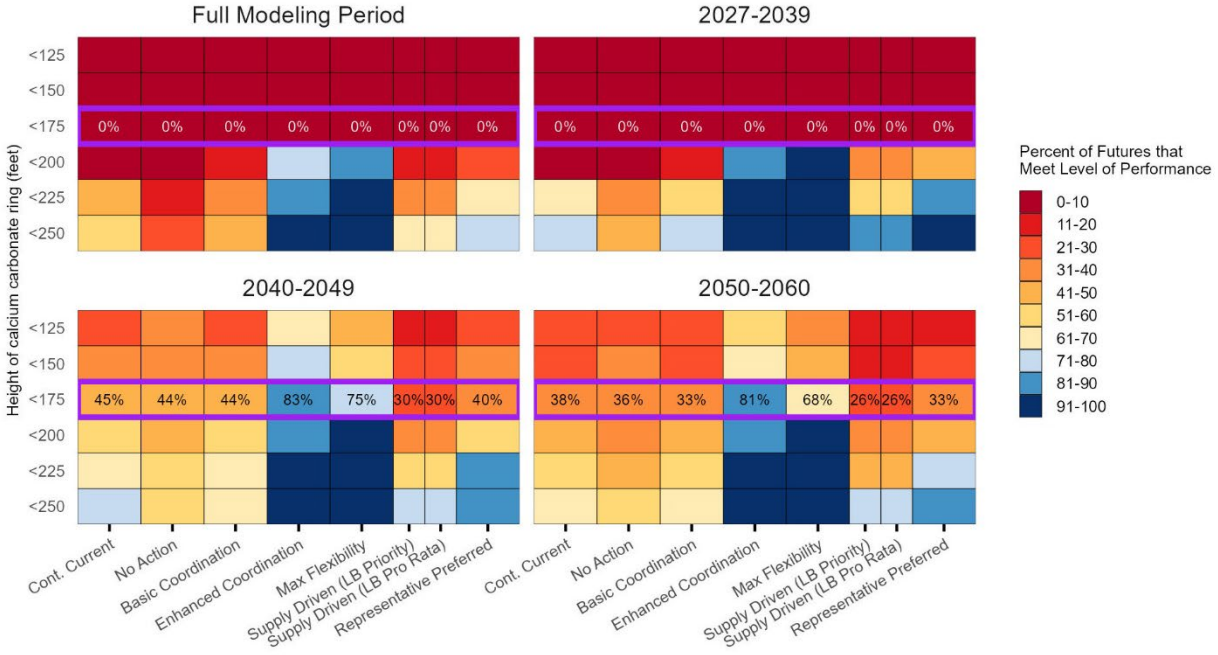

Figure TA 19-6
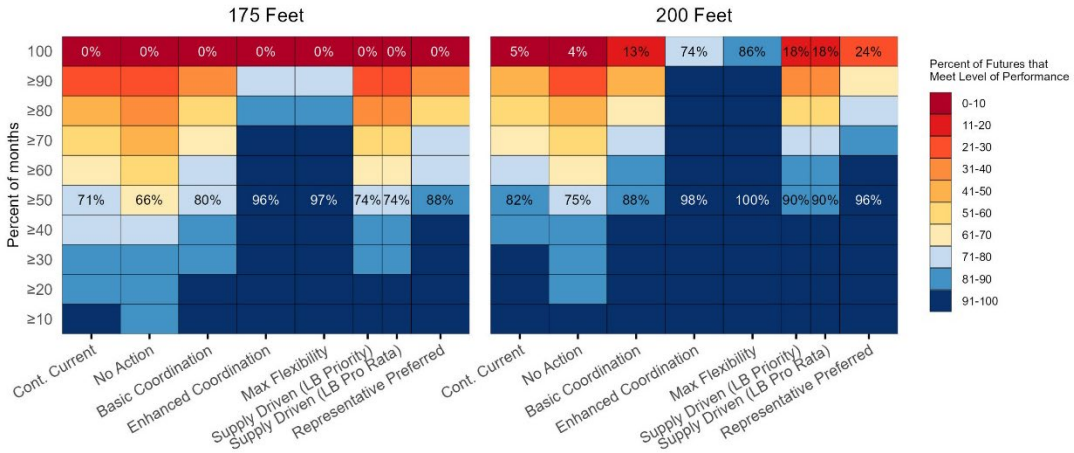
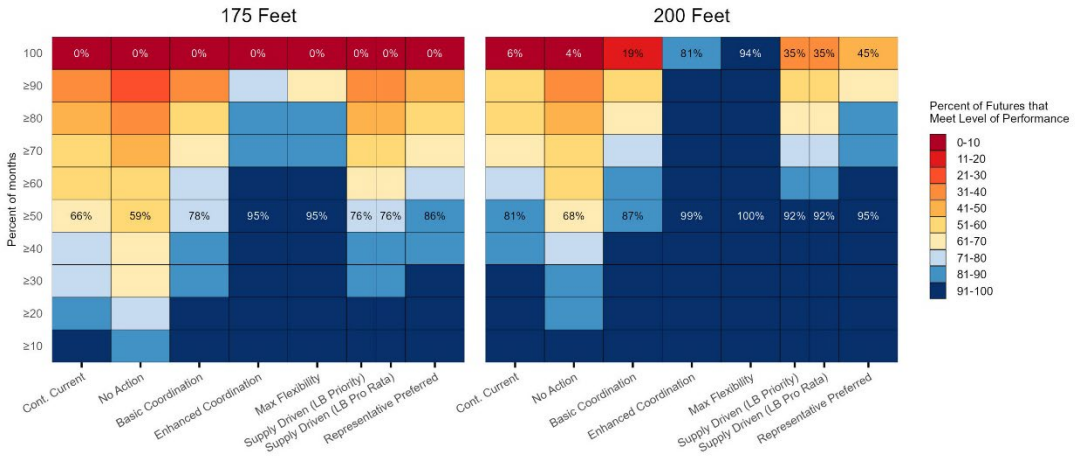
Monthly Height of Lake Powell Calcium Carbonate Ring Full Modeling Period: Robustness.
Percentage of futures in which the height of the calcium carbonate ring at Lake Powell is less than the reference height in the percentage of months specified by each row





