July 31, 2026

To: Readers of this Final EIS

Publication of this Final EIS comes at a crucial time in the modern history of the Colorado River Basin (Basin).

The need for sound water management strategies is of the utmost importance. The Colorado River Basin provides drinking water and power for over 40 million people, irrigation water for over 5 million acres of agricultural land and supports vital ecosystems across the seven Colorado River Basin states covering broad areas in the southwestern United States. In addition, on the other side of our southern border, two northern Mexico states rely on the Colorado River for essential municipal and agricultural water supplies. Several of the major reservoir- and water-management documents and agreements developed to guide Colorado River operations expire in 2026. The Secretary of the Interior, acting through the Bureau of Reclamation, proposes adoption of new guidelines and coordinated management strategies to address Lake Powell and Lake Mead through their full operating ranges to take effect when the current agreements expire in 2026. For the past 26 years, the Basin has been experiencing an unprecedented multi-decadal drought, resulting in historically low runoff and reservoir levels. During 2026, hydrologic conditions in the Basin have worsened; since publication of the Draft Environmental Impact Statement in January, it has become clear that the Basin will likely experience the lowest observed snowpack on record.

For decades, the Basin has relied on a reservoir system that has been able to buffer the impact of severe droughts by capturing and storing water during high flow periods. However, the extremely low hydrologic conditions over the past two and a half decades coupled with meeting water demands (albeit somewhat reduced by conservation and other activities) have resulted in very low conditions at the two largest reservoirs in the Basin, Lake Mead and Lake Powell. The combined contents of Lake Mead (behind Hoover Dam) and Lake Powell have not been this low since before Lake Powell began filling after the closure of the gates at Glen Canyon Dam in 1963.

Furthermore, current low Basin reservoir conditions, particularly at Lake Powell, have highlighted risks that could compromise the reliability and operational flexibility of Glen Canyon Dam that would affect the future ability to meet critical downstream water supply needs.

Since 2021, Colorado River operations have included a series of extraordinary operations designed to protect the infrastructure at Glen Canyon Dam and support continued reliable operations. Additional water from upstream reservoirs has been released to Lake Powell, and releases from Lake Powell to the Lower Basin have been reduced. This has been a coordinated and successful effort to date to keep Lake Powell above the critical elevation of 3,490 feet.

In the spring of this year, the Department of the Interior (Department) implemented unprecedented measures, including a decision to release 660,000 to 1 million acre-feet of additional flows from Flaming Gorge reservoir and reducing releases from Lake Powell to the Lower Basin down to 6 million acre-feet (a 1.5-million-acre-foot reduction). Despite all of these measures, due to the continued prolonged drought and water demands, the risk to the system has never been greater.

After a 2020 review of the preceding two decades of operations of Glen Canyon Dam and Hoover Dam, the Department began engaging the public to develop new operating guidelines that recognize the need to reduce water use in the Basin while protecting water delivery systems. Critical to this process, the Department and Bureau of Reclamation engaged extensively with the Basin States, Basin Tribes, and other

interested parties in pursuit of developing consensus-based long-term operational guidelines. Unfortunately, as of the publication of this Final Environmental Impact Statement, consensus on long-term operations has not been reached.

The Department published a Draft EIS in January 2026 because new operations must begin October 1, 2026. Due to the lack of consensus, the Draft EIS did not include a preferred alternative, preserving the opportunity for entities in the Colorado River to keep negotiating and reach consensus. In July, after another six months of negotiations since publication of the Draft EIS, no long-term consensus-based operation has been reached, and the Department must complete the NEPA process in order to have Colorado River operations in place for October 1, 2026.

The absence of a Basin consensus on water management strategies coupled with the ever-increasing hydrologic risk highlights the importance of the Secretary of the Interior's (Secretary) operational responsibilities under federal law to coordinate operations of Colorado River facilities and allow these facilities to meet their congressionally authorized purposes over the long term.

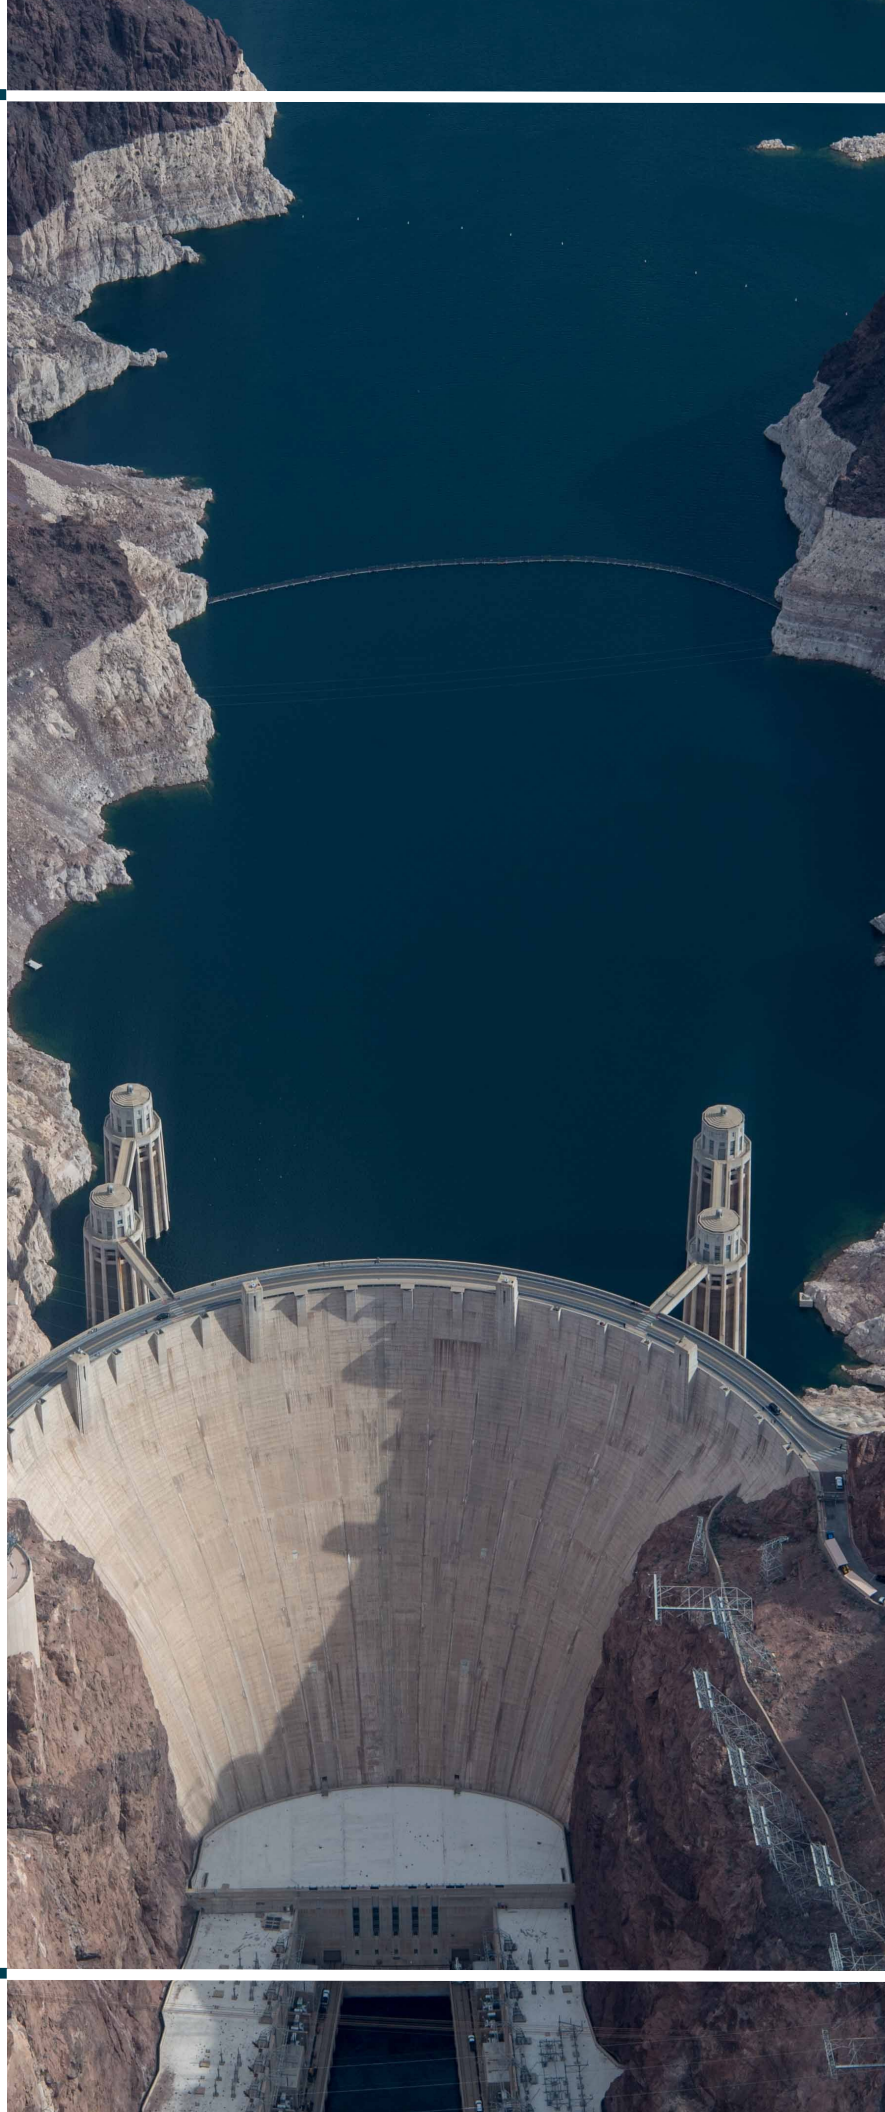
The Secretary has the statutory responsibility to make decisions about Colorado River operations that are based on actual hydrologic conditions, that consider conditions across the Basin as a whole, and that use flexible and responsive water management tools to protect operations at mainstem facilities, avoid operational risks to infrastructure at Glen Canyon Dam, and manage risks to the urban, agricultural, and natural systems that rely on the Colorado River. These responsibilities are particularly profound with reservoirs at historic low levels and declining river runoff anticipated to continue or worsen.

It is against this backdrop of hydrologic risk and lack of consensus that the Secretary has prepared the Preferred Alternative contained in this Final EIS for operations of Glen Canyon and Hoover Dams. The Preferred Alternative establishes an adaptive decision framework that will be used to develop operating guidelines that are designed to ensure reliable operations while being able to respond to changing conditions over a 10-year period.

The Preferred Alternative establishes a wide range of operations that provides the flexibility to develop specific operating guidelines within the 10-year period while preserving the opportunity for Basin negotiations to continue and, if successful, be incorporated in future operations.

The need for a flexible adaptive framework is clear given the history of the Basin since 2000. As reservoir elevations continued to fall and risk continued to increase, a series of interdependent agreements involving local, State, tribal and federal governments, water users and non-governmental organizations in both the United States and Mexico have enabled the system to operate by negotiated agreement rather than court determinations. Agreements have often included voluntary conservation programs and activities, demonstrating the capacity of the Basin to take necessary and innovative action to benefit reservoir storage. Today, Lake Mead is approximately 150 feet higher because of these agreements, and more conservation is planned in the coming years.

Maintaining the ability to negotiate and implement a consensus-based alternative remains a priority because a consensus-based solution is the most reliable way to ensure that operations balance the differing needs of water users across the entire Basin. This is particularly true as poor hydrology and reduced reservoir storage exacerbate longstanding disputes among Colorado River water users.



However, given the lack of consensus to date, decisions still need to be made for operations in the coming water year beginning October 1, 2026. The Preferred Alternative provides for flexible operations while creating opportunities for Basin entities to work together to achieve lasting Basin-wide solutions centered around cooperation, innovation, and partnerships.

Executive Summary

ES.1 Background

The Colorado River Basin (Basin) provides essential water supplies to approximately 40 million people, nearly 5.5 million acres of agricultural lands, and habitat for ecological resources across seven states which includes broad areas in the Southwestern United States (U.S.) and Northwestern United Mexican States (Mexico) (**Map ES-1**). Prudent management of the Basin is critically important because the Colorado River is the foundation for diverse resources across a large geographic region and faces exceptional challenges from prolonged drought and future uncertainty. States, tribes, and Mexico rely on the Colorado River to support essential municipal, agricultural, environmental, cultural, and hydropower needs. These resources are now at significant risk: since the onset of the current drought in 2000, the Basin's primary reservoirs, Lake Powell and Lake Mead, have fallen to historically low elevations. Several of the major reservoir- and water-management documents and agreements developed to guide Colorado River operations through the persistently dry conditions expire in 2026, including the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and Coordinated Operations for Lake Powell and Lake Mead (2007 Interim Guidelines; Reclamation 2007), the 2019 Colorado River Drought Contingency Plans (Reclamation 2019), and key international agreements between the U.S. and Mexico. Despite the significance of these agreements, actions taken over the past two decades have not been sufficiently robust to prevent continued decline of the reservoirs through the prolonged drought.

The Secretary of the Interior (Secretary), acting through the Bureau of Reclamation (Reclamation), proposes adoption of new guidelines and coordinated management strategies to address Lake Powell and Lake Mead through their full operating ranges to take effect when the current agreements expire in 2026. Management strategies will primarily focus on the operation of Glen Canyon Dam and Hoover Dam but may include actions upstream and downstream of these facilities to protect critical reservoir elevations, such as releases from the Colorado River Storage Project (CRSP) Upper Initial Units to increase the elevation at Lake Powell, and approaches to enhance opportunities for Lower Colorado River Basin (Lower Basin) water users to reduce water use (see **Map ES-1**).

This Final Environmental Impact Statement (EIS) has been prepared to inform the Secretary's timely adoption of a new set of objective guidelines that improve predictability to all water users and managers in the Basin. Developing new guidelines is difficult in this complex Basin, where critically low storage in Lake Powell and Lake Mead, significant hydrologic variability, and the anticipation of drier future conditions amplify the central tradeoff: balancing the potentially profound impacts of water-delivery reductions with the need to maintain reservoir storage. The alternatives in this Final EIS capture a broad range of management strategies to address this tradeoff, and they demonstrate that there are multiple ways to find a balance if conditions improve. If conditions do not improve, achieving a balance is more difficult, and, under critically dry futures, even large and unprecedented reductions may be needed and may not be enough to stabilize storage.

States in the Colorado River Basin (Wyoming, Colorado, Utah, and New Mexico are Upper Division states, and Arizona, California, and Nevada are Lower Division states)

Consistent with the Department of the Interior's (Department) longstanding preference for consensus-based management of the Colorado River System, the Department and Reclamation engaged extensively with the Basin States,[1] Basin Tribes,[2] and other interested parties during development of successor operating guidelines over the course of 4 years. However, despite those efforts, the Basin States did not reach consensus on long-term guidelines prior to the completion of this EIS. Accordingly, rather than adopting long-term operating guidelines of the same duration as the 2007 Interim Guidelines, the Secretary proposes in the Preferred Alternative to adopt an operational strategy consisting of an adaptive decision framework to develop operating guidelines for Lake Powell and Lake Mead for operating years 2027 through 2036. This framework provides for more robust operational provisions than the current guidelines while preserving the flexibility to respond to changing hydrologic conditions and to incorporate future consensus recommendations, should they be reached.

Reclamation, as the agency designated to act on the Secretary's behalf with respect to operation of Glen Canyon Dam and Hoover Dam and managing the mainstream waters of the lower Colorado River in accordance with federal law, is the lead federal agency for the purposes of compliance pursuant to the National Environmental Policy Act of 1969 (NEPA), as amended, for the development and implementation of the proposed interim guidelines. Five federal agencies are cooperating for purposes of assisting with environmental analysis and preparation of this EIS. The cooperating agencies are the Bureau of Indian Affairs, National Park Service, U.S. Fish and Wildlife Service, U.S. Section of the International Boundary and Water Commission (IBWC), and Western Area Power Administration. The Final EIS is organized into four volumes:

Volume I – EIS with the following chapters:

Chapter 1: Purpose and Need. Provides the background of Colorado River operations and describes why federal action is needed.

Chapter 2: Description of Alternatives. Describes the process of formulating alternatives, describes the Preferred Alternative, and presents a range of reservoir operation strategies and guidelines considered under each alternative. A summary of the performance tradeoffs between alternatives is provided at the end of Chapter 2.

Chapter 3: Affected Environment and Environmental Consequences. Describes the existing environmental conditions and evaluates potential impacts that could result from implementation of the alternatives.

Chapter 4: Consultation and Coordination. Describes public and stakeholder involvement process during the preparation of this Final EIS.

[1] Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming

[2] There are 30 federally recognized Native American tribes in the Basin: Ak-Chin Indian Community, Chemehuevi Indian Tribe, Cocopah Indian Tribe, Colorado River Indian Tribes, Fort McDowell Yavapai Nation, Fort Mojave Indian Tribe, Fort Yuma-Quechan Tribe, Gila River Indian Community, Havasupai Tribe, Hopi Tribe, Hualapai Tribe, Jicarilla Apache Nation, Kaibab Band of Paiute Indians, Las Vegas Paiute Tribe, Moapa Band of Paiute Indians, Navajo Nation, Pascua Yaqui Tribe, Pueblo of Zuni, Salt River Pima-Maricopa Indian Community, San Carlos Apache Tribe, San Juan Southern Paiute, Shivwits Band of Paiutes, Southern Ute Indian Tribe, Tohono O'odham Nation, Tonto Apache Tribe, Ute Indian Tribe of the Uintah and Ouray Reservation, Ute Mountain Ute Tribe, White Mountain Apache Tribe, Yavapai-Apache Nation, and Yavapai-Prescott Indian Tribe.

Volume II – Supporting appendices, primarily focused on modelling information, including modeling assumptions, analytical methods, and supporting calculations.

Volume III – Technical appendices for each of the environmental resources discussed in Chapter 3. These appendices provide supporting and more detailed information.

Volume IV – List of persons contributing to the preparation of this Final EIS, list of references cited in this Final EIS, glossary of commonly used terms, and index.

ES.1.1 Purpose and Need for Action

The proposed federal action is needed for the following reasons:

- *The Secretary is legally required to coordinate operations of Colorado River reservoirs:* The Colorado River Basin Project Act of 1968 directs the Secretary to adopt criteria for the coordinated long-range operation of Colorado River reservoirs. In compliance with this obligation, the Criteria for Coordinated Long-Range Operation of Colorado River Reservoirs Pursuant to the Colorado River Basin Project Act of September 30, 1968 (Long-Range Operating Criteria [LROC]; Colorado River Basin Project Act of 1968 [CRBPA]; Reclamation 1970) were developed and adopted by the Secretary in 1970. The LROC provides general narrative guidance regarding Lake Powell and Lake Mead operations but does not contain specific, objective criteria to guide annual operations. To address this inadequacy, the 2007 Interim Guidelines were developed to provide objective criteria used by the Department to implement the LROC. The 2007 Interim Guidelines have provided the predictability needed by the entities that receive Colorado River water to better plan for and manage available water supplies from the Colorado River and other sources.
- The *2007 Interim Guidelines are expiring:* Current operational guidelines expire during the 2026 operating year. The Department has determined that specific, objective operational guidelines are important to provide improved predictability and should be established for another interim period beyond 2026. Most of the federal and non-federal agreements associated with implementing provisions of the 2007 Interim Guidelines also expire after the 2026 operating year.
- *The 2007 Interim Guidelines have not sufficiently reduced risk:* Based on operational experience since 2007, the current guidelines are not robust enough to manage the system in a way that is sufficiently protective of the resources dependent on the Colorado River. Despite near-continuous drought-response actions in recent years, low reservoir conditions have persisted, and new infrastructure risks at Glen Canyon Dam have arisen. More robust and adaptive guidelines are needed for the efficient and sustainable management of the major mainstream Colorado River reservoirs and system resources.
- *Imbalance between water supply and demand will be exacerbated by increasingly likely low-runoff conditions:* The Basin is experiencing increased aridity due to climate variability, and long-term drought and low-runoff conditions are expected in the future. These conditions will exacerbate the now widely recognized imbalance between water supply and demand in the Basin. Robust and flexible guidelines are needed to manage the Colorado River system and its resources under a broad range of potential future hydrologic conditions.
- *Expanded and innovative use of conservation is needed:* Recognizing the anticipated future low-runoff conditions in the Basin, the Department has also determined a need for guidelines that provide

Colorado River water users, including Basin Tribes, expanded opportunities to conserve, store,exchange, and take subsequent delivery of water in and from Lake Mead and/or Lake Powell. The guidelines should also support and integrate future efficiency improvements and opportunities for augmentation.

- *Addressing tribal concerns regarding Basin management is needed:* Basin Tribes have expressed concern that the current approach to Colorado River water management is insufficient to address the range of interests, needs, and fundamental rights of the Basin Tribes. The Department has determined a need for guidelines that provide flexibility and predictability for Basin Tribes to remain able to benefit from their water rights and have opportunities to participate in voluntary conservation programs.