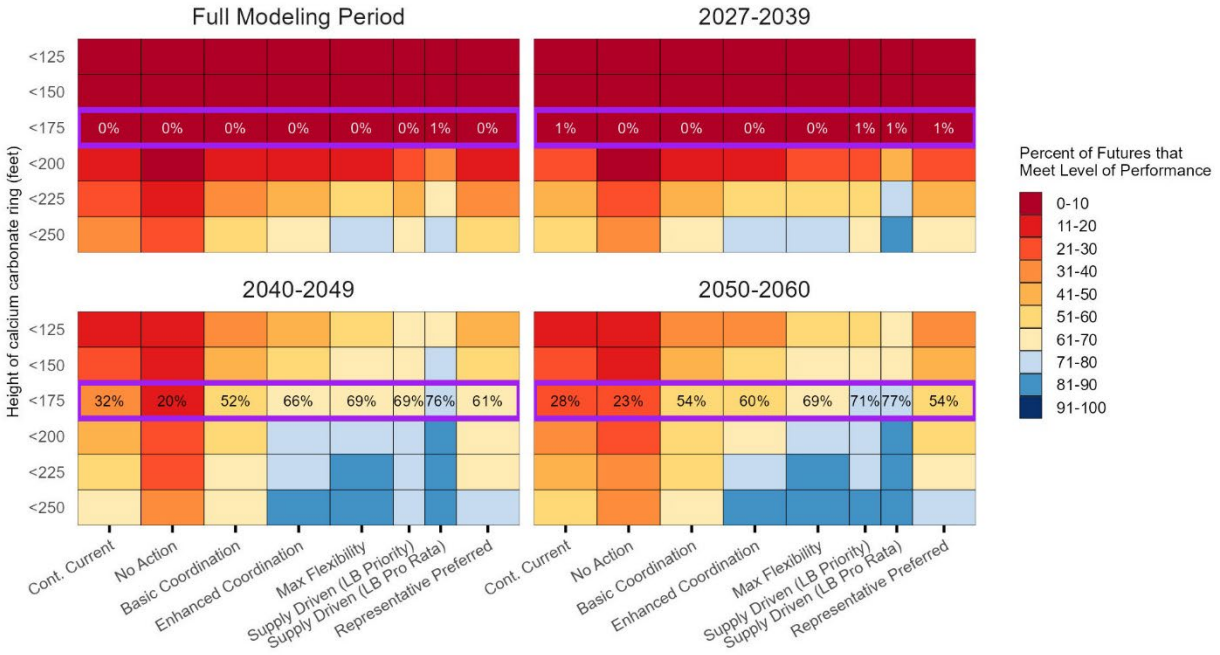


Figure TA 19-7
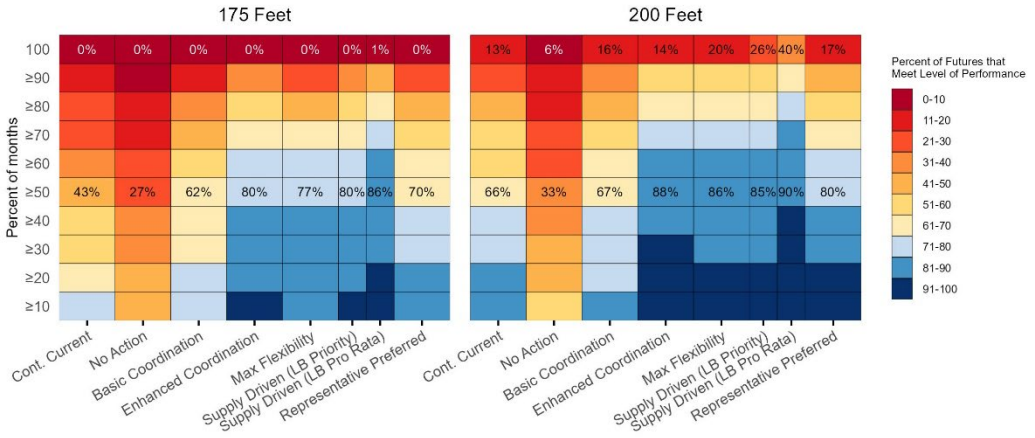
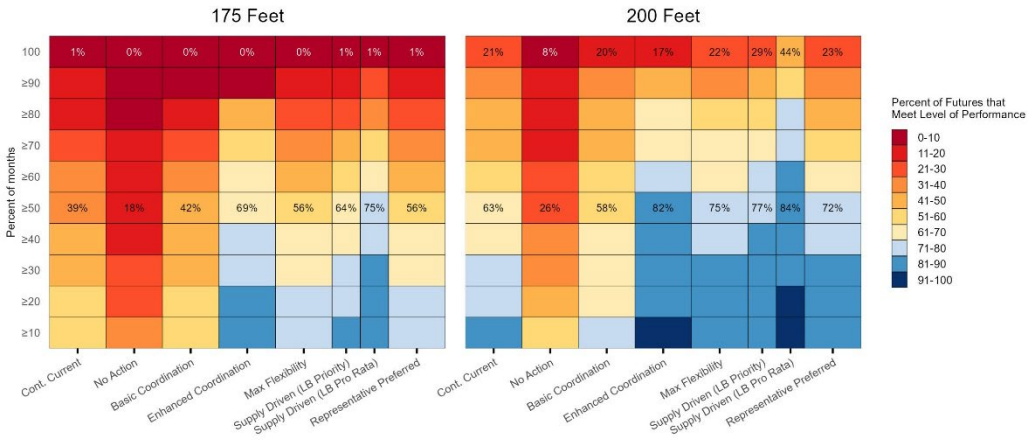
Monthly Height of Lake Powell Calcium Carbonate Ring 2027-2039: Robustness. Percentage of futures in which the height of the calcium carbonate ring at Lake Powell is less than the reference height in the percentage of months specified by each row



For Lake Mead, the tallest calcium carbonate ring was 180 feet, which occurred in July 2022. As shown in **Figure TA 19-8**, **Figure TA 19-9**, and **Figure TA 19-10**, based on updated modeling, all alternatives would exceed the historical maximum during the modeling period except for the Supply Driven Alternative (LB Pro Rata approach) which would have a 1 percent of futures where this threshold is not exceeded. In looking at a higher threshold of 200 feet tall the CCS Comparative Baseline and the No Action Alternative would result in more futures where calcium carbonate rings would exceed the 200-foot maximum during the modeling period, with only 13 percent and 6 percent of futures under these alternatives resulting in calcium carbonate rings being less than 200 feet tall for all the months of modeling. The Basic Coordination, Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives increase these percentages to 16 percent, 14 percent, 20 percent, and 40 percent. Considering the first 10 years (modeled 2027-2039), the CCS Comparative Baseline, No Action Alternative, and all action alternatives would have similar results as the full modeling period with all alternatives, including the No Action Alternative, resulting in slightly higher percentage of preferable futures over the first 10 years compared to the full modeling period. The Representative Preferred Alternative would likely exceed the 200-foot maximum height, with 23 percent of futures resuling in calcium carbonate rings being less than 200 feet for all months of modeling for the first 10 years (modeled 2027-2039 period) and 17 percent of futures during the full modeling period, with these results within the range analyzed associated with these alternatives.

Figure TA 19-8
Maximum Height of Lake Mead Calcium Carbonate Ring: Robustness. Percentage of futures in which the monthly calcium carbonate ring at Lake Mead is always less than the height specified by each row



Note: Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

Figure TA 19-9
Monthly Height of Lake Mead Calcium Carbonate Ring Full Modeling Period: Robustness.
Percentage of futures in which the height of the calcium carbonate ring at Lake Mead is less than the reference height in the percentage of months specified by each row

Note: Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

Figure TA 19-10
Monthly Height of Lake Mead Calcium Carbonate Ring 2027-2039: Robustness.
Percentage of futures in which the height of the calcium carbonate ring at Lake Mead is less than the reference height in the percentage of months specified by each row

Note: Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results differ primarily because of how the two shortage-distribution approaches interact with the modeled assumptions governing the storage and delivery of conserved water (see **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water).

As described in the 2007 Final EIS, sediment deltas would continue to build up over time and would be visible as the reservoir elevations decrease, including under the No Action Alternative. The expanding sediment deltas would become populated by vegetation, including tamarisk, which would introduce bright greens into the landscape that contrast with the arid landscapes adjacent to Lake Powell and Lake Mead. Additionally, the receding shorelines would expose trash and other debris, which would diminish the area's landscape character. The lower the lake levels become, impacts on landscape character associated with calcium carbonate rings, exposed shoreline with trash and other debris, and sediment deltas would increase accordingly. Additionally, lower lake levels would facilitate re-emergence of side canyons including public access for recreation (see **TA 14**, Recreation).

Both the calcium carbonate ring, exposed shoreline with trash and other debris, and sediment deltas would modify the landscape character along the edge of Lake Powell. These modifications would be visible for motorists on Utah State Route 95, boaters on Lake Powell, recreationists at developed and undeveloped recreation areas, and hikers on trails adjacent to Lake Powell. Similarly, the calcium carbonate ring, exposed shoreline with trash and other debris, and sediment deltas would modify the landscape character along the edge of Lake Mead; these modifications would be visible for motorists on U.S. Highway 93 (between Boulder City, Nevada, and the Hoover Dam), boaters on Lake Mead (including visitors to Overton Beach and Pearce Ferry), and hikers on trails adjacent to Lake Mead.

TA 19.2.4 Issue 3: How would management of releases from Glen Canyon Dam affect landscape character along the Colorado River?

The No Action Alternative and CCS Comparative Baseline would include lowering releases from Glen Canyon Dam as Lake Powell elevations decrease; this would result in releases as low as 7.0 maf when elevations drop below 3,525 feet. Since neither the No Action Alternative nor the CCS Comparative Baseline includes reducing releases from Glen Canyon Dam under 7.0 maf, including if Lake Powell drops below power pool but remains above dead pool, there would be minor, incremental impacts on the landscape character along the Colorado River, including through the Grand Canyon. The current trends of increasing bank armoring, associated with expanding riparian vegetation areas (including tamarisk), would continue under the No Action Alternative and CCS Comparative Baseline. If the elevation of Lake Powell were to drop below dead pool, flows from Glen Canyon Dam could dramatically decrease, resulting in more extensive impacts on the landscape character, including the appearance of river features previously not visible under current conditions. Additionally, the positive influence of the moving, turbulent Colorado River adds to the existing landscape character, which would be degraded if releases from Glen Canyon Dam were dramatically reduced. The No Action Alternative would result in relatively short and few HFE releases, resulting in fewer opportunities for sand bar volumes to increase compared to the CCS Comparative Baseline, which would result in longer and more frequent HFE releases with more opportunities for increased sand bar volumes as compared to the No Action Alternative.

The Basic Coordination Alternative would result in similar impacts as the No Action Alternative and CCS Comparative Baseline, since it includes a similar range of releases from Glen Canyon Dam, but would include an increased number of futures where HFEs are conducted. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would include lower releases, as low as 4.7 maf, which is lower than

historic minimum flows. Lower releases from Glen Canyon Dam would result in less water flowing along the Colorado River (and through the Grand Canyon), which could increase existing trends of bank armoring associated with more extensive riparian vegetation, including tamarisk. The Representative Preferred Alternative would also include lower releases, as low as 6.0 maf, which would result in similar impacts along the Colorado River as the other action alternatives but since these releases would result in more water flowing along Colorado River, the trends described above would be tempered. Lower releases also could limit the number of times an HFE could be triggered from Glen Canyon Dam, which would only occur when the HFE furthers maintenance of target reservoir elevations. The Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives would result in the most futures where HFEs are conducted These lower flows may also result in the appearance of river features previously not visible under current conditions and less movement of the river's natural sandbars. If yearly elevations facilitate releases of 7.0 maf or more under the Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives, the impact under these alternatives would be similar to those described under the No Action Alternative and CCS Comparative Baseline, as the lower releases from Glen Canyon Dam would be avoided. If the elevation of Lake Powell were to drop below dead pool, flows from Glen Canyon Dam could dramatically decrease, resulting in similar impacts as described under the No Action Alternative and CCS Comparative Baseline. For more information on the impacts on riparian vegetation, refer to **TA 9**, Vegetation Including Special Status Species; for impacts associated with sand bars including their volume, refer to **TA 5**, Geomorphology and Sediment; and for impacts on recreation, including visibility of river features, refer to **TA 14**, Recreation.

TA 19.2.5 Issue 4: How would management of water availability for the Lower Division States affect landscape character?

Since the No Action Alternative includes minor adjustments (0.6 maf) to the distribution of water for Arizona and Nevada (no adjustments for California), based on lowering Lake Mead elevations, there would initially be a limited incremental effect on irrigated landscapes, including those in agricultural use. If elevations in Lake Mead were to drop to dead pool (895 feet), flows from Lake Mead would dramatically decrease, resulting in lower water deliveries than currently allocated, affecting all three Lower Division States. As described in **TA 4**, Water Deliveries, the No Action Alternative would result in the most futures where dead pool–related shortage may be reached during the modeling period. Depending on the duration of these decreased water deliveries, the character of irrigated and agricultural landscapes within the Lower Division States would be modified through aridification of these areas; this would diminish the vivid greens associated with crops and ornamental plantings. The influence of the Colorado River on adjacent lands would narrow as these areas would transition to their natural, arid condition. This would result in large-scale changes to the landscape character compared with the existing condition. Additionally, the aridification of these lands could also result in more exposed soil, generating fugitive dust affecting visibility within the region, including from GCNP and other highly valued viewsheds. For more details on the impacts related to fugitive dust, please see **TA 7**, Air Quality.

CCS Comparative Baseline would include a series of water supply adjustments for the Lower Division States based on lower elevations of Lake Mead. If water levels in Lake Mead drop below 1,075 feet, similar effects as described under the No Action Alternative would occur, with

conservation measures tempering these effects. As lake levels continue to drop toward 1,025 feet, all three states would receive less water from the Colorado River under this alternative through proposed shortages and conservation measures. As Lake Mead approaches dead pool, to avoid a dramatic decrease in water releases from Hoover Dam affecting all three Lower Division States, more reductions could occur (up to 1.38 maf). These include further reductions in water deliveries based on extraordinary circumstances, as described in Section 7(D) of the 2007 Interim Guidelines. These reductions to avoid reaching dead pool would temper the impacts on the character of irrigated and agricultural landscapes within the Lower Division States, as described under the No Action Alternative. If Lake Mead reaches dead pool elevation during the planning period, impacts would be similar to those described under the No Action Alternative.

The Basic Coordination Alternative would have similar impacts as the No Action Alternative as there would be adjustments to the distribution of water for Arizona and Nevada, but no adjustments for California, based on lowering Lake Mead elevations. As Lake Mead elevation drops below 1,160 feet, shortages would begin with those increasing to 1.48 maf when Lake Mead is below 1,110 feet. Through increased shortages under this alternative, the number of futures where Lake Mead reaches dead pool would be reduced compared to the No Action Alternative and CCS Comparative Baseline, but there is still a risk of reaching dead pool under this alternative. As described in **TA 4**, Water Deliveries, the Basic Coordination Alternative would result in the second most futures where dead pool–related shortage may be reached during the modeling period. If Lake Mead reaches dead pool elevation during the planning period, impacts would be similar to those described under the No Action Alternative.

Under the Enhanced Coordination Alternative, there is a potential for larger shortages than proposed under the CCS Comparative Baseline and the No Action and Basic Coordination Alternatives, with shortages being distributed pro rata among mainstream lower Colorado River water users independent of state. Shortages would begin when Lake Powell effective storage and Lake Mead physical storage are equal to or less than 60 percent of combined capacity and greater than or equal to 30 percent combined capacity, resulting in a 1.3 maf shortage. This would increase to a 3.0 maf shortage when the sum of Lake Powell effective storage and Lake Mead physical storage is less than 30 percent of the combined capacity. These shortages would occur in all three Lower Division States and incrementally affect irrigated landscapes, including those in agricultural use, based on the extent of the shortage. These shortages are designed to avoid reaching dead pool, tempering the impacts on the character of irrigated and agricultural landscapes within the Lower Division States, and avoid more extensive impacts if Lake Mead reached dead pool. As described in **TA 4**, Water Deliveries, the Enhanced Coordination Alternative would result in the second fewest futures where dead pool–related shortage may be reached during the modeling period. If Lake Mead reaches dead pool elevation during the planning period, impacts would be similar to those described under the No Action Alternative.

Under the Maximum Operational Flexibility Alternative, there is a potential for larger shortages than under the CCS Comparative Baseline and the Enhanced Coordination, No Action, and Basic Coordination Alternatives, with shortages being based on priority. These shortages would occur based on the total system effective storage and capacity, as described in **Appendix S**, with shortages up to 4.0 maf. These shortages would occur in all three Lower Division States and

incrementally affect irrigated landscapes, including those in agricultural use, based on the extent of the shortage. These shortages are designed to avoid reaching dead pool, tempering the impacts on the character of irrigated and agricultural landscapes within the Lower Division States and avoid more extensive impacts if Lake Mead reached dead pool. As described in **TA 4**, Water Deliveries, the Maximum Operational Flexibility Alternative would result in the least number of futures where dead pool–related shortage may be reached during the modeling period. If Lake Mead reaches dead pool elevation during the planning period, impacts would be similar to those described under the No Action Alternative.

Under the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), there is a potential for larger shortages than proposed under the CCS Comparative Baseline and the No Action and Basic Coordination Alternatives, with shortages being distributed based on priority within that state or pro rata within that state as described in **Appendix S**. If water levels in Lake Mead drop below 1,145 feet, similar effects as described under the No Action Alternative are anticipated, with conservation measures tempering these effects. As lake levels continue to drop toward 1,000 feet, all three states would receive less water from the Colorado River under this Alternative through proposed shortages, up to 2.1 maf, and conservation measures. These shortages are designed to avoid reaching dead pool, tempering the impacts on the character of irrigated and agricultural landscapes within the Lower Division States, and avoid more extensive impacts if Lake Mead reached dead pool. As described in **TA 4**, Water Deliveries, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), similar to the Enhanced Coordination Alternative, would result in the second fewest futures where dead pool–related shortage may be reached during the modeling period. If Lake Mead reaches dead pool elevation during the planning period, impacts would be similar to those described under the No Action Alternative.

The Representative Preferred Alternative would result in shortages up to 3.0 maf, distributed based on Lower Basin consensus arrangements, if they exist, or otherwise distributed based on the priority system, with initial shortages beginning at 1.5 maf in 2027 and 2028. Consultation would occur if Lake Mead elevation were projected to be less than 1,000 feet to determine whether additional reductions are needed in the Lower Basin (including the United Mexican States). As described in **TA 4**, Water Deliveries, the Representative Preferred Alternative, similar to the Enhanced Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, would be in the group of alternatives with the second-fewest futures involving dead pool–related reductions during the modeling period (the Maximum Flexibility Alternative has the fewest futures). If Lake Mead reaches dead pool elevation during the planning period, impacts would be similar to those described under the No Action Alternative. These results are within the range analyzed across the other alternatives. For more information on the impacts on agricultural operations, refer to **TA 16**, Socioeconomics, and for more information on the specific, state-level water deliveries, refer to **TA 4**, Water Deliveries.

TA 19.2.6 Summary Comparison of Alternatives

In general, alternatives that facilitate higher reservoir elevations, maintain higher flows along the Colorado River, including through Grand Canyon, and support full water deliveries to the Lower Division States would result in the lowest impacts on visual resources and on landscape character. While some users may prefer lower lake levels in Lake Powell, to allow Cathedral in the Desert and

other attraction features inundated by Lake Powell to be visible and accessible, in general, higher water levels would result in lower impacts on landscape character, including shorter calcium carbonate rings, less exposed shoreline, including trash and other debris, and smaller sediment deltas.