The purpose of the proposed federal action is to:

- Update and expand management guidelines for Colorado River reservoirs, particularly for the coordinated operation of Lake Powell and Lake Mead
- Provide Colorado River water users a greater degree of predictability with respect to annual water availability in future years under anticipated increasing variability, low runoff, and low reservoir conditions
- Provide additional mechanisms for the conservation, exchange, storage, and delivery of water supplies in Colorado River reservoirs to increase the flexibility to meet water use needs
- Provide new or enhanced opportunities for Basin Tribes to benefit from their water rights
- Provide flexibility to build resilience and accommodate future needs and growth that are supported by Colorado River water supplies, including the integration of unquantified tribal water rights once they are resolved

ES.1.2 Proposed Federal Action

Reclamation, acting on behalf of the Secretary, proposes to adopt guidelines and coordinated reservoir management strategies to address operations of Lake Powell and Lake Mead through their full operating ranges. This action would improve predictability to all water users and managers in the Basin by developing and adopting objective guidelines for the operation of Glen Canyon Dam and Hoover Dam to take effect when the current operating guidelines expire in 2026. This action is designed to provide for the sustainable management of the Colorado River system and its resources under a wide range of potential future system conditions.

The proposed federal action considers the following operational elements that are collectively designed to address the purpose and need for the proposed federal action:

1) Identification of circumstances under which the Secretary would allocate the annual amount of water available for consumptive use from Lake Mead to the Lower Division states (Arizona, California, and Nevada) at, below, or above 7.5 million acre-feet (maf), pursuant to the Supreme Court Decree in *Arizona* v. *California,* 376 U.S. 340 (1964) (Final Decree entered in 2006).
2) Coordinated operations of Lake Powell and Lake Mead, particularly under low reservoir conditions.
3) Storage and delivery of conserved water in Lake Mead and/or Lake Powell to increase the flexibility to meet water use needs from both reservoirs, including the storage and delivery of

non-system water; exchanges; and water conserved through extraordinary measures by or for tribal, agricultural, or municipal entities.

The proposed federal action allows for development of robust operating guidelines for Lake Powell and Lake Mead without precluding upstream or downstream actions needed to protect critical reservoir elevations at Lake Powell and Lake Mead, such as the following:

- Approaches that consider total system storage in all major Colorado River reservoirs and/or actual inflows to determine coordinated operations of Lake Powell and Lake Mead.
- Approaches that include opportunities for conservation, augmentation, demand management, or other water management strategies (such as exchanges or transfers).
- Modified operations at upstream CRSP Upper Initial Units[3] to release additional water if needed to protect critical infrastructure at Glen Canyon Dam.

The Secretary intends that the guidelines be interim in nature and extend for the same duration as the 2007 Interim Guidelines (approximately 20 years). Adoption of new guidelines for an interim (or limited) period provides the opportunity to gain additional experience for operating the reservoirs, thereby informing future operational and water management decisions.

Recognizing additional authorities may be developed, the Department intends to adopt and implement the guidelines in a manner consistent with the Law of the River. The Department also intends that the guidelines be used to implement the LROC and applicable federal law through the issuance of the Annual Operating Plan for Colorado River Reservoirs.

ES.1.3 Geographic Scope

Consistent with the geographic scope analyzed in the 2007 Interim Guidelines Final EIS, the geographic scope that would be affected by the proposed federal action begins at full pool of Lake Powell at Gypsum Canyon and extends downstream along the mainstream Colorado River floodplain to the Southerly International Boundary (SIB) with Mexico. This proposed federal action would also potentially affect interests of water users in the Lower Division States in service areas that extend beyond the mainstream of the Colorado River.

Although the proposed federal action is focused on Lake Powell and Lake Mead operations, management strategies that include activities upstream of Lake Powell are being analyzed in this Final EIS. These activities include Upper Colorado River Basin (Upper Basin) conservation and, if warranted to protect critical reservoir elevations, coordinated operations of the CRSP Upper Initial Units to release additional water within their respective Records of Decision (RODs) to increase the elevation at Lake Powell. Operations at the CRSP Upper Initial Units specifically contemplated in this Final EIS are intended to remain within the scope of the existing RODs.[4] Since those RODs are covered by their own NEPA, this Final EIS does not need to expand the geographic scope of analysis

[3] CRSP Upper Initial Units include Flaming Gorge, Blue Mesa (a component of the Aspinall Unit), and Navajo reservoirs. Current RODs governing operations of these units were signed in 2006, 2012, and 2006, respectively.

[4] While the Secretary will consider and prioritize operations at these facilities that are consistent with existing RODs, the Secretary retains the authority to operate outside those RODs if necessary. The modeling assumptions regarding operation of the CRSP Upper Initial Units presented in this Final EIS are not intended to, and do not, limit the Secretary's ability to operate these facilities as necessary to respond to hydrologic conditions in accordance with applicable federal law, including operations for the authorized purposes as stated in the 1956 Colorado River Storage Project Act.

upstream of Lake Powell. With respect to Upper Basin conservation, the nexus to the proposed federal action is the storage and delivery of that conserved water in Lake Powell. The effects of this storage in and delivery from Lake Powell are within the scope of the EIS, while specific activities that may be undertaken in the Upper Basin to generate the conserved water are not within the scope of this EIS. Any such activities are unknown at this time and will not necessarily require federal decision making. Any federal decisions associated with these conservation activities will be assessed outside of this EIS.

ES.2 Alternatives

ES.2.1 Alternative Development

The process of developing the range of alternatives was informed by solicitation of input and extensive collaborative engagement with stakeholders throughout the Basin. This took place over a two-and-a-half-year period beginning with publication of the Scoping Report in October 2023 through publication of this Final EIS.

During the public involvement periods and the rest of the alternatives development process, Reclamation received considerable input from the Basin States, many Basin Tribes, conservation organizations, other federal agencies, other stakeholders, and members of the public. Input submitted ranged from detailed proposed alternatives to operational concepts and principles. Throughout the alternatives development phase, Reclamation met continuously with states, tribes, and other partners to review and discuss their input. For those proposals containing sufficient detail to be considered as a full alternative or a major component of an alternative, Reclamation worked extensively with these entities to not only understand and gather additional information, but also to model and perform preliminary analyses of their proposals to facilitate refinements. Additionally, Reclamation developed an online platform, the Post-2026 Operations Exploration Web Tool, allowing stakeholders, interested parties, and the public to independently or collaboratively design operational strategies to inform their input to the NEPA process.

On January 9, 2026, the Environmental Protection Agency published a notice in the *Federal Register* (91 *Federal Register* 2131) announcing the availability of the Draft EIS and beginning a public comment period that ran through March 2, 2026. Since Draft EIS publication, the Department has also continued to work with the Basin States and Basin Tribes to facilitate development of a consensus agreement. Despite this extensive engagement, a long-term consensus-based approach to Basin reservoir operations has not yet been achieved.

This Final EIS analyzes a No Action alternative and five action alternatives that incorporate over 4 years of input provided by stakeholders and the public and received through consultations with the Basin States and Basin Tribes. These alternatives capture a broad range of operational concepts and potential environmental impacts:

- Preferred Alternative (added since publication of the Draft EIS)
- No Action Alternative
- Basic Coordination Alternative
- Enhanced Coordination Alternative

- Maximum Operational Flexibility Alternative
- Supply Driven Alternative

ES.2.2 The Preferred Alternative

In the absence of a long-term consensus-based approach, Reclamation has developed a Preferred Alternative and analyzed it in this Final EIS. The Preferred Alternative is a 10-year decision framework. The decision framework establishes operational principles, sideboards (key thresholds and ranges for operational elements), and a process that would govern development and issuance of operating guidelines covering anticipated 2-year intervals, unless consensus-based agreements provide for a longer duration. The framework does not establish specific operating guidelines; rather, it provides the structure within which operating guidelines would be developed, reviewed, and periodically updated through 2036.

The decision framework in the Preferred Alternative offers a vehicle for continued work toward sustainable management in the Basin. It provides continuity following the expiration of the 2007 Interim Guidelines; establishes transparency and predictability for future decision making; preserves flexibility to respond to changing hydrology and evolving Basin circumstances; facilitates incorporation of future Basin consensus recommendations; and is consistent with applicable federal law. The framework (principles, sideboards, and process) would remain constant through 2036, unless modified through future federal action and appropriate environmental compliance.

ES.2.2.1 Operating Guidelines

Operating guidelines are the objective criteria that determine the operations of Lake Powell and Lake Mead for the anticipated 2-year interval. For each interval, the framework process would be carried out to develop and issue operating guidelines in accordance with the principles and sideboards described below. The operating guidelines would be adopted through the issuance of a decision document published in the *Federal Register*. Once issued, the operating guidelines would be implemented through Annual Operating Plans.

ES.2.2.2 Operational Principles

The operational principles are designed to ensure that operating guidelines adopted under the framework adhere to fundamental management priorities and provide a basis for review and reflection as new operating guidelines are developed.

The operational principles are listed below:

1. *Operations should be responsive to hydrology.* Annual operations and mid-year adjustments that account for evolving supply conditions should be adopted to ensure a flexible, adaptive approach to management.
2. *Critical federal infrastructure must be protected through practical and deliberate operations.* When Lake Powell is projected to fall below elevation 3,500 feet or when Lake Mead is projected to fall below elevation of 1,000 feet, processes and tools will be used to manage risks to infrastructure and prevent damage to federal facilities of regional and national importance. These elevations reflect current understanding of these facilities but do not preclude the identification of alternate or additional critical elevations.

3. *Operating guidelines should implement the LROC while also providing directions to address extraordinary circumstances.* Operating guidelines will provide objective criteria for operating under low reservoir conditions within the bounds of the LROC but may also provide for temporary operational actions that are not otherwise provided for under the LROC when necessary to protect critical federal infrastructure in accordance with applicable federal law.
4. *Operating guidelines should prioritize consensus-based recommendations.* The Department will support efforts to achieve consensus agreements that appropriately provide benefits to multiple parties, that offer innovative, inclusive solutions to operational and management challenges, and that are sufficiently protective of the system. Should such agreements arise, they will be prioritized as new operating guidelines are developed and adopted. In the absence of consensus-based arrangements, the Secretary will take the necessary management actions, consistent with applicable federal law.

ES.2.2.3 Operational Sideboards

The decision framework's operational sideboards are key thresholds and ranges for the four operational elements (described below) that create boundaries for the development of each set of operating guidelines and provide a basis for environmental compliance for the duration of the decision framework. The sideboards defined in **Table ES-1** were chosen to appropriately balance tradeoffs among resources and ensure that the Department would have the flexibility and environmental compliance to operate in accordance with the operational principles given future hydrologic uncertainty.

Table ES-1
Operational Sideboards for the Preferred Alternative

Operational Element	Operational Ranges
Lower Basin Shortage Guidelines	Up to 3.0 maf to provide protection of critical infrastructure at Hoover Dam in dry hydrologic conditions The allocation of shortages would be based on applicable law, including the Consolidated Decree. Deviation from applicable law would occur only if water entitlement holders have reached voluntary arrangements Consultation would occur if projected Lake Mead elevation < 1,000 ft to determine potential additional reductions to Lower Basin water deliveries
Coordinated Reservoir Operations	5.0 maf to 12.0 maf Lake Powell WY releases to provide protection for critical infrastructure at Glen Canyon Dam and sufficiently high releases necessary to prevent spill avoidance releases Consultation would occur if projected Lake Powell elevation < 3,500 ft to determine potential additional actions
Storage and Delivery of Conserved System and Non-system Water	Lake Powell: up to 3.0 maf Lake Mead: up to 8.0 maf (supports existing ICS, new ICS-type program, conservation pools, and exchange mechanisms)
Lower Basin Surplus Guidelines	Up to 500 kaf in addition to Flood Control and Quantified Surplus

Operational Element	Operational Ranges
Additional Activities Above Lake Powell	Potential for maximum use of CRSP Upper Initial Units within their respective RODs to release additional water if needed to protect critical infrastructure
	Voluntary Upper Basin contributions up to 200 kaf per year subject to hydrologic conditions

In contrast to the specified operations under the other alternatives analyzed in this Final EIS, the Preferred Alternative is designed to create the opportunity for subsequent decision making; because of this distinction, it is appropriate to include a modeling representation of operating guidelines that may be developed under the Preferred Alternative. The sideboards provide a basis for understanding the range of potential impacts, and analyzing these potential impacts provides a necessary and instructive comparison to the other alternatives included in this Final EIS. Taken together, the representation of the operational elements described below is referred to and analyzed in this Final EIS as the "Representative Preferred Alternative." The Representative Preferred Alternative is a set of modeling assumptions designed around the Preferred Alternative sideboards to approximate the range of operating guidelines that may be adopted for each interval during the 10-year framework. The specifications in the operational elements reflect how the Representative Preferred Alternative was modeled; exact operations would be subject to the guidelines in place during each interval and would adhere to consultation triggers.

ES.2.2.4 Process

Each set of operating guidelines would be implemented and evaluated through a process during which Reclamation would work with stakeholders to seek consensus, align with operational principles and sideboards, and account for system conditions, hydrology, and other Basin developments.

ES.2.3 Summary of Alternatives

Each alternative is comprised of four operational elements: (1) Guidelines to Reduce or Increase Deliveries from Lake Mead, (2) Coordinated Reservoir Operations (Lake Powell and Lake Mead), (3) Storage and Delivery of Conserved System and Non-System Water, and (4) Additional Activities Above Lake Powell. Each element is varied across the alternatives providing a reasonably broad range of Colorado River operations that capture an appropriate range of potential environmental impacts. **Table ES-2** summarizes the representation of these elements in the No Action Alternative and the five action alternatives considered and evaluated in this Final EIS.

Table ES-2
Summary Comparison of Alternatives

Preferred Alternative (Including Representation of Operational Elements)

The Preferred Alternative is a multi-year decision framework that establishes the process and criteria that would govern development and adoption of operating guidelines through 2036. The decision framework is anticipated to be implemented in two-year operating intervals, unless consensus-based agreements provide for a longer duration. Unlike other alternatives, the operating guidelines for each interval are not specified in this Final EIS, and each set of guidelines would be developed based on operational principles and fit within the framework's defined operational sideboards (thresholds and ranges for operational elements). The sideboards provide a basis for assumptions included in the Representative Preferred Alternative summarized in this table, which captures the range of operating guidelines that may be adopted during each interval. Lake Powell releases range from 5.0 maf to 12.0 maf depending primarily on Lake Powell elevation. Lower Basin shortages up to 3.6 maf (including assumptions about reductions to Mexico) are distributed using a combination of LB Priority (up to 1.5 maf, 2027-2028) and priority.

Shortage Guidelines to Reduce Deliveries from Lake Mead[3, 4]	Coordinated Reservoir Operations (Lake Powell and Lake Mead)	Storage and Delivery of Conserved System and Non-system Water[3]	Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]	Additional Activities Above Lake Powell
• Shortages up to 3.6 maf (including assumptions about reductions to Mexico) • In 2027-2028, shortages up to 1.5 maf are distributed based on the distribution developed by the Lower Division States and shortages exceeding 1.5 maf are distributed based on priority (Approach 1 of the Supply Driven Alternative) • After 2028, shortages are distributed based on priority, unless agreements are reached • Consultation to determine additional reductions if projected Lake Mead elevation is less than 1,000 feet	• Lake Powell releases determined based on Lake Powell elevation unless equalization releases are required • Releases range from 5.0 to 12.0 maf, unless more is required for equalization releases • Consultation to determine additional actions if projected Lake Powell elevation is less than 3,500 feet	• Storage up to 7.0 maf in Lake Mead with additional 1.0 maf Federally Managed Water Resources Pool; included for purposes of determining Lower Basin surplus and Shortage Conditions, as well as equalization releases from Lake Powell • Storage up to 3.0 maf at Lake Powell; included for purposes of determining Lake Powell releases • Existing ICS converted to new mechanism immediately • Expanded flexibilities: interstate exchanges within each basin, new tribal mechanism	• Surplus determinations based on Lake Mead elevation at or above 1,165 feet, 70R (spill avoidance strategy) or Flood Control conditions	• Potential maximum use of CRSP Upper Initial Units within their respective RODs to release additional water if needed to protect critical infrastructure at Glen Canyon Dam contingent on hydrologic conditions • Trigger additional releases when projected Lake Powell elevation is less than 3,525 feet • Voluntary Upper Basin contributions up to 200.0 kaf per year subject to hydrologic conditions

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

[4] As noted in **Section 2.4**, the anticipated guidelines for the first operating interval as of publication of this Final EIS are preliminary. Modeling assumptions for 2027-2028 regarding shortage distribution reflect the May 1, 2026, Lower Division States proposal. As described in **Table 2-1**, Operational Sideboards, absent voluntary arrangements, the distribution of shortages would be based on applicable law (i.e., the priority system). This distribution is modeled in the Representative Preferred Alternative for years 2029 and beyond. Both distribution methods are documented and analyzed in **Appendix C**, Shortage Allocation Model, and **Chapter 3**. Regarding maximum shortage volume, modeling assumptions provide for reductions above the 1.25 maf maximum if needed to avoid critically low elevations at Lake Mead.

No Action Alternative

The No Action Alternative is included as a requirement of NEPA. Operations would revert to annual determinations announced through the Annual Operating Plan. Pursuant to the LROC, the objective is to maintain a minimum release of water from Lake Powell of 8.23 maf, therefore Lake Powell releases are assumed to be 8.23 maf[1] unless a higher release is required for equalization or a lower release occurs due to Glen Canyon Dam infrastructure limitations.[2] Shortages to the Lower Basin would be based on priority and reach a maximum of 600.0 thousand acre-feet (kaf). This would not represent a continuation of current operations but is generally based on the operating guidance that was in place before the adoption of the 2007 Interim Guidelines. While the authority to use CRSP Upper Initial Units to respond to exigent and emergency conditions was recognized at that time, no specific framework for such activities had been developed, so no defined activities are included in this alternative. Existing Intentionally Created Surplus (ICS) would be delivered in accordance with existing agreements, but there would be no new storage and delivery mechanisms.

Shortage Guidelines to Reduce Deliveries from Lake Mead[3]	**Coordinated Reservoir Operations (Lake Powell and Lake Mead)**	**Storage and Delivery of Conserved System and Non-system Water[3]**	**Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]**	**Additional Activities Above Lake Powell**
• Shortages determined based on Lake Mead elevation • Shortage volume of 400.0, 500.0, and 600.0 kaf at elevations 1,075, 1,050, and 1,025 feet, respectively • Shortages distributed based on priority	• Lake Powell release of 8.23 maf unless more is required for equalization releases • Releases less than 8.23 maf below elevation 3,490 feet due to Glen Canyon Dam infrastructure limitations	• No new storage and delivery mechanism to replace ICS • Delivery of existing ICS in accordance with existing agreements	• Surplus determinations limited to 70R (spill avoidance strategy) and Flood Control conditions	• No specific additional activities above Lake Powell defined

[1] Article II(2) of the LROC states the "objective shall be to maintain a minimum release of water from Lake Powell of 8.23 [maf]." Reclamation recognizes that entities in the Basin have different legal positions regarding how this LROC statement incorporates other Law of the River elements to determine annual releases. Reclamation also recognizes that variation in releases of water above and below the minimum objective release of 8.23 maf can, in appropriate circumstances, be adopted.

[2] Releases from Glen Canyon Dam may be unable to achieve the specified annual release volume when Lake Powell is below elevation 3,490 feet due to infrastructure constraints. Modeling assumptions for all alternatives reflect this constraint (see **Appendix A**).

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

<table>
<tr><td>Basic Coordination Alternative</td><td colspan="5">This alternative is designed to be implementable absent new agreements among Basin water users. Lake Powell releases would primarily be 8.23 maf, with some releases above and below 8.23 maf, and minimum releases of 7.0 maf. Lake Powell elevations could be increased by releases from CRSP Upper Initial Units within their respective RODs to protect infrastructure at Glen Canyon Dam. Reclamation would identify triggers for when additional Upper Basin actions are needed to protect critical infrastructure. Lower Basin shortages up to 1.48 maf would be triggered based on Lake Mead elevation and distributed consistent with priority system. Existing ICS would be delivered in accordance with existing agreements, but there would be no new delivery and storage mechanisms.</td></tr>

</table>

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Enhanced Coordination Alternative

This alternative is based on concepts from Basin Tribes, federal agencies, and other stakeholders to achieve protection of critical infrastructure while benefitting key resources (e.g., natural, hydropower and recreation) through an approach to distributing storage between Lake Powell and Lake Mead. Lake Powell releases would be determined based on a combination of Lake Powell and Lake Mead elevations, 10-year running-average hydrology, and Lower Basin deliveries. This alternative would include storage and delivery mechanisms for Lake Powell and Lake Mead and extensive flexibilities for all users. The operations incorporate Basin-wide shared contributions to the system, including Upper Basin conservation that would be stored in Lake Powell and Lower Basin shortages starting at 1.3 maf, approximately the average annual evaporative and system losses at and below Lake Mead, and reaching a maximum of 3.0 maf. Shortages would be triggered based on combined storage in Lake Powell and Lake Mead and distributed pro rata.

Shortage Guidelines to Reduce Deliveries from Lake Mead[3]	**Coordinated Reservoir Operations (Lake Powell and Lake Mead)**	**Storage and Delivery of Conserved System and Non-system Water[3]**	**Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]**	**Additional Activities Above Lake Powell**
• Shortages determined based on combined storage in Lake Powell and Lake Mead • Shortages begin at 60% full at a volume of 1.3 maf, then increase linearly, reaching a maximum of 3.0 maf at 30% full and below • Shortages distributed pro rata	• Lake Powell releases determined based on a combination of Lake Powell and Lake Mead elevations, 10-year running-average hydrology, and Lower Basin deliveries • Releases range from 4.7 to 10.8 maf	• Storage up to 5.0 maf in Lake Mead with additional 2.0 maf Protection Pool; included for purposes of determining Lake Powell releases and shortages • Storage up to 2.0 maf in Lake Powell; included for purposes of determining Lake Powell releases but excluded from shortage determinations • Existing ICS converted to new mechanism immediately • Extensive flexibilities for all users: intra- and interstate transactions within each basin • Tribal water (both conserved consumptive use and unused) including in Lake Powell conservation pool and Lake Mead Protection Pool	• Surplus determinations limited to 70R (spill avoidance strategy) and Flood Control conditions	• Upper Basin conservation contributed to the Lake Powell conservation pool based on hydrologic conditions: up to 200.0 kaf per year for first 5 years, up to 275.0 kaf per year for second 5 years, up to 350.0 kaf starting in year 11

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Maximum Operational Flexibility Alternative

This alternative is informed by a proposal submitted by a consortium of conservation organizations and incorporates proactive responses, targeted reservoir management strategies, and innovative and flexible tools to address an increasingly variable set of future hydrologic conditions. Lake Powell releases would range from 5.0 to 11.0 maf and would be determined by total CRSP system storage and recent hydrology. Releases would switch to "run-of-river" when Lake Powell is at 3,510 feet or lower. The operations incorporate Basin-wide shared contributions, including up to 4.0 maf of shortages in the Lower Basin triggered by combined seven-reservoir storage (CRSP Upper Initial Units, Lake Mead, Lake Mohave, and Lake Havasu) and recent hydrology and voluntary water contributions from both basins.

Shortage Guidelines to Reduce Deliveries from Lake Mead[3]	**Coordinated Reservoir Operations (Lake Powell and Lake Mead)[3]**	**Storage and Delivery of Conserved System and Non-system Water**	**Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]**	**Additional Activities Above Lake Powell**
• Shortages determined based on combined seven-reservoir storage and recent hydrology • Shortages start at 80% full and increase linearly, subject to upward adjustment based on hydrology, reaching a maximum of 4.0 maf • Shortages distributed based on priority, as described in Approach 1 of the Supply Driven Alternative	• Lake Powell releases determined based on total Upper Basin system storage and recent hydrology • Releases subject to downward adjustment based on hydrology and range from 5.0 to 11.0 maf • Releases switch to "run-of-river" when Lake Powell is at elevation 3,510 feet or lower	• Storage up to 8.0 maf in either Lake Powell or Lake Mead; excluded for purposes of determining Lake Powell releases and shortages • Existing ICS converted to new mechanism over 5 years • Extensive flexibilities for all users: transactions within and across basins, including interstate and inter-basin	• Surplus determinations limited to Flood Control conditions	• Average of 200.0 kaf of Upper Basin annual conservation based on hydrologic conditions contributed to the Lake Powell conservation pool

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

<table>
<tr><td>Supply Driven Alternative</td><td colspan="5">Annual Lake Powell releases are determined based on a 65 percent of 3-year-average natural flow at Lees Ferry. Lake Powell elevations could be increased by releases from CRSP Upper Initial Units within their respective RODs to protect infrastructure at Glen Canyon Dam. This alternative would include new delivery and storage mechanisms for Lake Powell and Lake Mead. Lower Basin shortages up to 2.1 maf would be triggered based on Lake Mead elevation. This alternative analyzes two approaches to shortage distribution: state-based combined with Lower Basin-wide priority and state-based combined with Lower Basin-wide pro rata.</td></tr>

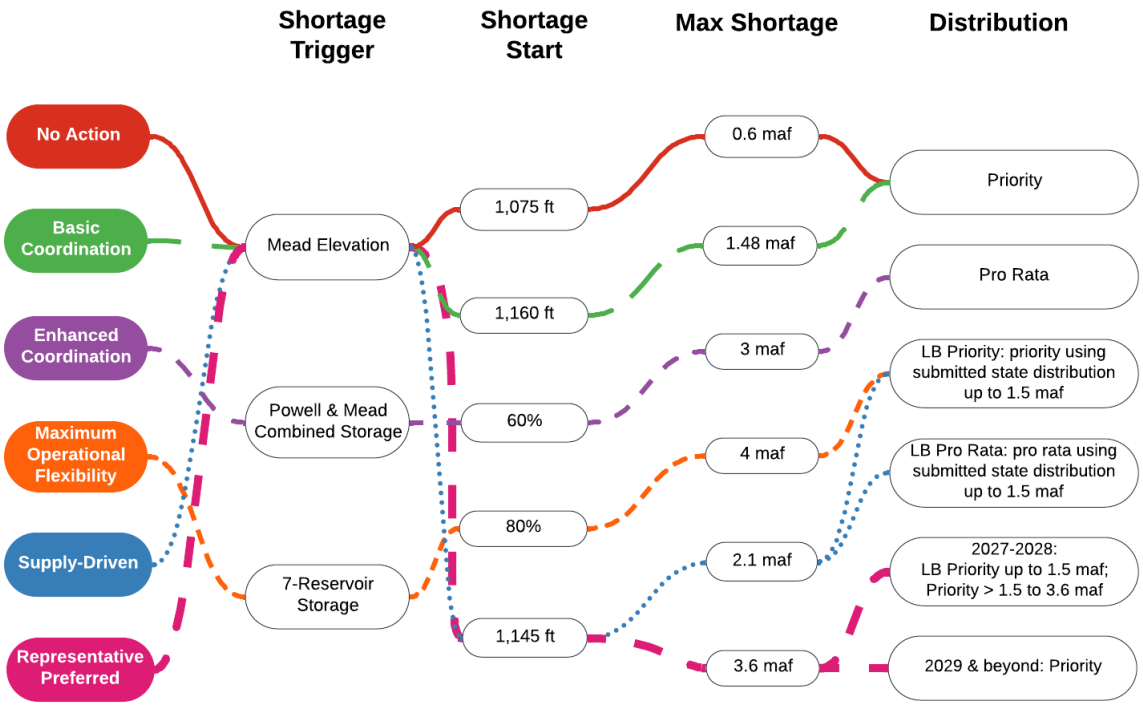
• In years when Lake Powell cannot meet its required water year release because of low elevation, additional “gap water” is introduced into the system and tracked to be released in subsequent years</td></tr>
</table>

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation’s modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.



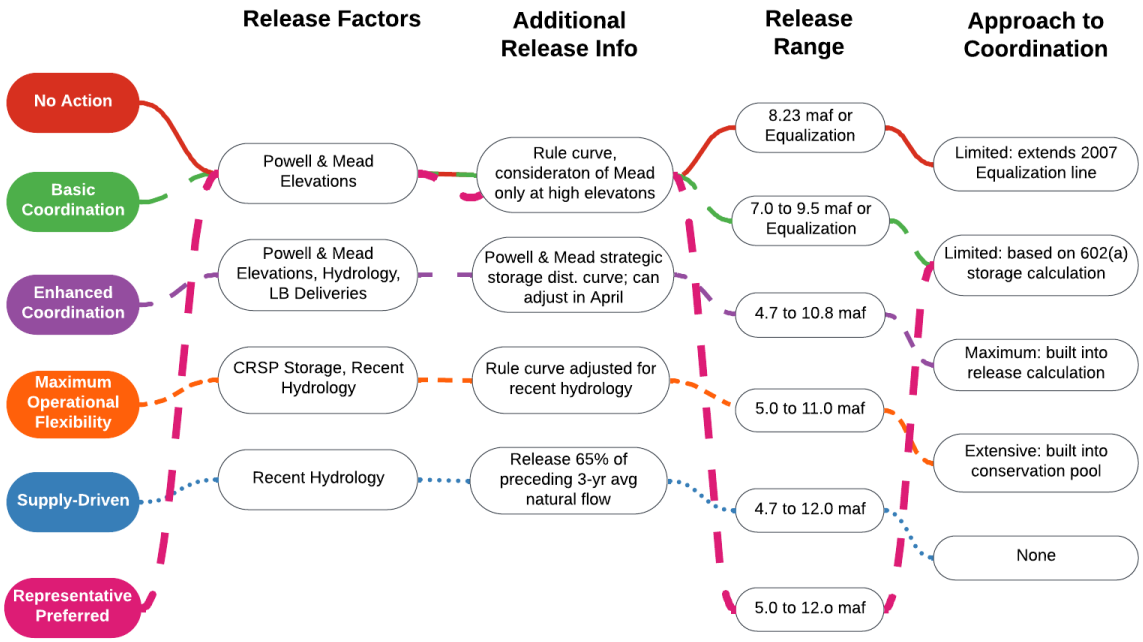
ES.2.4 Range of Alternatives

The Final EIS incorporates a reasonable and broad range of alternatives in accordance with NEPA. The figures below demonstrate the broad range of operational approaches incorporated into the alternatives by summarizing them across the following categories: Lower Basin Shortage Guidelines, Coordinated Reservoir Operations, Lake Mead Storage and Delivery of Conserved Water, and Activities above Lake Powell. For each figure below, the individual lines connect each alternative with the approach(es) that Reclamation has analyzed within that alternative.

ES.2.4.1 Lower Basin Shortage Guidelines

Figure ES-1, Lower Basin Shortage Guidelines, shows the range of approaches considered for factors that would trigger Lower Basin shortage, the level at which shortages would start, the maximum Lower Basin shortage amount, and the method(s) by which shortages would be distributed among Lower Basin water users.

Figure ES-1
Lower Basin Shortage Guidelines

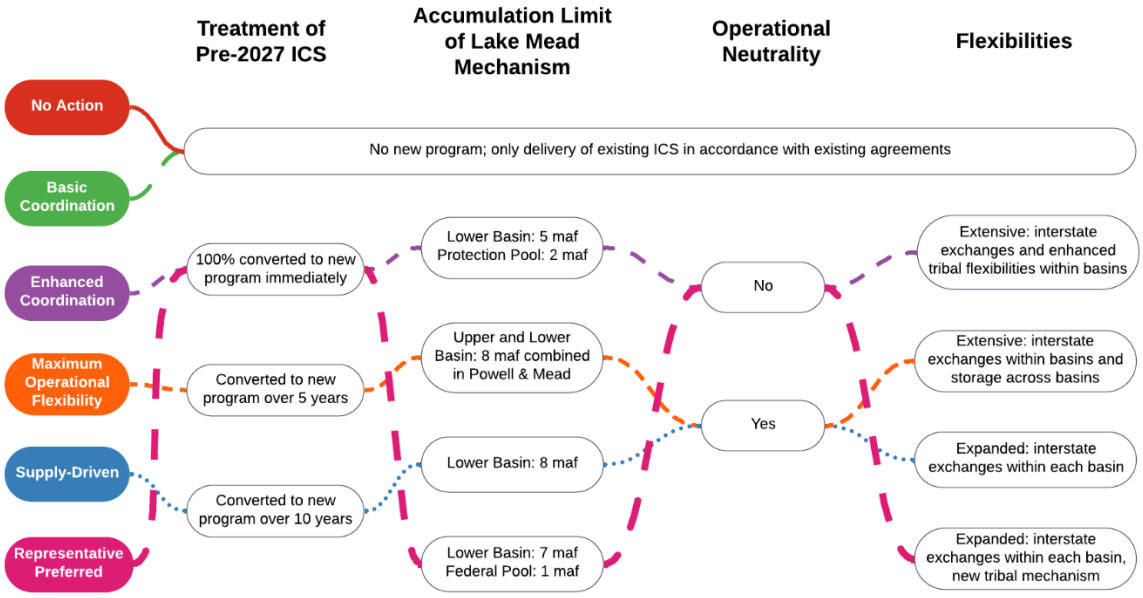


Notes: Additional restrictions in water deliveries will occur when Lake Mead is near dead pool, resulting in large reductions (referred to as "dead pool-related reductions"). These are not considered an operational element of the alternatives.
The "Representative Preferred Alternative" is a set of modeling assumptions designed around the Preferred Alternative sideboards. The specific operating guidelines for each operating interval during the term of the Preferred Alternative may differ.
Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

ES.2.4.2 Coordinated Reservoir Operations

Figure ES-2, Coordinated Reservoir Operations, shows the range of approaches considered for the factors that would determine Lake Powell water year release volumes, additional information about the structure of operations, the range of water year release volumes that could occur based on those factors, and the approach to coordination of operations between Lake Powell and Lake Mead (that is, how dependent operations of Lake Powell would be on conditions at Lake Mead).

Figure ES-2
Coordinated Reservoir Operations

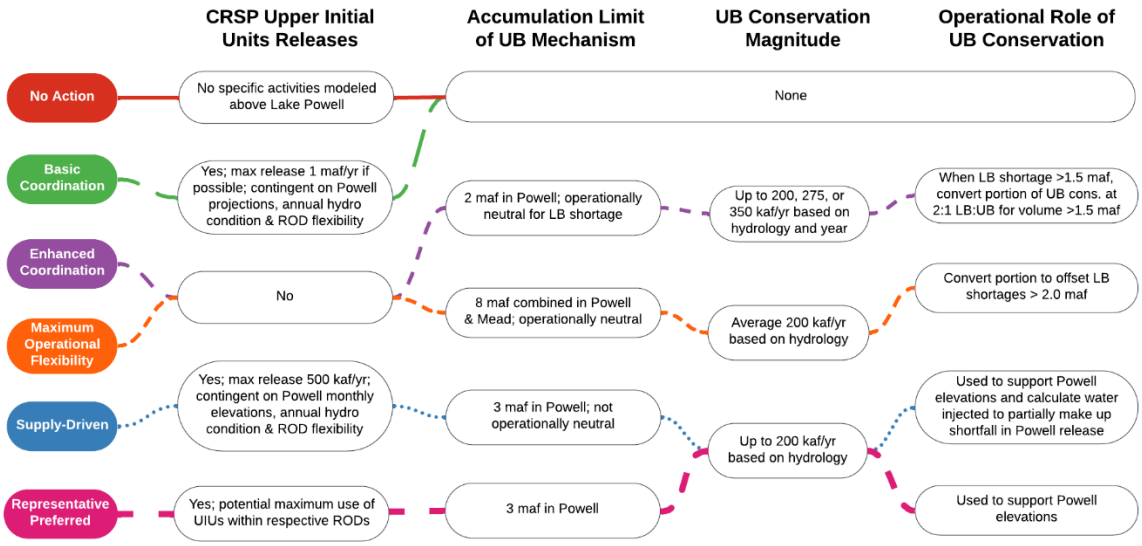


Note: The "Representative Preferred Alternative" is a set of modeling assumptions designed around the Preferred Alternative sideboards. The specific operating guidelines for each operating interval during the term of the Preferred Alternative may differ.

ES.2.4.3 Lake Mead Storage and Delivery of Conserved Water

Figure ES-3, Lake Mead Storage and Delivery of Conserved System Water, shows the range of approaches considered to incorporate this mechanism, including how Intentionally Created Surplus created prior to 2027 is converted into a new mechanism, the maximum amount of conserved water that could be stored in Lake Mead, whether stored conserved water is excluded from determinations of Lake Powell releases and shortage volumes ("operational neutrality"), and the level of flexibilities for transactions of stored conserved water between users.

Figure ES-3
Lake Mead Storage and Delivery of Conserved System Water



Notes: Accumulation limits include modeling assumptions for storage available to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.
The "Representative Preferred Alternative" is a set of modeling assumptions designed around the Preferred Alternative sideboards. The specific operating guidelines for each operating interval during the term of the Preferred Alternative may differ.

ES.2.4.4 Activities Above Lake Powell

Figure ES-4, Activities Above Lake Powell, shows the range of approaches to releases from CRSP Upper Initial Units to protect Glen Canyon Dam infrastructure, the maximum amount of conserved water that could be stored, assumptions about the amount of annual Upper Basin conservation, and rules for when Upper Basin conserved water would be converted to system water.

Figure ES-4
Activities Above Lake Powell

Note: The "Representative Preferred Alternative" is a set of modeling assumptions designed around the Preferred Alternative sideboards. The specific operating guidelines for each operating interval during the term of the Preferred Alternative may differ.

ES.3 Potential Environmental Effects

ES.3.1 Analysis Methods

The analysis for this Final EIS uses a Decision Making under Deep Uncertainty (DMDU) approach, drawn from a well-established branch of decision science, that is designed to account for uncertainty in future Basin conditions. The most impactful and largest source of uncertainty is future hydrology. Since 2000, hydrologic conditions drier than those in the previously observed record have continued to occur, confounding ongoing efforts to manage system risk. Reclamation began significant investments in research to improve hydrologic predictions and understanding of long-term supply outlooks in 2004, but there have been only limited improvements in prediction skill and long-term hydrologic projections continue to show a wide range of possibilities around the overall likelihood of a drier future. Therefore, long-term planning in the Basin must account for conditions of *deep uncertainty*, which occur when it is not possible to confidently assign probabilities to specific future conditions. Population growth and changes in water use in the Basin also contribute to the challenge of planning for a deeply uncertain future.

Alongside research into understanding hydrologic uncertainty, Reclamation has also invested in decision science research through the development of DMDU methods that allow for reliable analysis despite the uncertainty. Development of DMDU applications in the Basin stems from a collaboration with the RAND Corporation during the 2012 Colorado River Basin Water Supply and Demand Study, when the methods were introduced into Reclamation's long-term planning. The DMDU framework used here enhances the ability to evaluate the robustness of the alternatives – that is, their ability to meet important performance objectives in a wide range of futures. It also supports the identification of future conditions that could cause vulnerability to critical system conditions. A focus on robustness and vulnerability prevent overreliance on the types of probabilistic risk projections that, in previous planning efforts, did not convey the actual risks facing the system and contributed to insufficient protection against the ongoing drought.

The hydrologic modeling performed for this analysis employs DMDU by testing the system in 400 potential futures that cover a wide range of hydrologic conditions. This hydrologic modeling generated projections of future Colorado River system conditions (such as reservoir elevations, reservoir releases, and river flows) for the alternatives. These system projections serve as the basis for analyzing potential effects on other environmental resources (e.g., recreation, biological resources, and energy) and any associated resource specific models. For each resource, the analysis describes robustness across this wide range, identifies specific conditions that could cause vulnerability, and provides important context for interpreting those findings without overconfidently predicting system outcomes. This aligns with the guidance provided in Executive Order "Restoring Gold Standard Science" from May 2025, and provides a sound basis for comparing the alternatives' ability to meet key performance thresholds for resources throughout the Basin.

ES.3.2 Summary of Environmental Consequences

The analysis focuses on specific issues identified during internal and public scoping for all affected environmental resources (e.g., hydrologic, biologic, and socioeconomic). Resources considered but determined to not be significantly impacted by the action include transportation, noise, light, and minerals.

A summary of environmental consequences is provided in **Table ES-7**, Summary of Potential Effects of the Alternatives, located at the end of this Executive Summary. Performance indicators were developed to address the specific issues raised during scoping. Throughout, a higher percentage reflects better performance. Where quantitative or DMDU results are not possible, a qualitative description of potential impacts is provided. The affected environment and environmental consequences are discussed in detail in Chapter 3 and the associated resource appendices.

ES.4 Synthesis of Performance in Key Metrics

The action alternatives together capture a wide range of concepts across the operational elements that make up an alternative; this operational variety produces a wide range of potential system outcomes. The following sections provide an overview of performance and vulnerability over the period 2027-2036, which is significant because the Preferred Alternative is a 10-year decision framework. The Preferred Alternative, as analyzed in the Representative Preferred Alternative, is compared to the other

action alternatives, the No Action Alternative, and the Continued Current Strategies Comparative Baseline below.

ES.4.1 Performance Tradeoffs among Key System Metrics

ES.4.1.1 Introduction

Operations at Lake Powell and Lake Mead inherently involve tradeoffs among resources that benefit from different fundamental system elements: storage in each reservoir, dam releases, river flows, and water deliveries. For example, it is not possible for a set of operating guidelines to have the most robust performance with respect to maximizing protection of critical elevations, minimizing reductions in water deliveries, and maximizing hydropower generation all at once. With the extended period of dry hydrologic conditions since 2000 and the resulting depletion of storage, these tradeoffs have become more stark, and achieving a broadly acceptable balance between resources is now more difficult than ever before.

ES.4.1.2 Tradeoff Analysis

While there are many important metrics across Basin resources, it is instructive to summarize the high-level system impacts through five metrics related to Lake Powell and Lake Mead elevations, Lower Basin deliveries, and releases from Glen Canyon Dam. Analyzing tradeoffs among the metrics described in **Table ES-3** also provides important insight into the tradeoffs among other resources.