During wet hydrologic conditions, the range of alternatives would generally produce conditions where lake levels and flows along the Colorado River would result in minimal impacts on landscape character.

As conditions become drier, the No Action Alternative and CCS Comparative Baseline would result in the most futures where landscape character is affected by lower water levels in Lake Powell and Lake Mead compared to the Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives. The Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would result in a similar number of futures as the No Action Alternative and CCS Comparative Baseline with lower water levels in Lake Powell but would keep water levels higher in Lake Mead, similar to the Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives, resulting in more futures where water levels are higher in Lake Powell. The lower the lake levels become, impacts on landscape character associated with calcium carbonate rings, exposed shoreline with trash and other debris, and sediment deltas would increase accordingly.

Under drier conditions, releases from Glen Canyon would be tempered under the Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives, which include lower releases to avoid reaching dead pool. While these lower releases would result in incremental impacts on landscape character along the Colorado River, by avoiding dead pool, more intense impacts could be avoided. Under some futures, associated with the CCS Comparative Baseline and No Action Alternative, dead pool may be reached, which would result in flows from Glen Canyon Dam dramatically decreasing, resulting in more extensive impacts on the landscape character, including the appearance of river features previously not visible under current conditions.

Water availability for the Lower Division States associated with the alternatives, under drier conditions, would vary with the No Action Alternative resulting in minimal adjustments to water deliveries from lowering Lake Mead elevations, but if dead pool were reached, flows from Lake Mead would dramatically decrease. This would result in lower water deliveries than currently allocated, affecting all three Lower Division States. Depending on the duration of these decreased water deliveries, the character of irrigated and agricultural landscapes within the Lower Division States would be modified through aridification of these areas, diminishing the influence of the Colorado River on adjacent lands through reduction of vivid greens associated with crops and ornamental plantings. Additionally, the aridification of these lands could also result in more exposed soil, generating fugitive dust affecting visibility within the region, including from GCNP and other highly valued viewsheds. CCS Comparative Baseline and the Basic Coordination, Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives all include more expansive decreased water deliveries which are designed to avoid reaching dead pool, tempering the impacts on the character of

irrigated and agricultural landscapes within the Lower Division States and avoid more extensive impacts if Lake Mead reached dead pool. The Maximum Operational Flexibility, Enhanced Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives include the largest potential shortages to minimize the number of future conditions where dead pool could be reached based on DMDU modeling as described in **TA 4**, Water Deliveries.

BUREAU OF
RECLAMATION

Mission Statements

The **Department of the Interior** protects and manages the Nation's natural resources and cultural heritage; provides scientific and other information about those resources; and honors its trust responsibilities or special commitments to American Indians, Alaska Natives, and affiliated island communities.

The mission of the **Bureau of Reclamation** is to manage, develop, and protect water and related resources in an environmentally and economically sound manner in the interest of the American public.

List of Preparers

The Final EIS was prepared by Reclamation with resource modeling and analysis support from the National Park Service (NPS), Northern Arizona University (NAU), United States Geological Survey (USGS), and Western Area Power Administration (WAPA). This is a list of preparers who developed significant background material and various sections or they participated, to a significant degree, in the preparation of this Final EIS.

Bureau of Reclamation Team

Name	Project Role
Carly Jerla	Post-2026 Program - Project Lead
Wayne Pullan	Regional Leadership (Upper Colorado Basin)
Genevieve Johnson	Regional Leadership (Lower Colorado Basin)
Katrina Grantz	Regional Management (Upper Colorado Basin)
Dan Bunk	Regional Management (Lower Colorado Basin)
Carter Brown	Solicitor's Office Lead
KayLee Nelson	Post-2026 Program - Project Coordinator
Amy Witherall	Regional Management (Lower Colorado Basin, Binational Program)

Glossary

acre-foot (af)—Volume of water (43,560 cubic feet) that would cover 1 acre to a depth of 1 foot.

adaptive management—A method for examining alternative strategies for meeting goals and objectives, and then, if necessary, adjusting future management actions according to what is learned.

affected environment—Existing biological, physical, social, and economic conditions of an area that are subject to change, both directly and indirectly, as the result of a proposed human action.

algae—Simple plants containing chlorophyll; most live submerged in water.

algal bloom—An excessive growth of algae in a waterbody, typically associated with nutrient enrichment.

allocation, allotment—Refers to a distribution of water through which specific persons or legal entities are assigned individual rights to consume pro rata shares of a specific quantity of water under legal entitlements. For example, a specific quantity of Colorado River water is distributed for use within each Lower Division State through an apportionment. Water available for consumptive use in that state is further distributed among water users in that state through the allocation. An allocation does not establish an entitlement; the entitlement is normally established by a written contract with the United States government. *Refer to* Lower Basin/Lower Division States.

alluvium—Sedimentary material transported and deposited by the action of flowing water.

ambient—Surrounding natural conditions (or environment) in a given place and time.

amphibian—A vertebrate animal that has a life stage in water and a life stage on land. (Examples include salamanders, frogs, and toads.)

analysis area—Specific geographic boundary and timeframe used to evaluate the potential environmental effects of a proposed action.

anoxic—Describes water conditions in which dissolved oxygen is absent.

annual flow-weighted average concentration—A weighted average of monthly total dissolved solids (TDS) concentrations for a year, where the weight for each month is based on the relative flow for each month.

Annual Operating Plan for Colorado River Reservoirs (AOP)—A document describing how Reclamation will manage Colorado River resources over a 12-month period, consistent with the Long-Range Operating Criteria and the Supreme Court Decree in *Arizona v. California* 1964 . The AOP is prepared annually by Reclamation in cooperation with the Basin States, Mexico, appropriate

federal agencies, Indian tribes, state and local agencies, and the general public, including governmental interests, as required by federal law. As part of the AOP process, the Secretary of the Department of the Interior (Secretary) makes annual determinations regarding the availability of Colorado River water for deliveries to the Lower Division States of the Colorado River Basin. *Refer to* Lower Basin/Lower Division States.

apportionment—Refers to the distribution of water available to each Lower Division State in normal, surplus or shortage condition years, as set forth, respectively, in Articles II(B)(1), II(B)(2), and II(B)(3) of the 1964 Supreme Court Decree in the case of *Arizona v. California. Refer to* normal, surplus, and shortage.

appropriative rights—The right to divert a specified quantity of water at a specified point of diversion for reasonable and beneficial uses at a specified place of use for a specified manner of use. Appropriative rights are generally "first-in-time, first-in-right" (that is, one appropriative right has priority over appropriative rights established later).

backwater—A relatively small, generally shallow area of a river with little or no current.

banked groundwater—Water that has been stored temporarily in a groundwater aquifer. Banked groundwater can be recovered for use at a later time.

base load—Minimum load in a power system over a given period of time.

Basin States—In accordance with the Colorado River Compact of 1922, the Colorado River Basin within the United States consists of those parts of Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming within and from which waters drain naturally into the Colorado River. These seven states are referred to as the Basin States. *Refer to* Colorado River Compact of 1922.

bathymetrically—Pertaining to the measurement, mapping, or description of underwater topography.

benthic—Referring to the bottom (bed) of a waterbody.

Binational Intentionally Created Surplus (ICS)—An ICS is a mechanism to encourage and account for augmentation and conservation of water supplies that would minimize the likelihood and severity of potential future shortages. Binational types of ICS are created through the binational agreements of Minutes 319 and 323 to the 1944 Mexican Water Treaty and provide for the development and implementation of water conservation programs located in Mexico with compensation funding provided by partnering organizations in the United States.

biological assessment (BA)—A document identifying the likely effects of a proposed federal action on threatened and endangered species. To facilitate compliance with Section 7(a)(2) of the Endangered Species Act (ESA), federal agencies must prepare a BA pursuant to Section 7(c)(1) of the ESA. *Refer to* Endangered Species Act.

biological opinion (BO)—A document stating the opinion of the United States Fish and Wildlife Service (Service) and/or the National Marine Fisheries Service as to whether a federal action is likely to jeopardize the continued existence of an Endangered Species Act listed threatened or endangered species or result in the destruction or adverse modification of critical habitat.

broodstock—Sexually mature individuals maintained in captivity or managed populations for the purpose of producing offspring.

bug flows—Managed dam releases intended to enhance aquatic invertebrate production and diversity by mimicking natural flow patterns.

bypass flows—Saline agricultural return flows from the Wellton-Mohawk Irrigation and Drainage District that are routed to the Cienega de Santa Clara in Mexico to ensure compliance with the salinity provisions of Minute 242 of the 1944 Water Treaty.

bypass tubes—Another term for river outlet works. *Refer to* outlet works.

candidate species—A plant or animal species that is not yet officially listed as threatened or endangered under the Endangered Species Act but is undergoing status review by the Service.

capacity—The maximum amount of energy that can be instantaneously produced.

catch—At a recreational fishery, refers to the number of fish captured, whether they are kept or released.

channel (watercourse)—An open conduit either naturally or artificially created that periodically or continuously contains moving water, or that forms a connecting link between two bodies of water. Some terms used to describe natural channels are river, creek, run, branch, and tributary. Natural channels may be single or braided. Two terms used to describe artificial channels are canal and floodway.

channel migration—The lateral movement of a river or stream channel across its floodplain over time.