Table ES-3
High Level Performance Metrics Included in Figure ES-5

Metric Name	Description
Percent of months in which Lake Powell stays above elevation 3,500 feet	Elevation 3,500 feet provides a buffer above 3,490 feet, below which the reliability of infrastructure to meet critical downstream water supply needs may be compromised and hydropower cannot be produced at Glen Canyon Dam
Percent of months in which Lake Mead stays above elevation 975 feet	Elevation 975 feet provides a buffer above 950 feet, below which infrastructure may be critically impacted and hydropower cannot be produced at Hoover Dam
Percent of years in which Lake Mead dead pool-related reductions[5] are avoided	Delivery reductions due to Lake Mead being near dead pool (elevation 895 feet) resulting in large magnitudes of reductions to Lower Basin water users
Average annual shortage	The average annual shortage that occurs under each alternative provides important summary information for Lower Basin water users and context for reservoir-based performance
Average water year releases from Glen Canyon Dam	The average water year release from Glen Canyon Dam that occurs under each alternative provides important context for reservoir-based performance

[5] Dead pool and Hoover Dam infrastructure can start to impact Lake Mead's ability to make deliveries to the Lower Basin at elevation 950 feet. Restrictions in water deliveries will occur when Lake Mead is near dead pool, resulting in large reductions (referred to as "dead pool-related reductions"). Although not considered an operational element of the alternatives, accounting for such reductions is an important performance metric.

The elevations described in **Table ES-3** have operational relevance, and comparing alternative performance relative to these elevations provides meaningful insight. In practice, operational implementation would include identifying elevations above critical thresholds (i.e., 3,490 feet and 950 feet) at which additional responsive actions could be taken in advance to avoid reaching those critical elevations. The "buffer" elevations shown in **Table ES-3** (i.e., 3,500 feet and 975 feet) may or may not correspond to operational decision for actual implementation; here, they are used for analytical purposes in this Final EIS.

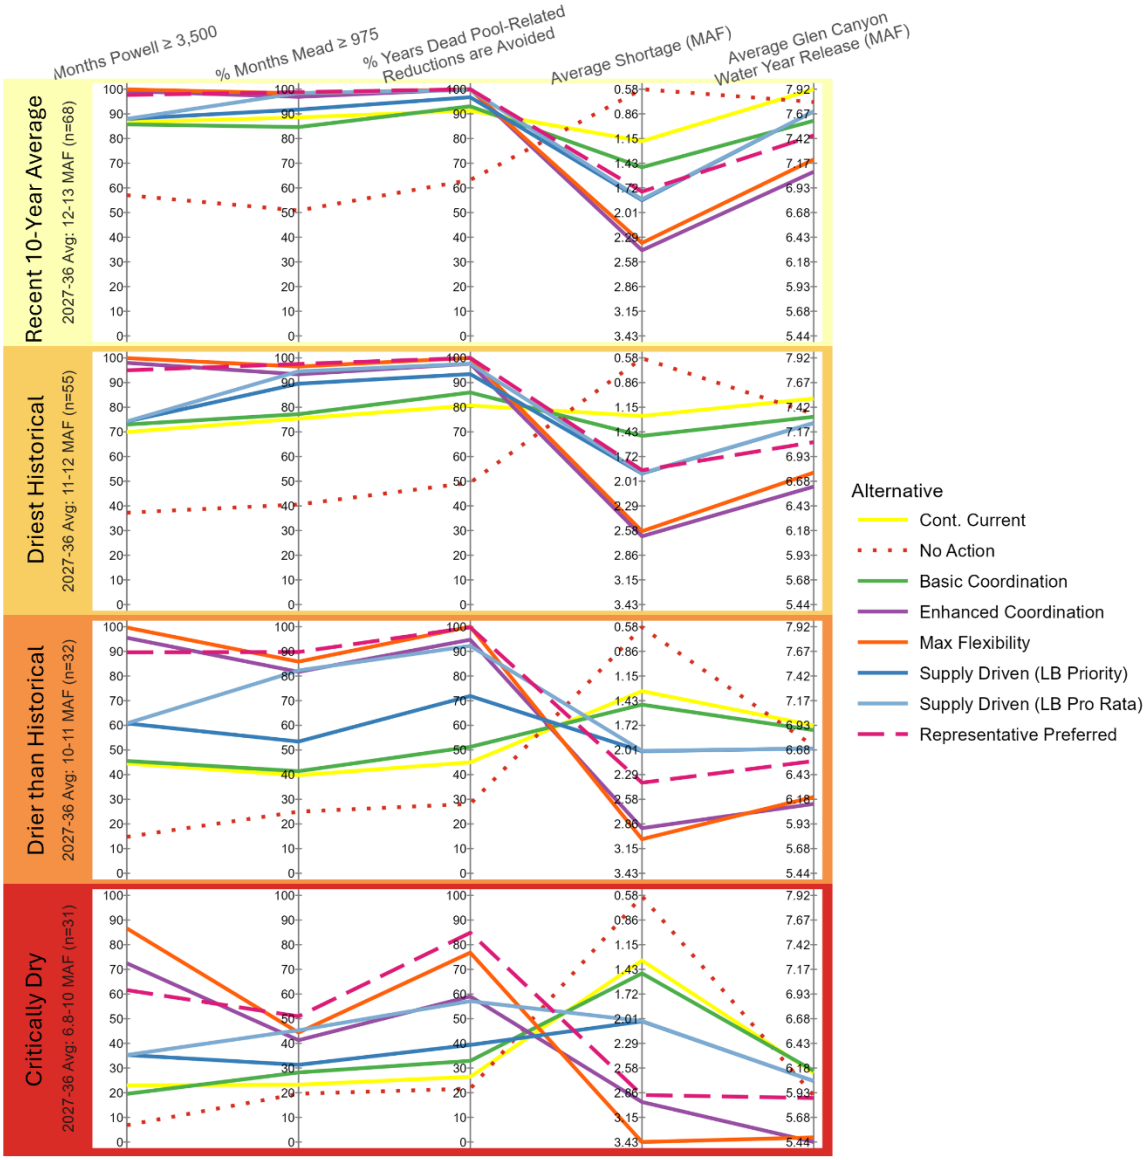


Figure ES-5 summarizes how the alternatives and the Continued Current Strategies Comparative Baseline[6] (labeled "Cont. Current") perform over the next 10 years in five vertical axes that correspond to the five key metrics described in **Table ES-3**. The performance of each alternative is captured by a colored, segmented line that crosses the axes at different vertical positions, where the height denotes performance. Crossing lines are a visual cue that there is a tradeoff between different performance metrics. The five-metric performance summary is divided into four categories of potential 2027-2036 future hydrologic conditions that get increasingly dry from top to bottom.[7] The hydrologic categories are summarized in **Table ES-4**. Results are divided into these categories to demonstrate how the alternatives respond under different assumptions about future hydrologic conditions and to explore the impacts of hydrology on performance tradeoffs.

Table ES-4
Hydrologic Categories Included in Figure ES-5

Hydrologic Category	Average Annual Simulated Lees Ferry Flow, 2027-2036 (maf)	Description
Recent 10-Year Average	12-13	Hydrologic conditions in this category are similar to the historical average from 2016-2025 (12.1 maf)[8]
Driest Historical	11-12	Hydrologic conditions in this category are similar to the driest 10-year period in the historical record (11.8 maf, 2012-2021)
Drier than Historical	10-11	Hydrologic conditions in this category are 7-15% (0.8 to 1.8 maf) drier than the driest 10-year period in the historical record
Critically Dry	<10	Hydrologic conditions in this category are 15-42% (1.8-5.0 maf) drier than the driest 10-year period in the historical record

[6] This scenario represents no changes from current operations and relies on strategies and agreements that expire in 2026. It is provided as a comparative baseline to inform an understanding of how the alternatives perform relative to current operations.
[7] Wetter futures were also tested and are included in the impact analysis; however, for this analysis the hydrologic categories shown are most informative.
[8] The 10-year average for 2014-2023 (12.8 maf), 2015-2024 (12.6 maf), and 2016-2025 (12.1 maf) are all between 12 and 13 maf.

Figure ES-5
Key Performance Tradeoffs in Different Hydrologic Conditions

Note: Differences in Lake Mead performance between Supply Driven (Lower Basin [LB] Priority) and the Supply Driven (LB Pro Rata) Alternatives reflect how different shortage distributions interact with assumptions regarding the use of the storage and delivery mechanism for conserved water.

A key performance tradeoff demonstrated by **Figure ES-5** is the tradeoff between percent of time in which critical reservoir elevations and dead pool-related reductions are avoided (first three axes from left) and average shortage (fourth axis from left). In the Recent 10-Year Average hydrologic category, this stands out as a difference between the No Action Alternative and the action alternatives, but in the drier hydrologic categories (especially Drier than Historical and Critically Dry), the performance differences between the action alternatives becomes clearer and the tradeoffs (indicated by the crossing lines) become steeper: the Maximum Operational Flexibility and Enhanced Coordination Alternatives incorporate large shortages and better protect the reservoirs, the Supply Driven Alternatives and the Basic Coordination Alternative have lower volumes of shortage and lower reservoir protection, and the No Action Alternative provides minimal protection and results in a high frequency of dead pool-related reductions while imposing minimal shortage. Across hydrologic categories, the Representative Preferred Alternative balances tradeoffs differently than other action alternatives. This is evident beginning in the Driest Historical hydrologic category, where it provides protection of Lake Powell and Lake Mead elevations similar to the most protective alternatives, while the average shortage volumes are similar to the Supply Driven Alternatives.

In Drier than Historical hydrologic futures, the Maximum Operational Flexibility and Enhanced Coordination Alternatives show that lower water year releases from Glen Canyon Dam provide more protection to keep Lake Powell above 3,500 feet, while the higher water year releases in Basic Coordination and Supply Driven result in significantly higher frequencies of Lake Powell falling below 3,500 feet. The Representative Preferred Alternative falls in between Supply Driven and Enhanced Coordination Alternatives: it releases less from Glen Canyon on average than the Supply Driven Alternative and better protects elevation 3,500 feet, but it releases more and offers less protection compared to the Enhanced Coordination Alternative. In the Critically Dry hydrologic category, water year releases are low across all alternatives, but only the Representative Preferred (62 percent of months), Enhanced Coordination (72 percent of months) and Maximum Operational Flexibility (87 percent of months) Alternatives protect 3,500 feet more than half of the time. The Supply Driven Alternatives and Basic Coordination Alternative maintain elevations above 3,500 feet in 35 percent and 20 percent of months, respectively.

The effectiveness of large shortages at preventing dead pool-related delivery reductions is clearest in the Critically Dry hydrologic category, where the Representative Preferred, Maximum Operational Flexibility, and Enhanced Coordination Alternatives rely on large average shortages to significantly outperform the other alternatives in avoiding dead pool-related reductions. However, in Critically Dry conditions, even these more protective alternatives result in Lake Mead elevations below 975 feet in 49, 56, and 59 percent of months, respectively.

Figure ES-1 is a quantitative representation of system tradeoffs and shows how those tradeoffs are exacerbated by drying hydrologic conditions. The analysis in this figure demonstrates how the sideboards of the Preferred Alternative, as analyzed in the Representative Preferred Alternative, appropriately balance the tradeoffs across key system metrics and provide protection in conditions drier than the ongoing, unprecedented drought. The Representative Preferred Alternative achieves good performance across key system metrics related to critical infrastructure in the driest hydrologic conditions the Basin has experienced (Driest Historical Hydrology) but imposes lower average shortages and enables higher Glen Canyon Dam releases than other similarly protective alternatives. In

conditions that are slightly drier than observed history (Drier than Historical Hydrology), the Representative Preferred Alternative maintains this moderate balance of performance between reservoir elevations, shortages, and Glen Canyon Dam releases. In the driest hydrologic conditions modeled (Critically Dry Hydrology), the ability of any set of operations to achieve good performance in these metrics is significantly diminished, but the Representative Preferred Alternative shows that the Preferred Alternative sideboards can protect critical infrastructure in the majority of these conditions while considering adverse impacts to Lower Basin water users.

ES.4.2 Vulnerability Analysis for Key Reservoir Elevations

The analysis related to **Figure ES-5** examines tradeoffs and the influence of different hydrologic scenarios on the alternatives' performance in important metrics. **Table ES-5** and **Table ES-6**, below, provide insight into what specific hydrology is likely to cause the system to be vulnerable to critical conditions under different alternatives and whether those conditions are similar to anything from the observed record. This context is helpful in understanding whether the conditions leading to vulnerability could be reasonably expected based on history.[9] Based on analysis of 400 modeled hydrologic futures, an average-flow threshold was identified for each alternative that skillfully predicted the occurrence of a critical system condition at least once within 10 years of implementation (between 2027 and 2036).

Table ES-5
Vulnerability to Lake Powell Falling Below Elevation 3,500 Feet at Least Once in the First 10 Years and Comparison to Historical Conditions

Alternative	Water Year 2027-2036 Average Natural Flow that Could Cause Vulnerability (maf/year)	Number of Years Below Threshold 2000-2025 (Historical Data)	Number of Years Below Threshold 1906-2025 (Historical Data)
Cont. Current	≤12.1	3	4
No Action	≤19.6	26	111
Basic Coordination	≤11.9	1	1
Enhanced Coordination	≤9.3	0	0
Max Flexibility	≤8.1	0	0
Supply Driven (LB Priority)	≤12.5	7	9
Supply Driven (LB Pro Rata)	≤12.5	7	9
Representative Preferred	≤10.1	0	0

[9] Information about how the vulnerability thresholds compare to projections of future conditions, which include the potential for a drier future, can be found in **Technical Appendix 3**, Hydrologic Resources.

Table ES-6
Vulnerability to Lake Mead Falling Below Elevation 975 Feet at Least Once in the First 10 Years and Comparison to Historical Conditions

Alternative	Water Year 2027-2036 Average Natural Flow that Could Cause Vulnerability (maf/year)	Number of Years Below Threshold 2000-2025 (Historical Data)	Number of Years Below Threshold 1906-2025 (Historical Data)
Cont. Current	≤11.6	0	0
No Action	≤14.5	23	67
Basic Coordination	≤11.3	0	0
Enhanced Coordination	≤9.7	0	0
Max Flexibility	≤10.0	0	0
Supply Driven (LB Priority)	≤11.1	0	0
Supply Driven (LB Pro Rata)	≤9.7	0	0
Representative Preferred	≤10.0	0	0

With respect to Lake Powell falling below elevation 3,500 feet at least once in the next 10 years, the Supply Driven Alternative is the most vulnerable action alternative: under these operations, Lake Powell would likely fall to critical elevations if the 10-year average natural flow at Lees Ferry is 12.5 maf or lower. Hydrologic conditions this dry or drier occurred in 7 years since 2000. With respect to Lake Mead falling below elevation 975 feet at least once in the next 10 years, the flow thresholds indicating vulnerability are drier for all of the action alternatives than any observed historical conditions. However, conditions this dry do occur in the set of 400 hydrologic traces analyzed in this EIS, which includes the potential for a future drier than historical observations (see **Appendix F**, Approach to Hydrologic Uncertainty, for information about the 400 hydrologic traces).

Modeling indicates that the Representative Preferred Alternative would likely be vulnerable to Lake Powell falling below 3,500 feet if the 2027-2026 average flow is 10.1 maf or less and Lake Mead falling below 975 feet if the 2027-2036 average flow is 10.0 maf or less. The Representative Preferred Alternative is reasonably unlikely to be vulnerable in the next 10 years because these conditions have not occurred and are about 15 percent drier than the driest 10-year period on record (2012-2021, average of 11.8 maf). However, estimates for 2026 natural flow suggest 2017-2026 will become the driest 10-year period on record (about 11.5 maf), reflecting that hydrology could continue to decline relative to the comparisons in this table. The possibility for a drier future is reflected in the set of 400 hydrologic traces analyzed in this EIS.

ES.4.3 Conclusions

A number of reservoir and water management decisional documents and agreements that govern operation of Colorado River facilities and management of Colorado River water are currently scheduled to expire at the end of 2026. The Secretary, acting through Reclamation, proposes adoption of new guidelines and coordinated management strategies to address Lake Powell and Lake Mead through their full operating range, to be implemented upon the expiration of the existing guidelines and agreements. Management strategies will primarily focus on the operation of Glen Canyon Dam and Hoover Dam but may include actions upstream and downstream of these facilities to protect critical reservoir elevations.

Since the adoption of the current guidelines in 2007, unprecedented drought has changed the Basin's understanding of hydrology. Hydrologic conditions drier than those in the previously observed record have continued to occur, confounding ongoing efforts to manage system risk. This reality poses both near- and long-term challenges in managing the Colorado River system to continue to provide predictability and certainty to Basin water users as well as operating flexibility to conserve and enhance water storage in Colorado River system reservoirs.

This Final EIS analyzes a reasonable and broad range of alternatives for the operational elements identified in the proposed federal action. These alternatives were developed through extensive engagement with a wide range of partners and stakeholders as well as the general public during a timeframe of over 4 years. In the absence of a consensus long-term agreement, Reclamation has included a Preferred Alternative decision framework in this Final EIS that establishes the operational principles, sideboards, and process that would govern development and adoption of operating guidelines through 2036. The sideboards of the Preferred Alternative were analyzed through the Representative Preferred Alternative, and the analysis of the potential impacts of these sideboards provides environmental compliance for decisions made consistent with the decision framework. Based on the analysis in this Final EIS and the key tradeoffs shown above, the Preferred Alternative, as analyzed in the Representative Preferred Alternative, appropriately balances the inherent system tradeoffs: it is a practical approach to robust protection of critical infrastructure while considering adverse impacts to water users and avoiding unnecessary impacts to other resources.

ES.5 Summary of Potential Effects

Table ES-7
Summary of Potential Effects of the Alternatives

Hydrology (See Section 3.3)

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Reservoir Elevations	Ranking of alternatives related to Lake Powell end of water year (EOWY) median elevations in the critically dry flow category.	**Ranked #6.** Lowest median elevations in the critcally dry flow category.	**Ranked #5**. Second lowest median elevations in the critcally dry flow category.	**Ranked #1.** Highest median elevations in the critcally dry flow category.	**Ranked #2.** Second highest median elevations in the critcally dry flow category.	**Tied Ranked #4.** Tied third lowest median elevations in the critcally dry flow category (same as Supply Driven Alternative [LB Pro Rata approach]).	**Tied Ranked #4.** Tied third lowest median elevations in the critcally dry flow category (same as Supply Driven Alternative [LB Priority approach]).	**Ranked #3.** Third highest median elevations in the critcally dry flow category.
	Percent of modeled futures in which *Lake Powell elevation stays above 3,500 feet 100% of the time*. The higher the percentage, the more likely Lake Powell will remain above the minimum power pool (3,490 feet) under most future hydrologic scenarios.	**4%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**19%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**81%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**94%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**35%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**35%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**58%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.
	Ranking of alternatives related to Lake Mead end of calendar year (EOCY) median elevations in the critically dry flow category.	**Ranked #7.** Lowest median elevations in the critcally dry flow category.	**Ranked #6.** Second lowest median elevations in the critcally dry flow category.	**Ranked #4.** Fourth lowest median elevations in the critcally dry flow category.	**Ranked #2**. Second highest median elevations in the critcally dry flow category.	**Ranked #3**. Third highest median elevations in the critcally dry flow category.	**Ranked #1**. Highest median elevations in the critcally dry flow category.	**Ranked #5.** Third lowest median elevations in the critcally dry flow category.
	Percent of futures in which *Lake Mead elevation stays above 975 feet 100% of the time*. The higher the percentage, the more likely Lake Mead will remain above the minimum power pool (950 feet) under most future hydrologic scenarios.	**32%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**62%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**74%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**77%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**69%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**81%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**72%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Reservoir Elevations *(continued)*	Lake Mohave and Lake Havasu end of year elevations.	No impact; the existing rule curves continue to determine elevations.						
System Storage	Ranking of alternatives related to Lake Powell + Lake Mead combined median storage capacity in all flow categories.	**Ranked #7.** Lowest combined storage in all flow categories.	**Ranked #6.** Second lowest combined storage in all flow categories.	**Ranked #1.** Highest combined storage in all flow categories.	**Ranked #2.** Second highest combined storage in all flow categories.	**Ranked #5.** Third lowest combined storage in all flow categories.	**Ranked #3.** Third highest combined storage in all flow categories.	**Ranked #4.** Fourth highest combined storage in all flow categories.
	Ranking of alternatives related to CRSP Reservoir (Flaming Gorge, Navajo, Blue Mesa, and Powell) combined median storage capacity in the two driest flow categories.	**Tied Ranked #4.** Tied second lowest combined storage in the driest flow categories (same as both Supply Driven Alternatives).	**Ranked #5.** Lowest combined storage in the driest flow categories.	**Ranked #1.** Highest combined storage in the driest flow categories.	**Ranked #2.** Second highest combined storage in the driest flow categories.	**Tied Ranked #4.** Tied second lowest combined storage in the driest flow categories. (same as Supply Driven Alternative [LB Pro Rata approach] and No Action).	**Tied Ranked #4.** Tied second lowest combined storage in the driest flow categories. (same as Supply Driven Alternative [LB Priority approach] and No Action).	**Ranked #3.** Third highest combined storage in the driest flow categories.
	Ranking of alternatives related to Seven-Reservoir (Flaming Gorge, Navajo, Blue Mesa, Powell, Mead, Mohave, and Havasu) combined median storage capacity in all flow categories.	**Ranked #7.** Lowest combined storage in all flow categories.	**Ranked #6.** Second lowest combined storage in all flow categories.	**Ranked #1.** Highest combined storage in the driest flow categories.	**Ranked #2.** Second highest combined storage in all flow categories	**Ranked #4.** Fourth highest combined storage in all flow categories	**Ranked #3.** Third highest combined storage in all flow categories.	**Ranked #5.** Third lowest combined storage in all flow categories.
Reservoir Releases	Annual Glen Canyon Dam EOWY releases under average and critically dry hydrology conditions (median values)	Releases of 8.23 maf in the average flow category. Releases of 6.36 maf the critically dry flow category.	Releases of 8.23 maf in the average flow category. Releases of 6.92 maf in the critically dry flow category.	Releases of 7.95 maf in the average flow category. Releases of 5.11 maf in the critically dry flow category.	Releases of 8.17 maf in the average flow category. Releases of 5.61 maf in the critically dry flow category.	Releases of 8.41 maf in the average flow category. Releases of 6.04 maf in the critically dry flow category.	Releases of 8.41 maf in the average flow category. Releases of 6.04 maf in the critically dry flow category.	Releases of 8.23 maf in the average flow category. Releases of 6.00 maf in the critically dry flow category.
	10-year Glen Canyon Dam releases under average and critically dry hydrology conditions (median values)	Releases of 80.8 maf in the average flow category. Releases of 74.3 maf Releases in the critically dry flow category.	Releases of 79.0 maf in the average flow category. Releases of 74.5 maf in the critically dry flow category.	Releases of 77.4 maf in the average flow category. Releases of 69.1 maf in the critically dry flow category.	Releases of 78.9 maf in the average flow category. Releases of 70.8 maf in the critically dry flow category.	Releases of 81.7 maf in the average flow category. Releases of 73.5 maf in the critically dry flow category.	Releases of 81.7 maf in the average flow category. Releases of 73.5 maf in the critically dry flow category.	Releases of 78.8 maf in the average flow category. Releases of 72.5 maf in the critically dry flow category.
	10-year Lee Ferry Compact Point flow volumes under average and critically dry hydrology conditions (median values)	Flows of 82.3 maf in the average flow category. Flows of 75.7 maf in the critically dry flow category.	Flows of 80.6 maf in the average flow category. Flows of 76.0 maf in the critically dry flow category. Mirrors trends for river flows in Reach 4. River flows decrease as flow categories get drier.	**Ranked #4**. Fourth highest river flows in the critically dry flow category. Mirrors trends for river flows in Reach 4. River flows decrease as flow categories get drier.
	Ranking of alternatives related to median river flows in Reach 6 (Imperial Dam to Northerly International Boundary [NIB])	**Tied Ranked #3**. Tied third highest median river flows in critically dry flow category (same as Representative Preferred Alternative). Releases of 0.9 maf in the critically dry flow category.	**Ranked #1**. Highest river flows in critically dry flow category. Releases of 1.0 maf in the critically dry flow category.	**Ranked #6**. Lowest median river flows in critically dry flow category. Releases of 0.8 maf in the average flow category.	**Ranked #4**. Third lowest median river flows in critically dry flow categories. Releases of 0.8 maf in the critically dry flow category.	**Ranked #2**. Second highest river flows in critically dry flow category. Releases of 0.9 maf in the critically dry flow category.	**Ranked #5.** Second lowest median river flows in critically dry flow category. Releases of 1.0 maf in the critically dry flow category.	**Tied Ranked #3**. Tied third highest median river flows in all flow categories (same as No Action Alternative). Releases of 0.8 maf in the critically dry flow category.
	Likelihood for infrequent river flows to occur in wetter flow categories in Reach 7 (NIB to SIB, below Morelos)	Flows below Morelos Dam are infrequent under all flow categories. **Least likely** for infrequent flows to occur in the wetter flow categories.	Flows below Morelos Dam are infrequent under all flow categories. **Least likely** for infrequent flows to occur in the wetter flow categories.	Flows below Morelos Dam are infrequent under all flow categories. **Among the middle performing** for infrequent flows to occur in the wetter flow categories.	Flows below Morelos Dam are infrequent under all flow categories. **Among the middle performing** for infrequent flows to occur in the wetter flow categories.	Flows below Morelos Dam are infrequent under all flow categories. **Most likely** for infrequent flows to occur in the wet flow category.	Flows below Morelos Dam are infrequent under all flow categories. **Most likely** for infrequent flows to occur in the wet flow category.	Flows below Morelos Dam are infrequent under all flow categories. **Among the middle performing** for infrequent flows to occur in the wetter flow categories.
Groundwater	Groundwater in Reach 1 (Glen Canyon Dam to Lake Mead).	**Ranked #6**. Least robust at keeping elevations at Lake Powell above 3,500 feet; changes to groundwater levels adjacent to Lake Powell may be affected by changes in reservoir elevations. Groundwater elevations through Grand Canyon are not anticipated to be affected.	**Ranked #5**. Second least robust at keeping elevations at Lake Powell above 3,500 feet; changes to groundwater levels adjacent to Lake Powell may be affected by changes in reservoir elevations. Groundwater elevations through Grand Canyon are not anticipated to be affected.	**Ranked #2**. Second most robust at keeping elevations at Lake Powell above 3,500 feet; changes to groundwater levels adjacent to Lake Powell may be affected by changes in reservoir elevations. Groundwater elevations through Grand Canyon are not anticipated to be affected.	**Ranked #1**. Most robust at keeping elevations at Lake Powell above 3,500 feet; changes to groundwater levels adjacent to Lake Powell may be affected by changes in reservoir elevations. Groundwater elevations through Grand Canyon are not anticipated to be affected.	**Tied Ranked #3**. Tied third most robust at keeping elevations at Lake Powell above 3,500 feet; changes to groundwater levels adjacent to Lake Powell may be affected by changes in reservoir elevations. Groundwater elevations through Grand Canyon are not anticipated to be affected.	**Tied Ranked #3**. Tied third most robust at keeping elevations at Lake Powell above 3,500 feet; changes to groundwater levels adjacent to Lake Powell may be affected by changes in reservoir elevations. Groundwater elevations through Grand Canyon are not anticipated to be affected.	**Ranked #4**. Third least robust at keeping elevations at Lake Powell above 3,500 feet; changes to groundwater levels adjacent to Lake Powell may be affected by changes in reservoir elevations. Groundwater elevations through Grand Canyon are not anticipated to be affected.
	Groundwater in Reach 2 (Hoover Dam to Lake Mohave)	Groundwater elevations through this reach are not anticipated to be affected.						

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. Groundwater elevations adjacent to Lake Havasu are not anticipated to be affected.	**Tied Ranked #2**. Tied second highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage. Groundwater elevations adjacent to Lake Havasu are not anticipated to be affected.	**Ranked #3**. Third highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage. Groundwater elevations adjacent to Lake Havasu are not anticipated to be affected.	**Ranked #4**. Third lowest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage. Groundwater elevations adjacent to Lake Havasu are not anticipated to be affected.
	Groundwater in Reach 4 (Parker Dam to Cibola Gage)	**Ranked #3**. Third highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #1.** Highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #7.** Lowest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #5.** Third lowest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #2.** Second highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #6**. Second lowest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #4.** Fourth highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.
	Groundwater in Reach 5 (Cibola Gage to Imperial Dam)	**Ranked #3.** Third highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #1.** Highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #7.** Lowest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #5.** Third lowest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #2.** Second highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #6.** Second lowest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.	**Ranked #4.** Fourth highest river flows in reach; changes to groundwater levels adjacent to the river may be affected by changes in river stage.
	Groundwater in Reach 6 (Imperial Dam to NIB)	Most of the river channel is bypassed with a series of canals and sluiceways. Groundwater elevations through this reach are not anticipated to be affected.						
	Groundwater in Reach 7 (NIB to SIB)	**Least likely** for infrequent flows to occur in this reach. Groundwater in the southern reach of the limitrophe may be affected by decreased flows.	**Least likely** for infrequent flows to occur in this reach. Groundwater in the southern reach of the limitrophe may be affected by decreased flows.	**Among the middle performing** for infrequent flows to occur in this reach. Groundwater in the southern reach of the limitrophe may be affected by decreased flows.	**Among the middle performing** for infrequent flows to occur in this reach. Groundwater in the southern reach of the limitrophe may be affected by decreased flows.	**Most likely** for infrequent flows to occur in this reach. Groundwater in the southern reach of the limitrophe may be affected by decreased flows.	**Most likely** for infrequent flows to occur in this reach. Groundwater in the southern reach of the limitrophe may be affected by decreased flows.	**Among the middle performing** for infrequent flows to occur in this reach. Groundwater in the southern reach of the limitrophe may be affected by decreased flows.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

Water Deliveries (See Section 3.4)

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Apportionments	Upper Division States	No impact	No impact	No impact	No impact	No impact	No impact	No impact
	Lower Division States	Shortages are distributed based on priority.	Shortages are distributed based on priority.	Shortages are distributed based on pro rata.	Shortages are distributed priority based on Lower Division States' submission.	Shortages are distributed priority based on Lower DivisionD States' submission.	Shortages are distributed pro rata based on Lower DivisionD States' submission.	Shortages are distributed based on priority.
Lower Division States Water Supply Determinations and Total Water Deliveries[2]	Percent of modeled futures in which *dead pool-related reductions are avoided in 100% of years*. The higher the percentage, the more likely dead pool-related reductions are avoided.	**41%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**68%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**88%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**94%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**77%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**88%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**95%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.
	Effects of modeling assumptions for Upper and Lower Basin conservation activity (comparison of shortage and depletion results when turning conservation activity on and off).	Median reductions remain **similar** with conservation on or off.[3]	Median reductions remain **similar** with conservation on or off.[1]	Median shortages **slightly higher with conservation off** compared to conservation on in all flow categories. Median depletions **slightly lower with conservation off** in all flow categories.	Median shortages **slightly lower with conservation off** compared to conservation on in **wetter flow** categories **but higher or similar** in **drier flow** categories. Median depletions **slightly higher with** conservation **off** compared to conservation on in **wetter flow categories but slightly lower in drier flow categories**.	Median shortages **slightly lower with conservation off** compared to conservation on. Median depletions **slightly higher with conservation off** compared to conservation on.	Median shortages **slightly lower with conservation off** compared to conservation on. Median depletions **slightly higher with conservation off** compared to conservation on.	Median shortages **higher with conservation off** compared to conservation on. Median depletions **slightly lower with conservation off** compared to conservation on.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

[2] Total shortage volumes and deliveries include assumptions related to reductions in water deliveries to Mexico. Appendix A provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

[3] While the No Action and Basic Coordination alternatives do not include mechanisms to conserve and store water in Lake Powell or Lake Mead, the model does include assumptions for the delivery of existing ICS that was conserved prior to 2027. In the conservation-off results, activity related to pre-2027 conservation is turned off for all the alternatives and the CCS Comparative Baseline. Refer to TA 4, Water Deliveries, for more details.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	**Basic Coordination Alternative**	**Enhanced Coordination Alternative**	**Maximum Operational Flexibility Alternative**	**Supply Driven Alternative (LB Priority)**	**Supply Driven Alternative (LB Pro Rata)**	**Representative Preferred Alternative**
Lower Division States Water Supply Determinations and Total Water Deliveries *(continued)*	Maximum shortage (maf) where shortage is any modeled reduction to the ability of an entitlement holder to exercise an entitlement as described in the assumptions of the model	Total Lower Basin: 0.60[4] Arizona: 0.47 California: 0.00 Nevada: 0.03	Total Lower Basin: 1.48[4] Arizona: 1.15 California: 0.00 Nevada: 0.08	Total Lower Basin: 3.00 Arizona: 0.93 California: 1.47 Nevada: 0.10	Total Lower Basin: 4.00 Arizona: 1.93 California: 1.28 Nevada: 0.20	Total Lower Basin: 2.10 Arizona: 1.22 California: 0.44 Nevada: 0.09	Total Lower Basin: 2.10 Arizona: 0.92 California: 0.76 Nevada: 0.07	Total Lower Basin: 3.6 Arizona: 1.96 California: 0.9 Nevada: 0.21
	Annual volume of Lower Basin shortage and dead pool-related reductions under critically dry hydrologic conditions (median values). Volumes are expressed as a total volume of reductions to the Lower Basin, including Mexico.	Median reductions increase as flow categories become drier. Shortage: 0.6 maf **Lowest** Dead pool-related reductions: 1.5 maf **Highest**	Median reductions increase as flow categories become drier. Shortage: 1.5 maf **Second lowest** Dead pool-related reductions: 0 maf **Tied lowest**	Median reductions increase as flow categories become drier. Shortage: 3.0 maf **Second highest** Dead pool-related reductions: 0 maf **Tied lowest**	Median reductions increase as flow categories become drier. Shortage: 3.1 maf **Highest** Dead pool-related reductions: 0 maf **Tied lowest**	Median reductions increase as flow categories become drier. Shortage: 2.0 maf **Third lowest** Dead pool-related reductions: 0 maf **Tied lowest**	Median reductions increase as flow categories become drier. Shortage: 1.9 maf **Third lowest** Dead pool-related reductions: 0 maf **Tied lowest**	Median reductions increase as flow categories become drier. Shortage: 2.1 maf **Third highest** Dead pool-related reductions: 0 maf **Tied lowest**
	Annual shortage by state under critically dry hydrology conditions (median values). Values are reported as percent of apportionment.	Arizona: 16.7%[4] **Lowest** California: 0% **Lowest** Nevada: 11% **Lowest**	Arizona: 41.1%[4] **Fourth highest** California: 0% **Lowest** Nevada: 27.2% **Fourth highest**	Arizona: 33.3% **Third lowest** California: 33.3% **Highest** Nevada: 33.3% **Third highest**	Arizona: 58.7% **Highest** California: 17.3% **Second highest** Nevada: 48.0% **Highest**	Arizona: 41.2% **Third highest** California: 10.0% **Second lowest** Nevada: 26.6% **Third lowest**	Arizona: 31.8% **Second lowest** California: 15.8% **Third lowest** Nevada: 22.0% **Second lowest**	Arizona: 53.1% **Second highest** California: 10.0% **Second lowest** Nevada: 36.3% **Second highest**
	Annual depletions (reported as percent of apportionment) by state under critically dry hydrology conditions (median values). Depletion is defined as total consumptive use (such as the amount of water diverted from the river) minus the return flow.	Arizona: 56.7% **Third lowest** California: 90.9% **Second highest** Nevada: 66.8% **Lowest**	Arizona: 58.9% **Second highest** California: 100% **Highest** Nevada: 83.3% **Second highest**	Arizona: 67.5% **Highest** California: 66.6% **Lowest** Nevada: 83.1% **Third highest**	Arizona: 42.5% **Lowest** California: 81.4% **Second lowest** Nevada: 69.8% **Second Lowest**	Arizona: 57.1% **Fourth highest** California 86.9% **Third highest** Nevada: 83.1% **Third highest**	Arizona: 58.2% **Third highest** California: 82.8% **Third lowest** Nevada: 86.6% **Highest**	Arizona: 51.8% **Second lowest** California: 86.0% **Fourth highest** Nevada: 73.3% **Third lowest**

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

[4] Note that these impacts are based on low maximum Lower Basin shortage volumes that translate to higher volumes of dead pool-related reductions (see **Figure TA 4-12**), which could result in significant but highly uncertain impacts.

Impact Category	Performance Indicator[1]	Impacts Summary

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
How would reservoir storage, reservoir releases, and corresponding changes in river flows downstream of the reservoirs affect projected **temperature**? *(continued)*	Annual average daily temperature of the Colorado River **at Pearce Ferry** under critically dry flow category (median values)	16.7 °C (62.1 °F)	16.7 °C (62.1 °F)	16.6 °C (61.9 °F)	16.8 °C (62.2 °F)	16.8 °C (62.2 °F)	16.8 °C (62.2 °F)	17 °C (62.6 °F)
	Annual maximum daily temperature of the Colorado River **at Pearce Ferry** under critically dry flow category (median values)	23.3 °C (73.9 °F)	23.5 °C (74.3 °F)	23.3 °C (73.9 °F)	23.6 °C (74.5 °F)	23.6 °C (74.5 °F)	23.6 °C (74.5 °F)	23.8 °C (74.8 °F)
How would reservoir storage, reservoir releases, and corresponding changes in river flows downstream of the reservoirs affect projected **dissolved oxygen**?	Percent of modeled futures in which *Lake Powell reservoir elevations stay above 3,490 feet and minimum dissolved oxygen concentration is greater than 2mg/L from Glen Canyon Dam releases in at least 90% of years.*	**20%** of modeled futures meet *the preferred minimum performance.*	**25%** of modeled futures meet *the preferred minimum performance.*	**79%** of modeled futures meet *the preferred minimum performance.*	**76%** of modeled futures meet *the preferred minimum performance.*	**34%** of modeled futures meet *the preferred minimum performance.*	**34%** of modeled futures meet *the preferred minimum performance.*	**44%** of modeled futures meet *the preferred minimum performance.*
How would reservoir storage, reservoir releases, and corresponding changes in river flows downstream of the reservoirs affect **harmful algal blooms and nutrients**?	Qualitative comparison of water year minimum Lake Powell reservoir elevations under critically dry flow category (median values)	Water year minimum Lake Powell elevation median is the lowest, which would pose the **highest increased risk** for cyanobacterial blooms.	Water year minimum Lake Powell elevation median is the second lowest, which would pose **increased risk** for cyanobacterial blooms.	Water year minimum Lake Powell elevation median is highest, which would pose a **decreased risk** for cyanobacterial blooms.	Water year minimum Lake Powell elevation median is the second highest, which would pose a **decreased risk** for cyanobacterial blooms.	Water year minimum Lake Powell elevation median is third lowest compared with the other alternatives, which would pose an **increased risk** for cyanobacterial blooms compared with the Enhanced Coordination and Maximum Operational Flexibility alternatives, but a **decreased risk** compared with the No Action and Basic Coordination alternatives.		Water year minimum Lake Powell elevation median is third highest, which would pose a **decreased risk** for cyanobacterial blooms.
How would reservoir storage, reservoir releases, and corresponding changes in river flows downstream of the reservoirs affect **dilution capacity**?	Qualitative comparison of water year minimum Lake Powell reservoir elevations under critically dry flow category (median values)	Water year minimum Lake Powell elevation median is the lowest, which would pose the **greatest increased risk** of greater concentrations of pollutants of concern but it is unlikely that any of the reservoir elevations of the alternatives would substantially reduce the dilution capacity and increase the concentration of pollutants of concern.	Water year minimum Lake Powell elevation median is the lowest, which would pose an **increased risk** of greater concentrations of pollutants of concern but it is unlikely that any of the reservoir elevations of the alternatives would substantially reduce the dilution capacity and increase the concentration of pollutants of concern.	Water yea minimum Lake Powell elevation median is the highest, which would pose a **decreased risk** of greater concentrations of pollutants of concern but it is unlikely that any of the reservoir elevations of the alternatives would substantially reduce the dilution capacity and increase the concentration of pollutants of concern.	Water year minimum Lake Powell elevation median is the highest, which would pose a **decreased risk** of greater concentrations of pollutants of concern but it is unlikely that any of the reservoir elevations of the alternatives would substantially reduce the dilution capacity and increase the concentration of pollutants of concern.	Water year minimum Lake Powell elevation median is third lowest compared with the other alternatives, which would pose an **increased risk** of greater concentrations of pollutants of concern compared with the Enhanced Coordination and Maximum Operational Flexibility alternatives, but a decreased risk compared with the No Action and Basic Coordination alternatives. However, it is unlikely that any of the reservoir elevations of the alternatives would substantially reduce the dilution capacity and increase the concentration of pollutants of concern.		Water year minimum Lake Powell elevation median is third highest, which would pose a **decreased risk** of greater concentrations of pollutants of concern but it is unlikely that any of the reservoir elevations of the alternatives would substantially reduce the dilution capacity and increase the concentration of pollutants of concern.