Cladophora—Filamentous green alga important to the food chain in the Colorado River downstream of Glen Canyon Dam.

Colorado River Basin (Basin)—The drainage area of the Colorado River system. The Basin occupies an area of approximately 250,000 square miles in the southwestern United States and 3,500 square miles in northwestern Mexico. The Colorado River Compact of 1922 divided the Colorado River system into two subbasins: the Upper Basin and the Lower Basin. It also divided the seven states within the Basin into the Upper Division and the Lower Division. Upper Division States include Colorado, New Mexico, Utah, and Wyoming; Lower Division States include Arizona, California, and Nevada. Additionally, 30 federally recognized tribes are in the Basin.

Colorado River Basin Project Act of 1968 (CRBPA)—An act authorizing construction of a number of water development projects, including the Central Arizona Project (CAP), and requiring

the Secretary to develop the Criteria for Coordinated Long-Range Operation of Colorado River Reservoirs, or Long-Range Operating Criteria (LROC).

Colorado River Basin Salinity Control Forum—The organization dedicated to controlling Colorado River salinity; it consists of representatives of the seven Basin States. *Refer to* Basin States.

Colorado River Compact of 1922—The agreement concerning the apportionment of the use of the waters of the Colorado River Basin, dated November 24, 1922, and executed by commissioners for Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming. It was approved and proclaimed effective by Herbert Hoover, the president of the United States, and representative of the United States for purposes of the Compact, on June 25, 1929.

Colorado River Simulation System (CRSS)—A core Colorado River system operations tool that provides monthly outputs of key variables including reservoir elevations, releases, river flows, and salinity.

Colorado River system—The portion of the Colorado River and its tributaries within the United States as defined in the Colorado River Compact of 1922. *Refer to* Colorado River Compact of 1922.

compact—The Colorado River Compact of 1922. *Refer to* Colorado River Compact of 1922.

compact point—The reference point designated by the Colorado River Compact of 1922 as dividing the Colorado River Basin into two subbasins, the Upper Basin and the Lower Basin. The compact point is Lee Ferry, Arizona. *See also* Colorado River Compact of 1922 and Lee Ferry Compact Point.

conductivity—A measure of water's ability to pass an electrical current.

conservation species—A species that has been identified by a management agency, conservation organization, or research program as needing special attention or protection.

Consolidated Decree—A decree entered by the United States Supreme Court on March 27, 2006, in the case of *Arizona v. California,* 547 US 150 (2006), incorporating all applicable provisions of the earlier-issued decisions and decrees in the matter. The Supreme Court reached a decision in the case of *Arizona v. California* in 1963 and implemented this decision in a 1964 decree, which was supplemented over time after its adoption.

consumptive use—Diversions of water from mainstream Colorado River, including water withdrawn from the mainstream through underground pumping, minus any measured and unmeasured return flows. A use which lessens the amount of water available for another use. Water uses normally associated with man's activities, primarily municipal, industrial, and irrigation uses that deplete water supplies. Water removed from available supplies without direct return to a water resource system, for uses such as manufacturing, agriculture, and food preparation.

contractors—Those who hold entitlements to Colorado River water. Contractors consist of the federal government, states, Indian tribes, and various public and private entities that are recognized

under the Consolidated Decree, hold a Section 5 Contract with the Secretary, or have a Secretarial Reservation of water. *Refer to* Consolidated Decree.

conveyance loss—Water that is lost in transit from a pipe, canal, conduit, or ditch by leakage or evaporation. If the water is lost due to leakage, it may be considered return flow if it percolates to an aquifer and is available for reuse. If the water evaporates, it is considered consumptive use. *Refer to* consumptive use.

cooperating agency—As described in the National Environmental Policy Act of 1969, as amended, a Federal, State, tribal, or local agency that has jurisdiction by law or special expertise with respect to any environmental impact involved in a proposal (42 U.S.C. 4321 et seq.)

covered species—Those species addressed in the Lower Colorado River Multi-Species Conservation Program (LCR MSCP) for which conservation measures would be implemented and for which authorization for "take" is being requested under Section 10 of the Endangered Species Act. *See also* take.

criteria—Standards used for making a determination.

critical habitat—As defined by the Endangered Species Act, areas within the geographical area occupied by the species, at the time it is listed in accordance with the provisions of section 4 of this Act, on which are found those physical or biological features (I) essential to the conservation of the species and (II) which may require special management considerations or protection; and specific areas outside the geographical area occupied by the species at the time it is listed in accordance with the provisions of section 4 of this Act, upon a determination by the Secretary that such areas are essential for the conservation of the species. (16 U.S.C. 1532.Definitions).

cubic foot per second (cfs)—A measure of water flow equal to 1 cubic foot of water passing a point on the stream in 1 second of time.

cultural resource—A building, site, district, structure, or object significant in history, architecture, archaeology, culture, or science.

dead pool—Elevation at which water cannot be regularly released from a reservoir, which would effectively preclude Colorado River diversions to downstream users.

dead storage—Reservoir space from which stored water cannot be evacuated by gravity.

debris fan—A fan-shaped deposit of sediment, rock, and other debris formed when high-velocity flows such as debris flows or flash floods exit a narrow conduit onto a flatter plain.

debris flow—fast-moving mass of water, soil, rock, and organic debris that flows downslope under the influence of gravity.

Decision Making under Deep Uncertainty (DMDU)—A method for making decisions using a framework that evaluates several solutions across multiple future scenarios.

delta sediment—Deposit formed at the mouth of the Colorado River and other rivers where they enter Lake Powell, Lake Mead, or the Gulf of California.

depletion—Loss of water from a stream, river, or basin resulting from consumptive use. *Refer to* consumptive use.

deposition—Settlement of material out of the water column and on to the streambed. Occurs when the energy of flowing water is unable to support the load of suspended sediment.

discharge (flow)—Volume of water that passes a given point within a given period of time; expressed in cubic feet per second (cfs). *Refer to* cubic foot per second.

desiccation—The process of drying out or losing moisture due to exposure to air, heat, or lack of water.

dissolved oxygen (DO)—Amount of free oxygen found in water; perhaps the most commonly employed measurement of water quality. Low DO levels adversely affect fish and other aquatic life. The ideal dissolved oxygen for fish life is between 7 milligrams per liter (mg/L) and 9 mg/L; most fish cannot survive when DO falls below 3 mg/L.

diversion(s)—Colorado River water withdrawn from the mainstream, including water diverted from reservoirs or drawn from the mainstream by underground pumping.

domestic use—Refers to the use of water for household, stock, municipal, mining, milling, industrial, and other like purposes; excludes the generation of electrical power.

downcutting—The process by which a stream or river erodes downward into its bed, deepening the channel through the removal of sediment and bedrock.

draw down—Lowering of a reservoir's elevation; process of depleting a reservoir or groundwater storage.

ecosystem—As defined by the United States Geological Survey (USGS), an ecosystem is made up of all of the living and non-living things in a geographic area. Plants, animals, soil, climate, and other features of the environment interact with each other to form an ecosystem.

electric power system—Physically connected facilities for electricity generation, transmission, and distribution that are operated as a unit under one control.

electrical demand—Energy requirement placed upon a utility's generation at a given instant or averaged over any designated period of time.

electrofishing—A method of sampling fish populations by applying a controlled electric current throughout the water to temporarily immobilize fish for capture, identification, and release.

endangered species—Any species which is in danger of extinction throughout all or a significant portion of its range. as defined by the Endangered Species Act (ESA) of 1973 (16 USC 1532.Definitions). *Refer to* threatened.