Shoreline Area	Percent of modeled futures in which ***Lake Mead*** *shoreline exposure area stays below 500 square kilometers in every month*.	**54%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**75%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**88%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**93%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**81%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.		**92%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.
	Percent of modeled futures in which ***Lake Powell*** *shoreline exposure area stays below 500 square kilometers in every month*.	**25%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**45%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**87%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**98%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**46%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.		**66%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.
Shoreline Dust Emissions	Percent of modeled futures in which ***Lake Mead*** *shoreline dust emissions stay below 500 kilograms in every month*.	**34%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**64%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**79%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**84%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**72%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.		**74%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.
	Percent of modeled futures in which ***Lake Powell*** *shoreline dust emissions stay below 450 kilograms in every month*.	**14%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**37%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**84%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**96%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.	**43%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.		**59%** of modeled futures meet *the preferred minimum performance* during the 2027-2039 modeling period.
How would lake reservoir elevations and releases impact power generation and carbon dioxide equivalent (**CO_2e**) emissions?	Change in CO_2e emissions due to a loss of hydropower generation at **Glen Canyon Dam** under average hydrology conditions.	Hydropower generation would be highly affected resulting in the **tied most CO_2e emissions** under this alternative. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be slightly less affected than under the Representative Preferred Alternative, resulting in the **third most CO_2e emissions** under this alternative. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be least affected, resulting in the **tied lowest CO_2e emissions** under this alternative. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be similar to that under the Enhanced Coordination Alternative, resulting in the **tied lowest CO_2e emissions** under this alternative. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be the same as under the No Action Alternative, resulting in the **tied most CO_2e emissions** under this alternative. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.		Hydropower generation would be slightly less affected than under the No Action Alternative, resulting in the **second most CO_2e emissions** under this alternative. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

Impact Category	Performance Indicator[1]	Impacts Summary

How would lake reservoir elevations and releases impact power generation and carbon dioxide equivalent (**CO_2e**) emissions? *(continued)*	Change in CO_2e emissions due to a loss of hydropower generation at **Hoover Dam** under average hydrology conditions.	Hydropower generation would be most affected resulting in the **most CO_2e emissions**, with potential decrease in CO_2e emissions. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be less affected than under the No Action Alternative, resulting in the **second most CO_2e emissions** under this alternative. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be similar to that under the Maximum Operational Flexibility Alternative.	Hydropower generation would be slightly more affected than under the Supply Driven Alternative, resulting in the **second lowest CO_2e emissions** under this alternative. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be least affected, resulting in the **lowest CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases. Hydropower generation would be the same between the two Supply Driven Alternatives with the Supply Driven (LB Pro Rata) having the **lowest CO_2e emissions**.		Hydropower generation would be similar to that under the Maximum Operational Flexibility Alternative.
	Change in CO_2e emissions due to a loss of hydropower generation at **Davis Dam** under average hydrology conditions.	Hydropower generation would be the least affected, resulting in the **lowest CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be slightly less affected than under the No Action Alternative, resulting in the **second lowest CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be highly affected, resulting in the **tied most CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be similar to that under the Enhanced Coordination Alternative, resulting in the **tied most CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be similar to that under the Enhanced Coordination Alternative. Hydropower generation would be similar between the two Supply Driven Alternatives with the Supply Driven (LB Pro Rata) having the **highest CO_2e emissions**.		Hydropower generation would be slightly less affected than under the Basic Coordination Alternative, resulting in the **third lowest CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.
	Change in CO_2e emissions due to a loss of hydropower generation at **Parker Dam** under average hydrology conditions.	Hydropower generation would be the least affected, resulting in the **tied least CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be similar to that under the No Action Alternative, resulting in the **tied least CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be highly affected, resulting in the **most CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Hydropower generation would be slightly more affected than under the Representative Preferred Alternative, resulting in the **third least CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.	Under the Supply Driven Alternative (LB Priority approach), hydropower generation would be similar to that under the Maximum Flexibility Alternative. Under the Supply Driven Alternative (LB Pro Rata approach), hydropower generation would be highly affected, resulting in the **second most CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.		Hydropower generation would be slightly more affected than under the No Action Alternative, resulting in the **second least CO_2e emissions**. This is due to the inverse correlation between CO_2e emissions from alternative energy sources and generation from reservoir elevations and releases.

Vegetation Including Special Status Species (See Section 3.9)

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Vegetation, including special status plant species	Marsh habitat (Lake Powell, Lake Mead, and Hoover Dam to SIB Reaches) – Changes in water fluctuations within a single year compared to historical conditions.	The No Action Alternative is **among the middle performing** alternative for the Lake Powell reach because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. The No Action Alternative is **among the best performing** alternatives for the Hoover Dam to SIB reaches because it has annual variability similar to historic conditions. The No Action Alternative is **among the least performing** alternatives for the Lake Mead reach because its annual variability is least like historic conditions.	The Basic Coordination Alternative is **among the middle performing** alternatives for the Lake Powell reach because is neither the most similar nor the least similar to historic conditions for these reaches. The Basic Coordination Alternative is **among the best performing** alternatives for the Lake Mead and Hoover Dam to SIB reaches because it has annual variability similar to historic conditions.	The Enhanced Coordination Alternative is **among the best performing** alternatives for the Lake Powell reach because it has annual variability similar to historic conditions. The Enhanced Coordination Alternative is **among the least performing** alternatives for the Lake Mead and Hoover Dam to SIB reach because its annual variability is least like historic conditions.	The Maximum Operational Flexibility Alternative is **among the best performing** alternatives for the Lake Powell, Lake Mead, and Hoover Dam to the SIB reaches because it has annual variability similar to historic conditions.	The Supply Driven Alternative is **among the best performing** alternative for the Hoover Dam to SIB reach because it has annual variability similar to historic conditions. The Supply Driven Alternative is **among the middle performing** alternative for the Lake Mead reach because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. The Supply Driven Alternative is **among the least performing** alternatives for Lake Powell because its annual variability is least like historic conditions.		The Representative Preferred Alternative is **among the middle performing** alternatives for the Lake Powell and Lake Mead reaches because is neither the most similar nor the least similar to historic conditions for these reaches in the first decade. The Representative Preferred Alternative is **among the least performing** alternatives for the Hoover Dam to the SIB because its annual variability is least like historic conditions in the first decade. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.
	Woody riparian habitat (Lake Powell, Lake Mead, and Hoover Dam to SIB Reaches) – Changes in water fluctuations in the preceding 5 years compared to historical conditions.	The No Action Alternative is **among the middle performing** alternative for the Lake Powell, Lake Mead, and Hoover Dam to SIB reaches because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches.	The Basic Coordination Alternative is **among the middle performing** alternative for the Lake Powell because the annual variability is neither the most similar nor the least similar to historic conditions for this reach. The Basic Coordination Alternative is **among the best performing** alternatives for the Lake Mead and Hoover Dam to SIB reaches because it has annual variability similar to historic conditions.	The Enhanced Coordination Alternative is **among the best performing** alternatives for the Lake Powell reach because it has annual variability similar to historic conditions. The Enhanced Coordination Alternative is **among the least performing** alternatives for Lake Mead and the Hoover Dam to SIB reach because its annual variability is least like historic conditions.	The Maximum Operational Flexibility Alternative is **among the middle performing** alternatives for the Lake Powell reach because it has annual variability similar to historic conditions. The Maximum Operational Flexibility Alternative is **among the best performing** alternatives for the Lake Mead reach because it has annual variability similar to historic conditions. The Maximum Operational Flexibility Alternative is **among the least performing** alternatives for the Hoover Dam to SIB reach because its annual variability is least like historic conditions.	The Supply Driven Alternative is **never the best performing** alternative because it never has variability most similar to historic conditions. The Supply Driven Alternative is **among the middle performing** alternative for the Lake Mead and Hoover Dam to SIB reaches because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. The Supply Driven Alternative is **among the least performing** alternatives for the Lake Powell reach because its annual variability is least like historic conditions.		The Representative Preferred Alternative is **among the middle performing** alternatives for all reaches because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	**Basic Coordination Alternative**	**Enhanced Coordination Alternative**	**Maximum Operational Flexibility Alternative**	**Supply Driven Alternative (LB Priority)**	**Supply Driven Alternative (LB Pro Rata)**	**Representative Preferred Alternative**
Vegetation, including special status plant species *(continued)*	Upland habitat (Lake Powell, Lake Mead, and Hoover Dam to SIB Reaches) – Changes in water fluctuations in either the preceding single year or preceding 5 years compared to historical conditions.	Upland habitat would be gained or lost depending on whether conditions are suitable for marsh or woody riparian habitat (see above).						
	Marsh habitat suitable area (Glen Canyon Dam to Lake Mead Reach) - A change from the median and interquartile ranges from modeled historic conditions	Considering all modeled natural flow conditions, no alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach. Across all sub-reaches, there is a general trend of less suitable habitat area for marsh vegetation under wetter conditions and more suitable habitat area under drier conditions compared to modeled historic conditions.						
	Woody Riparian habitat suitable area (Glen Canyon Dam to Lake Mead Reach) - A change from the median and interquartile ranges from modeled historic conditions.	Considering all modeled natural flow conditions, no alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach. Across all sub-reaches, there is a general trend of less suitable habitat area for woody riparian vegetation under wetter conditions and more suitable habitat area under drier conditions compared to modeled historic conditions.						
	Upland habitat suitable area	Upland habitat would be gained or lost depending on whether conditions are suitable for marsh or woody riparian habitat (see above).						
	Native Species Richness (Glen Canyon Dam to Lake Mead Reach) - A change from the median and interquartile ranges from modeled historic conditions.	Considering all modeled natural flow conditions and sub-reaches, no alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach. All alternatives show decreased native species richness compared to modeled historic conditions under all flow conditions.						
	Proportion Native Species Cover (Glen Canyon Dam to Lake Mead Reach) - A change from the median and interquartile ranges from modeled historic conditions.	Considering all modeled natural flow conditions, no alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach. Across all sub-reaches, there is a general trend of less proportion of native species cover under wetter conditions and more proportion of native species cover under drier conditions compared to modeled historic conditions.						

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Vegetation, including special status plant species *(continued)*	Annual Total Vegetation Cover (Glen Canyon Dam to Lake Mead Reach) - A change from the median and interquartile ranges from modeled historic conditions.	Considering all modeled natural flow conditions, no alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach. Across all sub-reaches, there is a general trend of less annual total vegetation cover under wetter conditions and more annual total vegetation cover under drier conditions compared to modeled historic conditions.						

Terrestrial Wildlife Including Special Status Species (See Section 3.10)

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Terrestrial wildlife species habitat availability, including for special status species	Terrestrial wildlife species using marsh habitat – Changes in water fluctuations within a single year compared to historical conditions.	The No Action Alternative is **among the middle performing** alternative for the Lake Powell reach because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. The No Action Alternative is **among the best performing** alternatives for the Hoover Dam to SIB reaches because it has annual variability similar to historic conditions. The No Action Alternative is **among the least performing** alternatives for the Lake Mead reach because its annual variability is least like historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.	The Basic Coordination Alternative is **among the middle performing** alternatives for the Lake Powell reach because is neither the most similar nor the least similar to historic conditions for these reaches. The Basic Coordination Alternative is **among the best performing** alternatives for the Lake Mead and Hoover Dam to SIB reaches because it has annual variability similar to historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.	The Enhanced Coordination Alternative is **among the best performing** alternatives for the Lake Powell reach because it has annual variability similar to historic conditions. The Enhanced Coordination Alternative is **among the least performing** alternatives for the Lake Mead and Hoover Dam to SIB reach because its annual variability is least like historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.	The Maximum Operational Flexibility Alternative is **among the best performing** alternatives for the Lake Powell, Lake Mead, and Hoover Dam to the SIB reaches because it has annual variability similar to historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.	The Supply Driven Alternative is **among the best performing** alternative for the Hoover Dam to SIB reach because it has annual variability similar to historic conditions. The Supply Driven Alternative is **among the middle performing** alternative for the Lake Mead reach because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. The Supply Driven Alternative is **among the least performing** alternatives for Lake Powell because its annual variability is least like historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.		The Representative Preferred Alternative is **among the middle performing** alternatives for the Lake Powell and Lake Mead reaches because is neither the most similar nor the least similar to historic conditions for these reaches in the first decade. The Representative Preferred Alternative is **among the least performing** alternatives for the Hoover Dam to the SIB because its annual variability is least like historic conditions in the first decade. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Terrestrial wildlife species habitat availability, including for special status species *(continued)*	Terrestrial wildlife species using woody riparian habitat – Changes in water fluctuations in the preceding 5 years compared to historical conditions.	The No Action Alternative is **among the middle performing** alternative for the Lake Powell, Lake Mead, and Hoover Dam to SIB reaches because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.	The Basic Coordination Alternative is **among the middle performing** alternative for the Lake Powell because the annual variability is neither the most similar nor the least similar to historic conditions for this reach. The Basic Coordination Alternative is **among the best performing** alternatives for the Lake Mead and Hoover Dam to SIB reaches because it has annual variability similar to historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.	The Enhanced Coordination Alternative is **among the best performing** alternatives for the Lake Powell reach because it has annual variability similar to historic conditions. The Enhanced Coordination Alternative is **among the least performing** alternatives for Lake Mead and the Hoover Dam to SIB reach because its annual variability is least like historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.	The Maximum Operational Flexibility Alternative is **among the middle performing** alternatives for the Lake Powell reach because it has annual variability similar to historic conditions. The Maximum Operational Flexibility Alternative is **among the best performing** alternatives for the Lake Mead reach because it has annual variability similar to historic conditions. The Maximum Operational Flexibility Alternative is **among the least performing** alternatives for the Hoover Dam to SIB reach because its annual variability is least like historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.	The Supply Driven Alternative is **never the best performing** alternative because it never has variability most similar to historic conditions. The Supply Driven Alternative is **among the middle performing** alternative for the Lake Mead and Hoover Dam to SIB reaches because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. The Supply Driven Alternative is **among the least performing** alternatives for the Lake Powell reach because its annual variability is least like historic conditions. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.		The Representative Preferred Alternative is **among the middle performing** alternatives for all reaches because the annual variability is neither the most similar nor the least similar to historic conditions for these reaches. Considering all modeled natural flow conditions, no Alternative is better performing compared to the modeled historic conditions in the Glen Canyon Dam to Lake Mead reach.
	Terrestrial wildlife species using upland habitat – Changes in water fluctuations in either the preceding single year or preceding 5 years compared to historical conditions.	Upland habitat would be gained or lost depending on whether conditions are suitable for marsh or woody riparian habitat (see above).						

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

Cultural Resources (See Section 3.11)

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Projected end-of-year lake elevations that may expose cultural resources to damage from wave action, wet/dry cycling, or increased ease of access	Projected end-of-year lake elevations for Lake Powell (EOWY) and Lake Mead (EOCY) and number of cultural resources potentially impacted	Lake Powell: Under average conditions, median water levels fall below 3,550 feet exposing at least 316 archaeological sites. Under critically dry conditions, median water levels drop below 3,440 feet, potentially leaving the most sites exposed with at least 415 sites exposed. Lake Mead: During average hydrologic conditions, median elevations are around 990below 980 feet potentially exposing at least 301 known sites. In critically dry conditions, all 310 sites would likely be exposed due to low reservoir elevations.	Lake Powell: Under average conditions, median water levels fall below 3,570 feet exposing at least 316 archaeological sites. Under critically dry conditions, median water levels drop below 3,490 feet with at least 415 sites exposed. Lake Mead: During average hydrological conditions, median elevations are around or below 1,060 feet exposing at least 280 sites. In critically dry conditions, median elevations drop below 980 feet, exposing at least 296 sites would likely be exposed.	Lake Powell: Under average conditions, median water levels drop to around 3,610 feet, leaving at more than 138 sites exposed. Under critically dry conditions, median water levels drop below 3,560 feet, potentially leaving at least 316 sites exposed. Lake Mead: Under average conditions, median elevations are around 1,110 feet exposing up to at least 265 sites. In critically dry conditions, all 310 sites could be exposed due to low reservoir elevations.	Lake Powell: Under average conditions, median water levels drop to around 3,600 feet, leaving at least 197 sites exposed. Under critically dry conditions, median water levels drop below 3,550 feet, potentially leaving at least 316 site exposed. Lake Mead: Under average conditions, median elevations are around or below 1,130 feet exposing up to at least 245 sites. Under critically dry conditions, median elevations are around 1,000 feet leaving at least 296 sites exposed.	Lake Powell: Under average conditions, median elevations are around 3,580 feet leaving at least 280 sites exposed. Under critically dry conditions, median water levels drop below 3,490 feet, potentially leaving the most sites exposed with at least 415 sites exposed. Lake Mead: During average conditions, median elevations are around or below 1,150 feet exposing at least 227 known sites. Under critically dry conditions, minimum elevations are below 1,030 feet and could potentially expose at least 291 sites. .		Lake Powell: Under average conditions, median elevations are just below 3,600 feet leaving at least 249 sites exposed. Under critically dry conditions, median water levels drop below 3,510 feet, potentially leaving the most sites exposed with at least 316 sites exposed. Lake Mead: During average conditions, median elevations are around or below 1,100 feet exposing at least 265 known sites. Under critically dry conditions, minimum elevations are below 990 feet and could potentially expose at least 296 sites.
	Lake Powell: Percent of modeled futures for the first decadal period (2027–2039) in which *the preservation risk at Lake Powell is below 2.72 in at least 90% of months* Lake Mead: Percent of modeled futures for the first decadal period (2027–2039) in which *the preservation risk at Lake Mead is below 2.24 in at least 90% of months*	Lake Powell: **12%** of modeled futures meet *the preferred minimum performance*. Lake Mead: **1%** of modeled futures meet *the preferred minimum performance*.	Lake Powell: **14%** of modeled futures meet *the preferred minimum performance*. Lake Mead: **2%** of modeled futures meet *the preferred minimum performance*.	Lake Powell: **30%** of modeled futures meet *the preferred minimum performance*. Lake Mead: **2%** of modeled futures meet *the preferred minimum performance*.	Lake Powell: **25%** of modeled futures meet *the preferred minimum performance*. Lake Mead: **3%** of modeled futures meet *the preferred minimum performance*.	Lake Powell: **12%** of modeled futures meet *the preferred minimum performance*. Lake Mead: **5%** of modeled futures meet *the preferred minimum performance*.		Lake Powell: **16%** of modeled futures meet *the preferred minimum performance*. Lake Mead: **3%** of modeled futures meet *the preferred minimum performance*.

		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Economic contributions and social conditions associated with changes in agriculture due to water shortages	Level of annual impacts on acres of fallowed agricultural lands during a maximum shortage	For Arizona non-tribal agriculture entitlement holders, the No Action Alternative has the **lowest level of impact** on acres of fallowed lands during a maximum shortage of 0.6 maf, with an increase of about 1,000 fallowed acres.[4] For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the No Action Alternative is among the alternatives with the **lowest level of impact** on acres of fallowed lands during a maximum shortage of 0.6 maf, with no change in fallowed acres. For Arizona tribal agriculture entitlement holders, the No Action Alternative has the **lowest level of impact** on acres of fallowed lands during a maximum shortage of 0.6 maf, with an increase of about 12,000 fallowed acres.	For Arizona non-tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with a **low level of impact** on acres of fallowed lands during a maximum shortage of 1.5 maf, with an increase of about 7,000 fallowed acres.[4] For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with the **lowest level of impact** on acres of fallowed lands during a maximum shortage of 1.5 maf, with no change in fallowed acres. For Arizona tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with a **medium level of impact** on acres of fallowed lands during a maximum shortage of 1.5 maf, with an increase of about 50,000 fallowed acres.	For Arizona non-tribal agriculture entitlement holders, the Enhanced Coordination Alternative is among the alternatives with a **medium level of impact** on acres of fallowed lands during a maximum shortage of 3.0 maf, with an increase of about 62,000 fallowed acres. For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the Enhanced Coordination Alternative has the **highest level of impact** on acres of fallowed lands during a maximum shortage of 3.0 maf, with an increase of about 283,000, 5,000, and 700 fallowed acres for California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, respectively. For Arizona tribal agriculture entitlement holders, the Enhanced Coordination Alternative is among the alternatives with a **medium level of impact** on acres of fallowed lands during a maximum shortage of 3.0 maf, with an increase of about 39,000 fallowed acres.	For Arizona non-tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative has the **highest level of impact** on acres of fallowed lands during a maximum shortage of 4.0 maf, with an increase of about 103,000 fallowed acres. For California non-tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative is among the alternatives with a **high level of impact** on acres of fallowed lands during a maximum shortage of 4.0 maf, with an increase of about 227,000 fallowed acres. For California tribal and Nevada tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative is among the alternatives with the **lowest level of impact** on acres of fallowed lands during a maximum shortage of 4.0 maf, with no change in fallowed acres. For Arizona tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative has the **highest level of impact** on acres of fallowed lands during a maximum shortage of 4.0 maf, with an increase of about 68,000 fallowed acres.	For Arizona non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a **low level of impact** on acres of fallowed lands during a maximum shortage of 2.1 maf, with an increase of about 8,000 fallowed acres. For California non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a **low level of impact** on acres of fallowed lands during a maximum shortage of 2.1 maf, with an increase of about 12,000 fallowed acres. For California tribal and Nevada tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with the **lowest level of impact** on acres of fallowed lands during a maximum shortage of 2.1 maf, with no change in fallowed acres. For Arizona tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a **high level of impact** on acres of fallowed lands during a maximum shortage of 2.1 maf, with an increase of about 54,000 fallowed acres.	For Arizona non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **medium level of impact** on acres of fallowed lands during a maximum shortage of 2.1 maf, with an increase of about 61,000 fallowed acres. For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **high level of impact** on acres of fallowed lands during a maximum shortage of 2.1 maf, with an increase of about 153,000, 3,000, and 500 fallowed acres for California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, respectively. For Arizona tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **medium level of impact** on acres of fallowed lands during a maximum shortage of 2.1 maf, with an increase of about 39,000 fallowed acres.	For Arizona non-tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on acres of fallowed lands during a maximum shortage of 3.6 maf, with an increase of about 91,000 fallowed acres. For California non-tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on acres of fallowed lands during a maximum shortage of 3.6 maf, with an increase of about 151,000 fallowed acres. For California tribal and Nevada tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with the **lowest level of impact** on acres of fallowed lands during a maximum shortage of 3.6 maf, with no change in fallowed acres. For Arizona tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on acres of fallowed lands during a maximum shortage of 3.6 maf, with an increase of about 67,000 fallowed acres.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

[4] Note that these impacts are based on low maximum Lower Basin shortage volumes that translate to higher volumes of dead pool-related reductions (see **Figure TA 4-12**), which could result in significant but highly uncertain impacts.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Economic contributions and social conditions associated with changes in agriculture due to water shortages *(continued)*	Level of annual impacts on market value of crop production from a maximum shortage	For Arizona non-tribal agriculture entitlement holders, the No Action Alternative has the **lowest level of impact** on market value of crops during a maximum shortage of 0.6 maf, with a loss in market value of about $1.8 million.[4] For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the No Action Alternative is among the alternatives with the **lowest level of impact** on market value of crops during a maximum shortage of 0.6 maf, with no loss in market value. For Arizona tribal agriculture entitlement holders, the No Action Alternative has the **lowest level of impact** on market value of crops during a maximum shortage of 0.6 maf, with a loss in market value of about $17.4 million.	For Arizona non-tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with a **low level of impact** on market value of crops during a maximum shortage of 1.5 maf, with a loss in market value of about $17.6 million.[4] For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with the **lowest level of impact** on market value of crops during a maximum shortage of 1.5 maf, with no change in market value. For Arizona tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with a **high level of impact** on market value of crops during a maximum shortage of 1.5 maf, with a loss in market value of about $82.3 million.	For Arizona non-tribal agriculture entitlement holders, the Enhanced Coordination Alternative is among the alternatives with a **medium level of impact** on market value of crops during a maximum shortage of 3.0 maf, with a loss in market value of about $79.6 million. For California non-tribal, agriculture entitlement holders, the Enhanced Coordination Alternative is among the alternatives with a **high level of impact** on market value of crops during a maximum shortage of 3.0 maf, with a loss in market value of about $691.8 million. For California tribal and Nevada tribal agriculture entitlement holders, the Enhanced Coordination Alternative has the **highest level of impact** on market value of crops during a maximum shortage of 3.0 maf, with a loss in market value of about $10.9 million and $0.6 million, for California tribal and Nevada tribal agriculture entitlement holders, respectively. For Arizona tribal agriculture entitlement holders, the Enhanced Coordination Alternative is among the alternatives with a **medium level of impact** on market value of crops during a maximum shortage of 3.0 maf, with a loss in market value of about $52.5 million.	For Arizona non-tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative has the **highest level of impact** on market value of crops during a maximum shortage of 4.0 maf, with a loss in market value of about $150.8 million. For California non-tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative has the **highest level of impact** on market value of crops during a maximum shortage of 4.0 maf, with a loss in market value of about $1,094.3 million. For California tribal and Nevada tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative is among the alternatives with the **lowest level of impact** on market value of crops during a maximum shortage of 4.0 maf, with no change in market value. For Arizona tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative has the **highest level of** on market value of crops during a maximum shortage of 4.0 maf, with a loss in market value of about $113.2 million.	For Arizona non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a **low level of impact** on market value of crops during a maximum shortage of 2.1 maf, with a loss in market value of about $21.0 million. For California non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a **low level of impact** on market value of crops during a maximum shortage of 2.1 maf, with a loss in market value of about $25.4 million. For California tribal and Nevada tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with the **lowest level of impact** on market value of crops during a maximum shortage of 2.1 maf, with no change in market value. For Arizona tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a **high level of impact** on market value of crops during a maximum shortage of 2.1 maf with a loss in market value of about $88.7 million.	For Arizona non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **medium level of impact** on market value of crops during a maximum shortage of 2.1 maf, with a loss in market value of about $78.2 million. For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **high level of impact** on market value of crops during a maximum shortage of 2.1 maf, with a loss in market value of about $473.8 million, $7.7 million, and $0.5 million, for California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, respectively. For Arizona tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **medium level of impact** on market value of crops during a maximum shortage of 2.1 maf with a loss in market value of about $51.7 million.	For Arizona non-tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on market value of crops during a maximum shortage of 3.6 maf, with a loss in market value of about $133.1 million. For California non-tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on market value of crops during a maximum shortage of 3.6 maf, with a loss in market value of about $812.7 million. For California tribal and Nevada tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with the **lowest level of impact** on market value of crops during a maximum shortage of 3.6 maf, with no change in market value. For Arizona tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on market value of crops during a maximum shortage of 3.6 maf, with a loss in market value of about $111.9 million.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

[4] Note that these impacts are based on low maximum Lower Basin shortage volumes that translate to higher volumes of dead pool-related reductions (see **Figure TA 4-12**), which could result in significant but highly uncertain impacts.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Economic contributions and social conditions associated with changes in agriculture due to water shortages *(continued)*	Level of annual impacts on economic contributions, including jobs, labor income, and total economic output from a maximum shortage	For Arizona non-tribal agriculture entitlement holders, the No Action Alternative has the **lowest level of impact** on economic contributions during a maximum shortage of 0.6 maf, with a loss of over 10 jobs, about $0.6 million in labor income, and $2.8 million in economic output.[4] For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the No Action Alternative is among the alternatives with the **lowest level of impact** on economic contributions during a maximum shortage of 0.6 maf, with no loss in jobs, labor income, or economic output. For Arizona tribal agriculture entitlement holders, the No Action Alternative has the **lowest level of impact** on economic contributions during a maximum shortage of 0.6 maf, with a loss of about 135 jobs, $10.7 million in labor income, and $34.8 million in economic output.	For Arizona non-tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with a **medium level of impact** on economic contributions during a maximum shortage of 1.5 maf, with a loss of about 135 jobs, $8.1 million in labor income, and $27.4 million in economic output.[4] For California non-tribal, California tribal, and Nevada tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with the **lowest level of impact** on economic contributions during a maximum shortage of 1.5 maf, with no change in jobs, labor income, or economic output. For Arizona tribal agriculture entitlement holders, the Basic Coordination Alternative is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 1.5 maf, with a loss of about 900 jobs, $48.1 million in labor income, and $162.2 million in economic output[4]	For Arizona non-tribal agriculture entitlement holders, the Enhanced Coordination Alternative is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 3.0 maf, with a loss of about 500 jobs, $29.0 million in labor income, and $126.8 million in economic output. For California non-tribal agriculture entitlement holders, the Enhanced Coordination Alternative is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 3.0 maf, with a loss of about 4,000 jobs, $246.5 million in labor income, and $1.0 billion in economic output. For California tribal and Nevada tribal agriculture entitlement holders, the Enhanced Coordination Alternative has the **highest level of impact** on economic contributions during a maximum shortage of 3.0 maf, with a loss of about 63 jobs, $3.9 million in labor income, and $15.9 million in economic output for California tribal entitlement holders, and a loss of about 13 jobs, $0.1 million in labor income, and $0.9 million in economic output for Nevada tribal agriculture entitlement holders. For Arizona tribal agriculture entitlement holders, the Enhanced Coordination Alternative is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 1.5 maf,	For Arizona non-tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative has the **highest level of impact** on economic contributions during a maximum shortage of 4.0 maf, with a loss of about 1,000 jobs, $56.5 million in labor income, and $237.7 million in economic output. For California non-tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative has the **highest level of impact** on economic contributions during a maximum shortage of 4.0 maf, with a loss of about 11,000 jobs, $824.7 million in labor income, and $1.8 billion in economic output. For California tribal and Nevada tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative is among the alternatives with the **lowest level of impact** on economic contributions during a maximum shortage of 4.0 maf, with no change in jobs, labor income, or economic output. For Arizona tribal agriculture entitlement holders, the Maximum Operational Flexibility Alternative has the **highest level of** on economic contributions during a maximum shortage of 1.5 maf, with a loss of about 1,000 jobs, $64.7 million in labor income, and $222.6 million in economic output.	For Arizona non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a **medium level of impact** on economic contributions during a maximum shortage of 2.1 maf, with a loss of about 160 jobs, $9.5 million in labor income, and $32.6 million in economic output. For California non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a low **level of impact** on economic contributions during a maximum shortage of 2.1 maf, with a loss of over 140 jobs, about $8.5 million in labor income, and $36.9 million in economic output. For California tribal and Nevada tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with the **lowest level of impact** on economic contributions during a maximum shortage of 2.1 maf, with no change in jobs, labor income, or economic output. For Arizona tribal agriculture entitlement holders, the Supply Driven Alternative (LB Priority approach) is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 1.5 maf, with a loss of about 900 jobs, $51.3 million in labor income, and $174.6 million in economic output.	For Arizona non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 2.1 maf, with a loss of 500 jobs, about $28.4 million in labor income, and $124.3 million in economic output. For California non-tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 2.1 maf, with a loss of about 3,000 jobs, $173.4 million in labor income, and $689.2 million in economic output. For California tribal and Nevada tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **low level of impact** on economic contributions during a maximum shortage of 2.1 maf, with a loss of about 45 jobs, $2.8 million in labor income, and $11.2 million in economic output for California tribal entitlement holders, and a loss of about 9 jobs, $0.1 million in labor income, and $0.6 million in economic output for Nevada tribal agriculture entitlement holders. For Arizona tribal agriculture entitlement holders, the Supply Driven Alternative (LB Pro Rata approach) is among the alternatives with a **high level of impact** on economic contributions during a	For Arizona non-tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 3.6 maf, with a loss of 900 jobs, about $50.5 million in labor income, and $210.7 million in economic output. For California non-tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 3.6 maf, with a loss of 9,000 jobs, about $718.1 million in labor income, and $1.3 billion in economic output. For California tribal and Nevada tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with the **lowest level of impact** on economic contributions during a maximum shortage of 3.6 maf, with no change in jobs, labor income, or economic output. For Arizona tribal agriculture entitlement holders, the Representative Preferred Alternative is among the alternatives with a **high level of impact** on economic contributions during a maximum shortage of 3.6 maf, with a loss of 1,000 jobs, about $64.0 million in labor income, and $220.0 million in economic output.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

[4] Note that these impacts are based on low maximum Lower Basin shortage volumes that translate to higher volumes of dead pool-related reductions (see **Figure TA 4-12**), which could result in significant but highly uncertain impacts.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	**Basic Coordination Alternative**	**Enhanced Coordination Alternative**	**Maximum Operational Flexibility Alternative**	**Supply Driven Alternative (LB Priority)**	**Supply Driven Alternative (LB Pro Rata)**	**Representative Preferred**
Economic contributions and value associated with Lake-Based Recreation	Changes in recreation visitor spending and associated regional employment, labor income, and total economic output from lake-based recreation-related activities	Under No Action and all Action Alternatives, declining reservoir elevations at Lake Powell and Lake Mead reduce access to boating, marina operations, and shoreline recreation in dry conditions. This is expected to lead to a decrease in visitation and associated spending on lodging, food services, and transportation-related spending in nearby gateway communities. Businesses that rely on water-based visitation, including marinas, guide services, motels, and equipment rentals, are expected to experience losses in jobs and labor income. Downstream economic effects also weaken, reducing Potential for overall economic output.	Decreases in visitation and associated spending would occur under dry conditions as described under the No Action Alternative. For Lake Powell, economic contributions associated with recreational use are likely to be similar to existing conditions For Lake Mead, there is more robust performance related to recreation site access and navigation thresholds, therefore visitation and spending associated with this reservoir are anticipated to be maintained at levels at or above that of the No Action Alternative.	Decreases in visitation and associated spending would occur under dry conditions as described under the No Action Alternative. This alternative is among the most robust in terms of meeting thresholds for navigation in Lake Powell, and recreation access and Lake Mead. Consequently, Employment and income losses remain but occur at lower levels relative to No Action and Basic Coordination Alternatives. Gateway communities experience more consistent seasonal activity.	Decreases in visitation and associated spending would occur under dry conditions as described under the No Action Alternative. As discussed under for the Maximum Operational Flexibility Alternative, consequently, economic contributions from lake-based recreation would likely be higher than the CCS Comparative Baseline and No Action Alternative due to more robust maintenance of access for recreation sites and navigation Consequently Employment and income losses remain but occur at lower levels relative to No Action and Basic Coordination Alternatives. Gateway communities experience more consistent seasonal activity.	Decreases in visitation and associated spending would occur under dry conditions as described under the No Action Alternative. For Lake Powell recreation site and navigation access would be less robust than the No Action Alternative which could further impact recreational spending and gateway businesses and concessionaire associated with Lake Powell. In contrast, for Lake Mead, the Supply Driven Alternative (LB Priority approach) modeling represents the most robust outcomes for recreation site access and navigation, supporting continued or increased spending associated with recreation activities for this reservoir.	Decreases in visitation and associated spending would occur under dry conditions as described under the No Action Alternative. Impacts would be the same as described for the Supply Driven Alternative (LB Priority approach).	Decreases in visitation and associated spending would occur under dry conditions as described under the No Action Alternative. On Lake Powell, the Representative Preferred would be slightly more robust in terms of maintenance of critical thresholds for navigation than the No Action Alternative and CCS Comparative Baseline. Compared to other action alternatives, this is better than the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), but less robust than the Enhanced Coordination and Maximum Operational Flexibility Alternatives in terms of support for recreational spending. For reservoir-based recreation on Lake Mead, the Representative Preferred modeling represents less robust outcomes for recreational site access as compared to the CCS Comparative Baseline but slightly more robust outcomes than the No Action Alternative This is a similar level of performance to the other action alternatives. For navigation, the Representative Preferred Alternative is more robust at meeting defined thresholds than both the No Action and CCS Comparative Baseline.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred
Economic contributions and value associated with Lake-Based Recreation *(continued)*	*(see above)*	*(see above)*	*(see above)*	*(see above)*	*(see above)*	*(see above)*	*(see above)*	Overall, recreational spending and gateway businesses and concessionaire associated with Lake Mead would be similar to other action alternatives.
	Percent of modeled futures in which *the annual recreational value[5] of whitewater boating exceeds 32 million dollars at least 90% of years* over the first decadal period. This threshold indicates when modeled futures achieve recreation values at least as high as the lowest 10% of outcomes for recreation value based on recent historic hydrologic data (2020-2023).	**60%** of modeled futures meet *the preferred minimum performance.*	**78%** of modeled futures meet *the preferred minimum performance.*	**18%** of modeled futures meet *the preferred minimum performance.*	**36%** of modeled futures meet *the preferred minimum performance.*	**38%** of modeled futures meet *the preferred minimum performance.*	**38%** of modeled futures meet *the preferred minimum performance.*	**37%** of modeled futures meet *the preferred minimum performance.*

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

[5] Recreational value of whitewater boating is calculated based on net economic value changes for whitewater rafting in Grand Canyon. This approach follows the methods used in the Glen Canyon Dam Long-Term Experimental and Management Plan Final Supplemental Environmental Impact Statement, where past survey research (Neher et al. 2017, Bishop et al. 1987) informed models to project the change in net economic value under different river flow scenarios. These models link willingness-to-pay estimates for boaters to hydrologic conditions, providing a measure of recreation benefits that extends beyond market spending. Reclamation used similar methods for the analysis of potential impacts on recreation as were used in the 2007 Final EIS and 2024 Near-term Colorado River Operations Final Supplemental Environmental Impact Statement (2024 Final SEIS) to assess the effects on recreation value associated with white-water boating.

[6] Recreational value of angling is calculated based on net economic value changes for angling in Glen Canyon. This approach follows the methods used in the Glen Canyon Dam Long-Term Experimental and Management Plan Final Supplemental Environmental Impact Statement, where past survey research (Neher et al. 2017, Bishop et al. 1987) informed models to project the change in net economic value under different river flow scenarios. These models link willingness-to-pay estimates for boaters to hydrologic conditions, providing a measure of recreation benefits that extends beyond market spending. Reclamation used similar methods for the analysis of potential impacts on recreation as were used in the 2007 Final EIS and 2024 Final SEIS to assess the effects on recreation value associated with angling.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
How would anticipated water shortages and changes in water levels in reservoirs and river segments affect access and quality of nonmarket values?	Changes in existence and symbolic values of the river due to shifts in scenic character or ecological conditions.	Lower reservoir elevations and increased shoreline exposure reduce opportunities for solitude, as well as access to quiet coves, beaches, and natural shorelines. These conditions diminish the experiential qualities that many users value. Extended low-flow periods could also impact river-based experiences in Grand Canyon due to changes in setting which could impact perceived naturalness (see **TA 14, Recreation**). Cultural and spiritual values tied to iconic landscapes and cultural artifacts could also be impacted in low-hydrologic flow periods (see **TA 11, Cultural Resources**). Ecological services such as riparian habitat stability may decline, influencing non-use values related to wildlife and vegetation communities (see **TA 8, Biological Resources – Fish and Other Aquatic Resources**).	Under dry conditions nonmarket values could be impacted as discussed under the no action alternative. More frequent low-elevation conditions could occur in the Basic Coordination Alternative, which could noticeably affect nonmarket values tied to lake-based recreation and scenic quality (see **TA 14, Recreation**) although at a reduced level compared to the No Action Alternative. Reduced reservoir levels may expose previously submerged areas, altering visual character and diminishing opportunities for solitude. Overall impacts are similar to the No Action.	Under dry conditions nonmarket values could be impacted as discussed under the no action alternative. The Enhanced Coordination Alternative is more robust in terms of the support for nonmarket values, particularly for values associated with Lake Powell, as reservoir levels would be maintained at thresholds supporting access for boating and camping in more modeled futures, supporting experiential benefits and cultural connections (see **TA 11, Cultural Resources**). River-based recreation quality is expected to remain high, due to increased stability with flow-dependent activities (see **TA 14, Recreation**). Non-use values tied to ecosystem services, such as wildlife habitat and riparian vegetation, would also be supported (see **TA 8, Biological Resources – Fish and Other Aquatic Resources**).	Under dry conditions nonmarket values could be impacted as discussed under the no action alternative. Similar to the Enhanced Coordination Alternative, this alternative is more robust in terms of the support for nonmarket values, particularly for values associated with Lake Powell, and for river Based recreation, due to increased stability with flow-dependent activities (see **TA 14, Recreation**).	Outcomes produced by the Supply Driven Alternative (LB Priority approach) vary depending on hydrology and location. In wet years, nonmarket values remain similar to the No Action Alternative but in dry sequences, reduced reservoir elevations and altered flow regimes diminish scenic quality and access for boating and angling (see **TA 14, Recreation**), for Lake Powell. For Lake Mead, the Supply Driven Alternatives (both LB Priority and LB Pro Rata approaches) are the most robust for supporting reservoir levels at Lake Mead which support non-market values. River-based recreation experiences moderate variability in trip quality, while ecosystem services and associated non-use values fluctuate with water availability (see **TA 8, Biological Resources – Fish and Other Aquatic Resources**). Cultural and spiritual values tied to river corridors may also be affected during extended drought periods (see **TA 11, Cultural Resources**).	Impacts would be as described for the Supply Driven Alternative (LB Priority approach).	Under dry conditions nonmarket values could be impacted as discussed under the no action alternative. For values associated with lake-based recreation, modeled results show reduced low-elevation outcomes in Lake Powell and Mead compared to more vulnerable alternatives, but vulnerability remains under drier future hydrologic conditions (**TA 3, Hydrology**). The Representative Preferred Alternative generally performs in the middle of the range of alternatives for both Lake Powell and Lake Mead elevations as well as river flow, showing moderate robustness in terms of overall support for recreation associated benefits (**TA 14, Recreation**). Overall, this alternative would provide moderate protection for riverine habitat to support cultural values (see TA 13, Tribal). The preferred alternative provides a framework that allows for shortage distributions to be negotiated in different ways, consistent with sideboards described in Chapter 2, as a result, impacts for any given sub-period in the planning period may differ from those described.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. [1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.
[4] Note that these impacts are based on low maximum Lower Basin shortage volumes that translate to higher volumes of dead pool-related reductions (see **Figure TA 4-12**), which could result in significant but highly uncertain impacts.
[7] Normal delivery refers to a full supply of domestic water delivery throughout this table.