Endangered Species Act (ESA)—The Endangered Species Act (ESA) of 1973 (16 USC 1531–1544), establishes protections for fish, wildlife, and plants that are listed as threatened or endangered; provides for adding species to and removing them from the list of threatened and endangered species, and for preparing and implementing plans for their recovery; provides for interagency cooperation to avoid take of listed species and for issuing permits for otherwise prohibited activities; provides for cooperation with States, including authorization of financial assistance; and implements the provisions of the Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES).

endemic—Native to and confined within a particular geographic area or habitat type.

energy—What is produced by powerplants; measured in kilowatt hours.

entitlement—Refers to an authorization to beneficially consume Colorado River water pursuant to a decreed right; a contract with the United States through the Secretary of the Interior or a Secretarial Reservation of water.

entrained—Drawn into and carried along by the movement of water.

ephemeral—Describing a stream that conveys flow only during and shortly after a precipitation event.

epilimnion—Thermal layering of water in lakes and streams. *See also* stratification.

equalization line—the Equalization Tier from the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead defined by an elevation schedule that would be used in determining when equalization releases would be made from Lake Powell.

escapement—Fish moving and surviving through Glen Canyon Dam and into the Grand Canyon.

euryhaline—Describes organisms capable of surviving and functioning across a broad range of salinities.

Extraordinary Conservation Intentionally Created Surplus (ICS)—An ICS is a mechanism to encourage and account for augmentation and conservation of water supplies that would minimize the likelihood and severity of potential future shortages. Extraordinary Conservation types of ICS are created through such conservation measures as fallowing, canal lining programs, and desalination programs.

federally listed species—A species that has been officially designated as endangered or threatened.

fish barrier—Any natural or artificial structure that prevents or limits the upstream or downstream movement of fish.

firm energy or power—Non-interruptible energy or power guaranteed by the supplier to be available at all times except for reasons of uncontrollable forces or "continuity of service" contract provisions.

flood—An overflow or inundation that comes from a river or other body of water and causes or threatens damage. Any relatively high streamflow overtopping the natural or artificial banks in any reach of a river or stream. A relatively high flow as measured by either gage height or discharge quantity.

flood control pool—Reservoir volume above the active conservation and joint-use pool that is reserved for flood runoff and then evacuated as soon as possible to keep that space ready for the next flood.

flood control release—The release of water from Lake Mead and the operation of Hoover Dam for flood control purposes pursuant to the reservoir operating criteria specified in the February 8, 1984, Field Working Agreement between the United States Army Corps of Engineers (USACE) and the Bureau of Reclamation (Reclamation), and the USACE regulations contained in 33 Code of *Federal Regulations* (CFR) 208.11.

flow—Volume of water passing a given point per unit of time expressed in cubic foot per second. *See also* cubic foot per second.

forage fish—Generally, small fish that reproduce prolifically and are consumed by predators.

fore bay—Impoundment immediately above a dam or hydroelectric plant intake structure. The term is applicable to all types of hydroelectric developments (storage, run-of-river, and pumped storage).

Fossil—Any remains, trace, or imprint of a plant, animal, or other organism that has been preserved in the geologic record. Fossils can include body fossils (for example, bones, teeth, shells, and leaves), trace fossils (for example, tracks, trails, burrows, coprolites, and chemical signatures), and various kinds of microfossils (for example, pollen grains, spores, and diatoms). Fossils are generally considered to be older than about 11,700 years (the end of the Pleistocene Epoch), but remains older than middle Holocene age (about 5,000 years) can also be considered to represent fossils because they are part of the record of past life.

fry—Life stage of fish between the egg and fingerling stages.

full pool—Volume of water in a reservoir at maximum design elevation.

gaging station—Specific location on a stream where systematic observations of hydrologic data are obtained through mechanical or electrical means.

gigawatt-hour (GWh)—One billion watt-hours of electrical energy.

grow-out—The stage in aquaculture or fish culture during which young fish are raised to a larger or more mature size until they are ready for release.

habitat conservation plan (HCP)—A planning document describing general and species-specific conservation measures for species listed under the Endangered Species Act.

headwater—The source and upper part of a stream.

hepatotoxins—Toxins that damage or interfere with liver functions.

high-flow experiments (HFEs)—Scheduled releases of water from a dam above powerplant capacity to benefit key resources by simulating pre-dam floods.

historic property—Any district, site, building, structure, or object listed on or eligible for listing on the National Register of Historic Places (36 CFR 800.16(l)(1)).

hydropower—The use of water to produce electricity.

hypolimnetic zone—The deep portion of a lake or reservoir volume generally classified as below the level of the thermocline. *Refer to* thermocline.

hypolimnion—Thermal layering of water in lakes and streams; the lower stratum of the water column of a reservoir. This layer is generally undisturbed, and respiration and decomposition predominate. *Refer to* stratification.

important farmlands—Prime farmland, unique farmland, farmland of statewide importance, and farmland of local importance, as defined by the United States Department of Agriculture Natural Resources Conservation Service (formerly the Soil Conservation Service). The categorization of farmland is based on a soil classification system that accounts for the physical and chemical characteristics of the land and the suitability of the land for producing crops. Important farmlands are afforded special protection due to their importance to agricultural production.

Imported Intentionally Created Surplus (ICS)—An ICS is a mechanism to encourage and account for augmentation and conservation of water supplies that would minimize the likelihood and severity of potential future shortages. Imported types of ICS are created by introducing non-Colorado River System water in that entitlement holder's state into the mainstream.

impoundment—Body of water created by a dam.

in situ—In archaeology, and as used in this EIS, an artifact that has not been moved from its original place of deposit.

Indian trust assets (ITAs)—An Indian trust asset is something the Federal government holds in trust for the benefit of a Native American individual or tribe. In the case of trust lands, this means that an individual or tribe earns money when companies lease rights to that land and earn income.

inflow—Water flowing into a lake or reservoir from a river and/or its tributaries, or water entering a river from tributaries.

inundated—Covered or submerged by water.

irrigated area—The gross farm area upon which water is artificially applied for the production of crops, with no reduction for access roads, canals, or farm buildings.

irrigation—The controlled application of water to arable lands to supply water requirements not satisfied by rainfall.

juvenile—Young fish older than 1 year but not having reached reproductive age.

kilowatt-hour (kWh)—One thousand watt-hours of electrical energy.

land cover type—A classification system to describe vegetation and other habitat types (such as cottonwood willow, honey mesquite, and marsh).

landscape character—Overall visual appearance of a given landscape based on the form, line, color, and texture associated with the landscape's vegetation, landforms/water, and human-made modifications. These factors give the area a distinctive quality that distinguishes it from its immediate surroundings.

Las Vegas Valley—The topographic basin containing the city of Las Vegas, the city of North Las Vegas, the city of Henderson, and certain unincorporated townships of Clark County in the State of Nevada.

Las Vegas Wash—The natural drainage channel for the entire Las Vegas Valley. It is dominated by wastewater flows from the city of Las Vegas, Clark County Sanitation District, and city of Henderson wastewater treatment plants. It terminates in the Las Vegas Bay of Lake Mead in the State of Nevada.

Law of the River—As applied to the Colorado River, a body of documents the Secretary of the Interior (Secretary) uses to carry out the responsibility to manage the mainstream waters of the Lower Basin pursuant to applicable federal law. The Secretary is vested with this responsibility. This collective set of documents is comprised of numerous operating criteria, regulations, and administrative decisions from federal and state statutes, interstate compacts, court decisions and decrees, an international treaty, and contracts. The Secretary apportions the Colorado River waters and regulates the use and management of the Colorado River among the seven Basin States and Mexico. *Refer to* Colorado River Compact of 1922 and Basin States.

lead agency—An agency initiating and overseeing the preparation of an EIS. For this EIS, Reclamation is the lead agency for compliance with NEPA.

Lee Ferry Compact Point—Identified reference point that marks the division between the two subbasins—the Upper Basin and the Lower Basin—created by the division of the Colorado River Basin in the Colorado River Compact of 1922. This reference point is in the mainstream Colorado

River in Arizona, one mile below the confluence of the Colorado River with the Paria River. *Refer to* Colorado River Compact of 1922.

Lees Ferry Gaging Station—The site of the United States Geological Survey (USGS) stream gage (Lees Ferry Gaging Station) in Arizona on the Colorado River upstream of its confluence with the Paria River, downstream of Glen Canyon Dam. Also, the location of Colorado River ferry crossings (1873 to 1928).

limitrophe—a border state or area.

limnology—Scientific study of physical characteristics and the biology of lakes, ponds, and streams.

littoral—The shallow, nearshore zone of a lake or reservoir.

load—Amount of electrical power or energy delivered or required at a given point.

Lower Basin (States)—Those parts of the states of Arizona, California, Nevada, New Mexico, and Utah within and from which waters drain naturally into the Colorado River below the Lee Ferry Compact Point in Arizona. The Colorado River Compact of 1922 divided the Colorado River system into two subbasins: the Upper Basin and the Lower Basin. *See also* Lee Ferry Compact Point.

Lower Division (States)—Arizona, California, and Nevada. The Colorado River Compact of 1922 divided the seven Colorado River Basin states into two groups: Upper Division States and Lower Division States. The Lower Division States are Arizona, California, and Nevada. *See also* Basin States.

mainstream—The primary channel of a river system carrying the largest and most continuous flow.

magnitude—A number characteristic of a quantity and forming a basis for comparison with similar quantities, such as flows. *Refer to* flows.

mean monthly flow—Average flow for the month, usually expressed in cubic feet per second.

mean sea level (msl)—The average height of the surface of the oceans and seas measured throughout all stages of the tidal cycle, determined from hourly readings of tidal height, and computed over a long (usually 19-year) period. It is used as a datum plane (that is, it serves as the reference surface from which elevations and depths are measured).

median—Middle value in a distribution, above and below which lie an equal number of values.

megawatt (MW)—One million watts of electrical power (capacity).

megawatt-hour (MWh)—One million watt-hours of electrical energy.

mesolimnion—The middle layer in a stratified lake or reservoir.

Mesozoic era—The second-to-last era of earth's geological history, lasting from about 252 to 66 million years ago, comprising the Triassic, Jurassic, and Cretaceous periods.

metalimnion—Thermal layering of water in lakes and streams. *Refer to* stratification.

milligram per liter (mg/L)—As defined by the United States Geological Survey (USGS), a unit of the concentration of a constituent in water or wastewater. It represents 0.001 gram of a constituent in 1 liter of water. It is approximately equal to one part per million (ppm).

minimum power pool—The reservoir elevation below which water can no longer produce power because the water does not reach the intakes for hydropower generation.

monomictic—Describes a lake or reservoir that undergoes complete mixing once a year, usually because of seasonal changes in air and water temperature.

National Critical Infrastructure—those assets, systems, and networks, whether physical or virtual, are considered so vital to the United States that their incapacitation or destruction would have a debilitating effect on security, national economic security, national public health or safety, or any combination thereof. Presidential Policy Directive 21 (PPD-21): Critical Infrastructure Security and Resilience advances a national policy to strengthen and maintain secure, functioning, and resilient critical infrastructure.

National Environmental Policy Act of 1969, as amended (NEPA) (43 U.S.C. 4321 et seq.)—As described on the Department of Energy's NEPAnet web site, NEPA requires Federal agencies to assess the environmental effects of proposed major Federal actions prior to making decisions. Section 101 of NEPA sets forth a national policy "to use all practicable means and measures, including financial and technical assistance, in a manner calculated to foster and promote the general welfare, to create and maintain conditions under which man and nature can exist in productive harmony, and fulfill the social, economic, and other requirements of present and future generations of Americans." 42 U.S.C. 4331(a). Section 102 of NEPA establishes procedural requirements, applying that national policy to proposals for major Federal actions significantly affecting the quality of the human environment by requiring Federal agencies to prepare a detailed statement on: (1) the environmental impact of the proposed action; (2) any adverse effects that cannot be avoided; (3) alternatives to the proposed action; (4) the relationship between local short-term uses of man's environment and the maintenance and enhancement of long-term productivity; and (5) any irreversible and irretrievable commitments of resources that would be involved in the proposed action. (42 U.S.C. 4332(2)(C)).

National Register of Historic Places (NRHP)—The Nation's official list of historic places worthy of preservation. Authorized under the National Historic Preservation Act of 1966, the NRHP is part of a national program to coordinate and support public and private efforts to identify, evaluate, and protect our historic and archaeological resources. Properties listed on the NRHP include districts, sites, buildings, structures, and objects that are significant in American history, architecture, archaeology, engineering, and culture.

natural flow—The flow of any stream un-depleted by human activities.

neurotoxins—Toxic substances that interfere with the normal function of the nervous system.

non-system water—Waters originating from outside the Colorado River system.

normal condition—When the Secretary has determined that there is available for annual release 7.5 million acre-feet (maf) to satisfy consumptive use in the Lower Division States pursuant to Article II(B)(1) of the Consolidated Decree. *Refer to* Lower Division States and Consolidated Decree.

oligotrophic—A body of water characterized by low dissolved plant nutrient and organic matter, and rich in oxygen at all depths.

outlet works—A combination of structures and equipment required for the safe operation and control of water released from a reservoir to serve various purposes, i.e., regulate stream flow and quality; release floodwater; and provide irrigation, municipal, and/or industrial water. Included in the outlet works are the intake structure, conduit, control house-gates, regulating gate or valve, gate chamber, and stilling basin. A series of components located in a dam through which normal releases from the reservoir are made. A device to provide controlled releases from a reservoir. A pipe that lets water out of a reservoir, mainly to supply downstream demands.

Paleontological resources—Any fossilized remains, traces, or imprints of organisms preserved in or on the earth's crust.

Paleontology—The study of life in past geologic time based on fossil remains, including their anatomy, phylogeny, ecology, relationships to existing plants, animals, and environments, and the chronology of the earth's history.

Paleozoic era (541–252 million years ago)—Means ancient life. The oldest animals on earth appeared just before the start of this era.

Pangea—A supercontinent that existed from about 300 to 200 million years ago and included most of the continental crust of the earth.

peak flow—Maximum instantaneous flow in a specified period of time.

peak load—Maximum electrical demand in a stated period of time.

pelagic—Relating to the open-water zone of a lake or reservoir, away from the shore and bottom.

penstock—Conduit pipe used to convey water from the reservoir through the dam under pressure to the turbines of a hydroelectric plant.

percentile—A statistical term. A descriptive measure that splits ranked data into 100 parts, or hundredths. For example, the 10th percentile is the value that splits the data in such a way that 10 percent of the values are less than or equal to the 10th percentile.

piscivorous—Habitually feeding on fish.

PIT scanning—The process of detecting and recording Passive Integrated Transponder (PIT) tags implanted in fish using an electronic reader.

PM_{10} (PM10)—Particulate matter (PM) (dust particles) standard that includes particles with a diameter of 10 micrometers or less.

$PM_{2.5}$ (PM2.5)—Particulate matter (PM) (dust particles) standard that includes particles with a diameter of 2.5 micrometers or less.

power—Electrical capacity generated, transferred, or used.

Present Perfected Right (PPR)—Many Colorado River water rights that originated as "perfected rights" specified in the 1964 United States Supreme Court Decree in the case of *Arizona v. California.* PPRs are the highest-priority Colorado River water rights that the 1964 Decree defines as those perfected rights existing on June 25, 1929 (the effective date of the Boulder Canyon Project Act of 1928). *Refer to* Consolidated Decree.

priority—A ranking with respect to diversions of water relative to other water users.

pro rata shortage distribution—distribution of policy shortages on a proportional basis (i.e., at the same percentage reduction from each user's entitlement) across all Lower Basin water users, including Mexico.

probability—The relative frequency with which a range of modeled values occurs.

propagule—Various forms of reproductive material (e.g., smallmouth bass larvae).

public involvement—Process of obtaining citizen input during each stage of development of planning documents. For EISs, NEPA requires Federal agencies, "…*request public comment on alternatives or impacts and on relevant information, studies, or analyses with respect to the proposed agency action."* (43 U.S.C. 4321 et seq).

Quaternary period—A geologic time period that encompasses the most recent 2.6 million years, including the present day.

ramp rate—The rate of change in instantaneous output from a powerplant. The ramp rate is established to prevent undesirable effects due to rapid changes in loading or, in the case of hydroelectric plants, discharge.

rated head—Water depth for which a hydroelectric generator and turbines were designed.

reach—A specified segment of a river, stream, channel, or other water conveyance.

rearing—The period in which juvenile fish grow and develop before migrating or recruiting into older life stages.

recruitment—Survival of young plants and animals from birth to a life stage less vulnerable to environmental change.

refuge ponds—Off-channel or low-flow ponded areas that provide shelter for fish during unfavorable conditions such as high temperatures or low flows.

remote sensing—The collection and interpretation of information about the earth's surface or atmosphere without direct physical contact.

repatriated—Refers to the intentional reintroduction of a species into an area of its historical range from which it has been locally extinct.

reregulating reservoir—A reservoir for reducing diurnal fluctuations resulting from the operation of an upstream reservoir for power production.

resampling—The digital process of changing the sample rate or dimensions of sampled data (for example, digital imagery or audio) by temporarily or areally analyzing and sampling the original data.

reserved water—In the case of Indian reservations, rights based on the doctrine of Indian reserved rights; in the case of federal establishments other than Indian reservations, a federal reservation of water for use on property under federal jurisdiction.

reservoir—A pond, lake, or basin, either natural or artificial, for the storage, regulation, and control of water.

resilience—The capacity of a species to absorb disturbance, maintain essential functions, and recover to a stable condition within a reasonable amount of time.

return flow—The portion of water previously diverted from a river or stream and subsequently returned to that river or stream and is available for consumptive use by others. *Refer to* consumptive use.

return flow credit—In the accounting of consumptive use in the Lower Basin, Colorado River water that is returned to the river and is available for consumptive use by others in the year in which it was diverted and is credited against a water user's total diversions. *Refer to* consumptive use.

riffle—A stretch of choppy water caused by an underlying rock shoal or sandbar.

riparian—Of, on, or pertaining to the bank of a river, pond, or lake.

river mile (RM)—A unit of measurement (in miles) used on rivers. For the purposes of this EIS, river miles are numbered along the Colorado River from south to north starting with RM 0.0 at the Southerly International Boundary (SIB) with Mexico. Dam locations are noted at their respective river miles.

river outlet works—Dam structures that conduct water from the reservoir to the river without passing through a powerplant; also referred to as jet tubes, bypass tubes, or outlet works. *Refer to* bypass tubes and outlet works.

river stage—Water surface elevation of a river above a datum. As described by the United States Geological Survey, river stage is an important concept when analyzing how much water is moving in a stream at any given moment. Stage is the water level above some arbitrary point, usually with the zero height being near the river bed, in the river and is commonly measured in feet.

riverine—Relating to or characteristic of a river or stream.

RiverWare™—A commercial river system simulation computer program that was configured to simulate operation of the Colorado River.

robustness—The degree to which a model or conclusion remains valid and reliable under different assumptions, datasets, or analytical conditions.

runoff—That part of the precipitation that appears in surface streams. It is the same as streamflow unaffected by artificial diversions, storage, or other works of humans in or on the stream channels.

sacred site—A specific location identified by a Native American tribe as sacred for its religious significance to, or ceremonial use by, a Native American religion.

salinity—Saltiness. The relative concentration of dissolved salts, usually sodium chloride, in a given water supply. A measure of the concentration of dissolved mineral substances in water.

sandbar—A long, narrow deposition of sediment within a river.

Secretary—The Secretary of the Department of the Interior.

sediment—Any finely divided organic and/or mineral matter deposited by air or water in nonturbulent areas. Unconsolidated solid material that comes from weathering of rock and is carried by, suspended in, or deposited by water or wind.

sediment load—Mass of sediment passing through a stream section in a specified period of time, expressed in millions of tons (mt). Amount of sediment carried by running water. The sediment that is being moved by a stream.

seepage—The slow movement or percolation of water through soil or rock. Movement of water through soil without formation of definite channels. The movement of water into and through the soil from unlined canals, ditches, and water storage facilities. The slow movement or percolation of water through small cracks, pores, interstices, etc., from an embankment, abutment, or foundation.

shortage condition—When the Secretary of the Interior has determined that there is available for annual release less than 7.5 maf to satisfy consumptive use in the Lower Division States pursuant to Article II(B)(3) of the Consolidated Decree. *Refer to* Lower Division States and Consolidated Decree.

sonic tagged—Describes a fish that has been implanted with or attached to an acoustic sounder that emits sound pulses and can be detected by receivers to track movement and habitat use.

spawn—To lay eggs, especially fish.

spills—Water releases from a dam in excess of powerplant capacity.

spillway—A structure that passes normal and/or flood flows in a manner that protects the structural integrity of the dam. Overflow channel of a dam or impoundment structure. A structure over or through which flow is discharged from a reservoir. If the rate of flow is controlled by mechanical means such as gates, it is considered a controlled spillway. If the geometry of the spillway is the only control, it is considered an uncontrolled spillway. Any passageway, channel, or structure designed to discharge surplus water from a reservoir.

spinning reserves—Available capacity of generating facilities synchronized to the interconnected electric system so that it can be called upon for immediate use in response to system problems or sudden load changes.

stage—Same as elevation or depth of water. The height of a water surface above an established datum.

standards—A means established by authority as a rule for the measure of quality, such as cosmetic effects (such as skin or tooth discoloration) or aesthetic effects (such as taste, odor, or color) in drinking water.

State-regulated sportfish—Fish species managed by a state natural resource or wildlife agency for recreational fishing.

stocked—Describes fish that have been intentionally introduced into a waterbody.

storage—Water artificially impounded in surface or underground reservoirs for future use. Water naturally detained in a drainage basin, such as groundwater, channel storage, and depression storage. The term "drainage basin storage" or simply "basin storage" is sometimes used to refer collectively to the amount of water in natural storage in a drainage basin. *See also* conservation storage and dead storage.

stormwater—Consists of water that originates from precipitation, such as heavy rain or snow.

stratification—Thermal layering of water in lakes and streams. Lakes usually have three zones of varying temperature: (1) epilimnion—top layer with essentially uniform warmer temperature, (2) metalimnion—middle layer of rapid temperature decrease with depth, and (3) hypolimnion—bottom layer with essentially uniform colder temperatures.

streamflow—The discharge that occurs in a natural channel. Although the term "discharge" can be applied to the flow of a canal, the word streamflow uniquely describes the discharge in a surface stream course. The term "streamflow" is more general than runoff, as streamflow may be applied to discharge whether it is affected by diversion or regulation.

suspended load—Sediment that is supported by the upward components of turbulence in a stream and that stays in suspension for an appreciable length of time.

surplus condition—When the Secretary of the Interior has determined that there is available for annual release more than 7.5 maf to satisfy consumptive use in the Lower Division States pursuant to Article II(B)(2) of the Consolidated Decree. *Refer to* Lower Basin/Lower Division States and Consolidated Decree.

system conservation—A voluntary reduction of consumptive use of Colorado River water that can be estimated or measured. *Refer to* consumptive use.

System Efficiency Intentionally Created Surplus (ICS)—An ICS is a mechanism to encourage and account for augmentation and conservation of water supplies that would minimize the likelihood and severity of potential future shortages. System Efficiency types of ICS are created when an entitlement holder makes a capital contribution to the Secretary of the Interior for use in funding projects designed to realize system efficiencies that save water that would otherwise be lost from the mainstream of the United States.

system storage—The total volume of water available in the Colorado River Basin at a specific point in time.

system water—Waters originating from the Colorado River system. *Refer to* Colorado River system.

tail water—Water immediately downstream of the outlet from a dam or hydroelectric powerplant where the water is more similar to that in the reservoir than farther downstream.

take—To harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or to attempt to engage in any such conduct as defined by the Endangered Species Act (ESA) of 1973 (16 U.S.C. 1532.Definitions).

talus—An accumulation of loose, angular rock fragments that collect at the base of cliffs or steep valley walls.

thermocline—The zone of maximum change in temperature in a waterbody, separating upper (epilimnetic) from lower (hypolimnetic) zones.

trammel-netting—A fish sampling technique that uses a three-layered gill net designed to capture fish of various sizes.

threatened species—A species or subspecies that is likely to become endangered in the foreseeable future throughout all or a significant portion of its range as defined by the Endangered Species Act (ESA) of 1973 (16 USC 1532.Definitions). *Refer to* endangered.

total dissolved solids (TDS)—Dissolved materials in the water, including ions such as potassium, sodium, chloride, carbonate, sulfate, calcium, and magnesium. In many instances, the term "TDS" is used to reflect salinity, since these ions are typically in the form of salts.

traces—Multiple time series of forecasted streamflow used in hydrological modeling. Multiple traces are sometimes referred to as an ensemble.

traditional cultural place—A type of historic property that is rooted in a community's history and important to that community's cultural identity.

tributary—River or stream flowing into a larger river or stream.

turbidity—Cloudiness of water, measured by how deeply light can penetrate into the water column from the surface.

turbine—A rotary mechanical device that uses water flow to turn and convert it into energy.

Upper Basin (States)—Those parts of the states of Arizona, Colorado, New Mexico, Utah, and Wyoming within and from which waters drain naturally into the Colorado River above the Lee Ferry Compact Point in Arizona. The Colorado River Compact of 1922 divided the Colorado River system into two subbasins: the Upper Basin and the Lower Basin. *Refer to* Lee Ferry Compact Point.

Upper Colorado River Commission—Commission established by the Upper Colorado River Compact of appointed members from the Upper Division States whose purpose is to secure the storage of water for beneficial consumptive use in the Upper Basin.

Upper Division (States)—Colorado, New Mexico, Utah, and Wyoming. The Colorado River Compact of 1922 divided the seven Colorado River Basin states into two groups: Upper Division States and Lower Division States. The Upper Division States are Colorado, New Mexico, Utah, and Wyoming. *Refer to* Basin States and Lower Division (States).

varial zone—The zone along the margins of a river or lake that alternates between submerged and exposed due to changes in water level.

visual resources—Physical features that make up the visible landscape (features such as land, water, vegetation, topography, and human-made features such as buildings, roads, utilities, and structures) as well as the response of viewers to those features.

Water Year (WY)—Period of 12 months ending September 30 of each year.

watershed—The drainage area upstream of a specified point on a stream.

young-of-year—Fish that were born or hatched during the current year.