		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Comparison of impacts on senior and junior entitlements	Shortage to domestic water users, across the first decade of the modeling period	>80% of normal domestic water delivery to senior entitlements (Arizona (AZ) P2 & P3; AZ PPR; California (CA) PPR; and Nevada (NV) P1-7 priority groups) and some junior entitlements (CA P4 and NV P8 priority groups) occurs in all potential futures. In contrast, for Arizona junior entitlements (AZ CAP NIA-A and NIA-B; AZ CAP Indian, M&I, and 4(i) priority groups) there are no potential futures in which >80% normal domestic water delivery occurs.[4] AZ CAP Indian, M&I, and 4(i) receives >60% of normal domestic water delivery in all potential futures There are no potential futures in which Arizona CAP NIA-A and NIA-B priorities receive any percentage of normal domestic water delivery. While this alternative results in all senior priority groups and some Arizona, California, and Nevada junior priority groups receiving domestic water delivery closest to normal conditions, it results in severe domestic shortage impacts to Arizona CAP NIA-A and NIA-B.	>80% of normal domestic water delivery to senior entitlements (AZ P2 & P3; AZ PPR; CA PPR; and NV P1-7 priority groups) and some junior entitlements (CA P4 priority group) occurs in all potential futures. In contrast, for Arizona and Nevada junior entitlements (AZ CAP NIA-A and NIA-B; AZ CAP Indian, M&I, and 4(i); and NV P8 priority groups) there are no potential futures in which >80% normal domestic water delivery occurs.[4] NV P8 receives >60% of normal domestic water delivery in all potential futures. There are no potential futures in which Arizona junior priority receive any percentage of normal domestic water delivery. While this alternative results in all senior priority groups and some California junior priority groups receiving domestic water delivery closest to normal conditions, it results in severe domestic shortage impacts to Arizona junior priority groups.	>60% of normal domestic water delivery to all Arizona, California, and Nevada priority groups occurs in all potential futures. While this alternative results in more priority groups receiving domestic water delivery closer to normal conditions, it results in domestic shortage impacts on Arizona, California, and Nevada senior entitlements that would otherwise receive domestic water deliveries consistent with normal conditions.	>80% of normal domestic water delivery to some senior priority groups (AZ PPR; CA PPR; and NV P1-7 priority groups) occurs in all potential futures. In contrast, for all Arizona, California, and Nevada junior entitlements (AZ CAP NIA-A and NIA-B; AZ CAP Indian, M&I, and 4(i); CA P4; and NV P8 priority groups) there are no potential futures, in which >80% of normal domestic water delivery occurs. AZ P2 & P3 receives >60% and >80% of normal delivery in 26% and 35% of potential futures, respectively. NV P8 receives >60% and >80% of normal domestic water delivery in 1% and 22% of potential futures, respectively. There are no potential futures in which Arizona and California junior entitlements receive any percentage of normal domestic water delivery. While this alternative results in Arizona and California PPR and Nevada senior priority groups receiving domestic water delivery closest to normal conditions, it results in severe domestic shortage impacts to all Arizona and California junior priority groups.	>80% of normal domestic delivery to some senior entitlements (AZ P2 & P3; AZ PPR; CA PPR; and NV P1-7 priority groups) occurs in all potential futures. In contrast, for junior entitlements (AZ CAP NIA-A and NIA-B; AZ CAP Indian, M&I, and4(i); CA P4; and NV P8 priority groups), there are no potential futures, in which >80% of normal domestic water delivery occurs. NV P8 receives >60% of normal domestic water delivery in all potential futures. AZ CAP Indian, M&I, and 4 (i) receives >20% of normal domestic water delivery in 31-40% of potential futures. There are no potential futures in which Arizona CAP NIA-A and NIA-B and CA P4 priority groups receive any percentage of normal domestic water delivery. While this alternative results in all senior priority groups receiving domestic water delivery closest to normal conditions, it results in severe domestic shortage impacts to some Arizona and California junior priority groups.	>80% normal domestic water delivery occurs in all potential futures for all California priority groups. >60% of normal domestic delivery to all Arizona and Nevada priority groups occurs in all potential futures. While this alternative results in more Arizona junior priority groups receiving domestic delivery closer to normal conditions, it results in domestic shortage impacts on Arizona and Nevada senior entitlements that would otherwise receive deliveries consistent with normal conditions.	>80% of normal domestic water delivery to some senior priority groups (AZ PPR; CA PPR; and NV P1-7 priority groups) occurs in all potential futures. In contrast, for all Arizona, California, and Nevada junior entitlements (AZ CAP NIA-A and NIA-B; AZ CAP Indian, M&I, and 4(i); CA P4; and NV P8 priority groups) there are no potential futures, in which >80% of normal domestic water delivery occurs. AZ P2 & P3 receives >60% and >80% of normal delivery in 54% and 58% of potential futures, respectively. NV P8 receives >60% and >80% of normal domestic water delivery in 0% and 51% of potential futures, respectively. There are no potential futures in which Arizona and California junior entitlements receive any percentage of normal domestic water delivery. While this alternative results in Arizona and California PPR and Nevada senior priority groups receiving domestic water delivery closest to normal conditions, it results in domestic shortage impacts to all Arizona and California junior priority groups.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
How would operational changes affect irrigated agricultural land?	Acres of irrigated agricultural land within the analysis area and potential for changes based on agricultural water availability	Frequent and severe shortages for junior-priority irrigation users likely lead to fallowing, crop switching, and long-term land retirement in Arizona counties (La Paz, Mohave and Yuma); Imperial Valley impacts are more limited.	Concentrated impacts for junior users in Arizona still drive significant agricultural land use changes; California and senior priority holders see limited more limited impacts	Pro rata distribution mitigates concentrated impacts for junior users but introduces broader reductions, increasing risk of widespread crop switching and fallowing in both Arizona and California.	Large shortage volumes and reliance on conservation participation create high uncertainty; potential for extensive land retirement if participation is low.	Concentrates impacts on junior users, preserving senior districts but accelerating land use change in Arizona counties (La Paz, Mohave and Yuma).	Distributes shortages broadly, increasing exposure for senior priority holders California and potentially leading to widespread fallowing and crop switching across the Basin.	The representative preferred alternative for 2027-2028 would result in shortages, with impacts concentrated on junior users. In the longer term (2029-2060) modeled outcomes indicate potential for additional fallowing land and crop switching, with impacts concentrated on junior users. However, the distribution of shortage under any specific operating guidelines adopted under the Preferred Alternative decision framework may differ from the priority distribution method reflected here for the Representative Preferred Alternative, as a result, the potential for fallowing, crop switching, and other associated long term land - use patterns in any given area may vary and impacts may be mitigated in part by specific operational guidelines

		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Lake Powell and Lake Mead landscape character	Percent of futures in which ***Lake Powell*** *elevation would result in calcium carbonate rings remaining under historic maximums for 100% of the modeling period*. Based on updated modeling, the analysis focused on a threshold of 200 feet instead of the historic maximum. The higher the percentage, the more likely calcium carbonate rings at Lake Powell will remain shorter than historic maximums.	**4%** of modeled futures meet *the preferred minimum performance*.	**19%** of modeled futures meet *the preferred minimum performance*.	**81%** of modeled futures meet *the preferred minimum performance*.	**94%** of modeled futures meet *the preferred minimum performance*.	**35%** of modeled futures meet *the preferred minimum performance*.		**45%** of modeled futures meet *the preferred minimum performance*.
	Percent of futures in which ***Lake Mead*** *elevation would result in calcium carbonate rings remaining under historic maximums for 100% of the modeling period*. Based on updated modeling, the analysis focused on a threshold of 200 feet instead of the historic maximum. The higher the percentage, the more likely calcium carbonate rings at Lake Mead will remain shorter than historic maximums.	**8%** of modeled futures meet *the preferred minimum performance*.	**20%** of modeled futures meet *the preferred minimum performance*.	**17%** of modeled futures meet *the preferred minimum performance*.	**22%** of modeled futures meet *the preferred minimum performance*.	**44%** of modeled futures meet *the preferred minimum performance*.		**23%** of modeled futures meet *the preferred minimum performance*.
Colorado River landscape character	Qualitative description of the effect associated with proposed flow rates and the potential to conduct HFEs from Glen Canyon Dam under each alternative.	Initially, there would be less impacts as flows would remain above 7.0 maf; however, if Lake Powell reaches dead pool, impacts would be extensive and immediate due to a dramatic reduction in flows. The current trends of increasing bank armoring, associated with expanding riparian vegetation areas (including tamarisk), would continue under the No Action Alternative. This alternative has the **fewest futures** where HFEs are conducted during the full modeling period.	Impacts would be similar to the No Action since it includes a similar range of releases from Glen Canyon Dam. This alternative would have an **increased number of futures** where HFEs are conducted compared to the No Action Alternative.	Based on yearly projections, if releases as low as 4.7 maf are needed, there would be increased impacts on the river's landscape character. If releases are above 7.0 maf, impacts would be the same as the No Action Alternative. This alternative would result in the **second most futures** where HFEs are conducted.	Based on yearly projections, if releases as low as 5.0 maf are needed, there would be increased impacts on the river's landscape character. If releases are above 7.0 maf, impacts would be the same as the No Action Alternative. This alternative would result in the **most futures** where HFEs are conducted.	Based on yearly projections, if releases as low as 4.7 maf are needed, there would be increased impacts on the river's landscape character. If releases are above 7.0 maf, impacts would be the same as the No Action Alternative. This alternative has the **second fewest futures** where HFEs are conducted during the full modeling period.		Based on yearly projections, if releases as low as 6.0 maf are needed, there would be increased impacts on the river's landscape character. If releases are above 7.0 maf, impacts would be the same as the No Action Alternative. This alternative has the **second fewest futures** where HFEs are conducted during the full modeling period similar to the Supply Driven Alternative.

[1] Some performance indicator descriptions include italics to denote a definition of the "*preferred minimum performance*" that was used as a significant reference point for technical analysis. The following were considered when determining preferred minimum performance: input from resource experts, the severity of negative outcomes associated with not satisfying a given performance level, historical (observed) data, and/or reasonably expected outcomes if current operations and recent hydrology continued. To find more information about preferred minimum performance levels, see Volume III – Technical Appendices.

Impact Category	Performance Indicator[1]	Impacts Summary						
		No Action Alternative	Basic Coordination Alternative	Enhanced Coordination Alternative	Maximum Operational Flexibility Alternative	Supply Driven Alternative (LB Priority)	Supply Driven Alternative (LB Pro Rata)	Representative Preferred Alternative
Lower Division States' landscape character	Qualitative description of the effects associated with potential decreases in water availability for the Lower Division States on the broader landscape character including the potential to reach dead pool.	Initially, there would be lower impacts; however, if Lake Mead reaches dead pool, dramatic decreases in water availability could affect the landscape character in all three Lower Division States. Depending on the duration of these decreased water deliveries, the character of irrigated and agricultural landscapes within the Lower Division States would be modified through aridification of these areas; this would diminish the vivid greens associated with crops and ornamental plantings. This alternative has the **most futures** where dead pool shortage is reached.	Impacts would be similar to the No Action except this alternative includes increased shortages to Arizona and Nevada (up to 1.48 maf). While the potential to reach dead pool is reduced under this alternative, compared to the No Action Alternative, there is still a risk to reach dead pool under some futures. This alternative has the **second most futures** where dead pool shortage is reached.	Shortages up to 3.0 maf are possible under this alternative, which would incrementally affect all three Lower Division States including irrigated and agricultural landscapes. These shortages are designed to avoid reaching dead pool, tempering the impacts on the character of irrigated and agricultural landscapes within the Lower Division States and avoid more extensive impacts if Lake Mead reached dead pool. This alternative has the **second fewest** futures where dead pool shortage is reached.	Shortages up to 4.0 maf are possible under this alternative, which would incrementally affect all three Lower Division States including irrigated and agricultural landscapes. The shortages are designed to avoid reaching dead pool. This alternative has the **fewest futures** where dead pool shortage is reached.	Shortages up to 2.1 maf are possible under this alternative, which would incrementally affect all three Lower Division States including irrigated and agricultural landscapes. The shortages are designed to avoid reaching dead pool. This alternative, similar to the Enhanced Coordination Alternative, has the **second fewest futures** where dead pool shortage is reached.		Shortages up to 3.0 maf are possible under this alternative, which would incrementally affect all three Lower Division States including irrigated and agricultural landscapes. The shortages are designed to avoid reaching dead pool. This alternative, similar to the Enhanced Coordination Alternative, has the **second fewest futures** where dead pool shortage is reached.

Interior Regions 7 and 8

BUREAU OF
RECLAMATION

Mission Statements

The **Department of the Interior** protects and manages the Nation's natural resources and cultural heritage; provides scientific and other information about those resources; and honors its trust responsibilities or special commitments to American Indians, Alaska Natives, and affiliated island communities.

The mission of the **Bureau of Reclamation** is to manage, develop, and protect water and related resources in an environmentally and economically sound manner in the interest of the American public.

Western Area Power Administration

Abstract:

The Secretary of the Department of the Interior, acting through the Bureau of Reclamation, proposes the adoption of new guidelines and coordinated management strategies to address Lake Powell and Lake Mead through their full operating range to take effect when the current agreements expire in 2026. Management strategies will primarily focus on the operation of Glen Canyon Dam and Hoover Dam, but may include actions upstream and downstream of these facilities to protect critical reservoir elevations. This Final EIS has been prepared to inform the Secretary's timely adoption of a new set of guidelines that would be sufficiently robust and provide improved predictability to all water users and managers in the Colorado River Basin.

This Final EIS has been prepared pursuant to the National Environmental Policy Act to address the formulation and evaluation of specific interim criteria and to identify the potential environmental impacts of implementing such criteria.

For further information regarding this Final EIS, contact:

Chapter 1. Purpose and Need

1.1 Introduction

The Colorado River Basin (Basin) provides essential water supplies to approximately 40 million people, nearly 5.5 million acres of agricultural lands, and habitat for ecological resources across seven states which includes broad areas in the Southwestern United States and Northwestern United Mexican States (Mexico) (**Map 1-1**). Prudent management of the Basin is critically important because the Colorado River is the foundation for diverse resources across a large geographic region and faces exceptional challenges from prolonged drought and future uncertainty. States, tribes, and Mexico rely on the Colorado River to support essential municipal, agricultural, environmental, cultural, and hydropower needs. These resources are now at significant risk: since the onset of the current drought in 2000, the Basin's primary reservoirs, Lake Powell and Lake Mead, have fallen to historically low elevations. Several of the major reservoir- and water-management documents and agreements developed to guide Colorado River operations through the persistently dry conditions expire in 2026, including the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and Coordinated Operations for Lake Powell and Lake Mead (2007 Interim Guidelines; Reclamation 2007a), the 2019 Colorado River Drought Contingency Plans (DCP; Reclamation 2019), and key international agreements between the United States and Mexico.[1] Despite the significance of these agreements, actions taken over the past two decades have not been sufficiently robust to prevent continued decline of the reservoirs through the prolonged drought.

The 2007 Interim Guidelines have provided operating criteria for Lake Powell and Lake Mead, including provisions designed to provide Colorado River water users, particularly those in the Lower Division States, a greater degree of predictability with respect to the timing and volumes of potential water delivery reductions, as well as additional operating flexibility to conserve and enhance water storage in Lake Mead. The 2007 Interim Guidelines were adopted for a limited period ("interim") to provide an opportunity for the Bureau of Reclamation (Reclamation) and interested entities to gain valuable experience in the management of Lake Powell and Lake Mead under modified operations, with the goal of improving the analytical basis for making future operational decisions, whether during the interim period or after. The valuable experience managing Lake Powell and Lake Mead gained since the adoption of the 2007 Interim Guidelines has informed important considerations in developing new guidelines for the post-2026 period.

The Secretary of the Interior (Secretary), acting through Reclamation, proposes adoption of new guidelines and coordinated management strategies to address Lake Powell and Lake Mead through their full operating ranges to take effect when the current agreements expire in 2026. Management

[1] International agreements are pursuant to the U.S.-Mexico Treaty on Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande (1944 Water Treaty; IBWC 1944). The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the U.S. Section of the International Boundary and Water Commission (USIBWC) in consultation with the Department of State.

strategies will primarily focus on the operation of Glen Canyon Dam and Hoover Dam but may include actions upstream and downstream of these facilities to protect critical reservoir elevations, such as use of the Colorado River Storage Project (CRSP) Upper Initial Units to release additional water if needed to protect critical infrastructure at Glen Canyon Dam, and approaches to enhance opportunities for Lower Basin water users to reduce water use (see **Map 1-1**). This Final Environmental Impact Statement (EIS) evaluates a range of operational alternatives for post-2026 reservoir management.

Developing new guidelines is difficult in this complex Basin, where critically low storage in Lake Powell and Lake Mead, significant hydrologic variability, and the anticipation of drier future conditions amplify the central tradeoff: balancing the potentially profound impacts of water-delivery reductions with the need to maintain reservoir storage. The alternatives in this Final EIS capture a broad range of management strategies to address this tradeoff, and they demonstrate that there are multiple ways to find a balance if conditions improve. If conditions do not improve, achieving a balance is more difficult, and, under critically dry futures, even large and unprecedented reductions may be needed and may not be enough to stabilize storage.

Since 2000, the Basin has been experiencing one of the worst multi-decade droughts of the last 1,200 years.[2] In the early part of this period, falling reservoir elevations, together with the lack of objective criteria for managing the reservoirs at lower levels, prompted the adoption of the 2007 Interim Guidelines. Since their adoption, average annual flows have continued to decline, and flows have been significantly below average in nearly half of the years from 2008 to 2025.[3] Despite additional responsive actions to reduce the risk to the Colorado River system's critical infrastructure[4] and water supplies, including the 2019 Colorado River DCP, storage in Lake Powell and Lake Mead continued to fall. Due to three consecutive years of below-average hydrology ending with this year's extreme dry hydrologic conditions (with the lowest snowpack since records began in 1930s), in the spring of 2026 the Department of the Interior (Department) implemented extraordinary operational measures to protect critical infrastructure at Glen Canyon Dam. At the time of publication of this Final EIS, the combined contents of Lake Powell and Lake Mead is approximately 12.5 maf, a low that has not been seen since before Glen Canyon Dam began filling in 1963.

Consistent with the Department's longstanding preference for consensus-based management of the Colorado River System, the Department and Reclamation engaged extensively with the Basin States,[5]

[2] The average streamflow from 2000 to 2025 is drier than any 26-year period in the reconstructed paleo record developed by Meko, et al, which extends back to 760 AD (Meko et al. 2007).
[3] From 2008 to 2025, Lees Ferry, AZ, natural flow was less than 75 percent of the 1991-2020 average in 7 out of 18 years.
[4] A primary concern for the Department has been to identify and implement actions to ensure Glen Canyon Dam and Hoover Dam continue to provide downstream water releases as designed and intended. Refer to **Sections 1.8.4.1 and 1.8.4.2** for more information on critical elevations.

— BUREAU OF —
RECLAMATION

Map 1-1
Colorado River Basin

- Major dam
- Lee Ferry Compact Point
- Lees Ferry Gaging Station
- Colorado River
- Major Colorado River tributary
- Colorado River Basin, Upper and Lower Basins
- States in the Colorado River Basin (Wyoming, Colorado, Utah, and New Mexico are Upper Division states, and Arizona, California, and Nevada are Lower Division states)

Basin Tribes,[6] and other interested parties during development of successor operating guidelines over the course of 4 years. However, despite those efforts, the Basin States did not reach consensus on long-term guidelines prior to the completion of this EIS. Accordingly, rather than adopting long-term operating guidelines of the same duration as the 2007 Interim Guidelines, the Secretary proposes in the Preferred Alternative to adopt an operational strategy consisting of an adaptive decision framework to develop operating guidelines for Lake Powell and Lake Mead for operating years 2027 through 2036. This framework provides for more robust operational provisions than the current guidelines while preserving the flexibility to respond to changing hydrologic conditions and to incorporate future consensus recommendations, should they be reached. Should no consensus emerge, the Preferred Alternative ensures that the Secretary will have the flexibility to make necessary operational decisions.

The Secretary intends to consider, adopt, and implement the proposed federal action[7] consistent with the Law of the River,[8] including the Colorado River Compact of 1922 (Compact; 43 U.S. Code [USC] § 617l), the Consolidated Decree entered by the U.S. Supreme Court in the case of *Arizona v. California*, 547 U.S. 150 (2006; Consolidated Decree), and other provisions of applicable federal law and also recognizes that additional authorities may need to be developed. The proposed federal action would be used each year by the Department to implement the Criteria for Coordinated Long-Range Operation of Colorado River Reservoirs Pursuant to the Colorado River Basin Project Act of September 30, 1968 (Long-Range Operating Criteria [LROC]; Colorado River Basin Project Act of 1968 [CRBPA]; Reclamation 1970) through the issuance of the Annual Operating Plan for Colorado River Reservoirs (AOP).

This Final EIS has been prepared in compliance with the National Environmental Policy Act (NEPA)[9] for the Post-2026 Operational Guidelines and Strategies for Lake Powell and Lake Mead (Post-2026 process). It analyzes a broad and reasonable range of alternatives for potential future guidelines and reservoir management strategies for the Colorado River. This Final EIS analyzes the tradeoffs between the frequency and magnitude of shortages, the potential effects on water storage in Lake Powell and Lake Mead, and on water supplies, power production, recreation, and other environmental resources and, in doing so, identifies the potential relevant environmental issues associated with implementing the proposed federal action.

[6] There are 30 federally recognized Native American tribes in the Basin: Ak-Chin Indian Community, Chemehuevi Indian Tribe, Cocopah Indian Tribe, Colorado River Indian Tribes, Fort McDowell Yavapai Nation, Fort Mojave Indian Tribe, Fort Yuma-Quechan Tribe, Gila River Indian Community, Havasupai Tribe, Hopi Tribe, Hualapai Tribe, Jicarilla Apache Nation, Kaibab Band of Paiute Indians, Las Vegas Paiute Tribe, Moapa Band of Paiute Indians, Navajo Nation, Pascua Yaqui Tribe, Pueblo of Zuni, Salt River Pima-Maricopa Indian Community, San Carlos Apache Tribe, San Juan Southern Paiute, Shivwits Band of Paiutes, Southern Ute Indian Tribe, Tohono O'odham Nation, Tonto Apache Tribe, Ute Indian Tribe of the Uintah and Ouray Reservation, Ute Mountain Ute Tribe, White Mountain Apache Tribe, Yavapai-Apache Nation, and Yavapai-Prescott Indian Tribe.

[7] The phrase "proposed federal action" is used herein to refer to the action that the Secretary may take to meet the purpose and need. A range of alternatives are considered in this document; a Preferred Alternative has been included in this Final EIS based on public review of the Draft EIS.

[8] The treaties, compacts, decrees, statutes, regulations, and other legal documents and agreements applicable to the allocation, appropriation, development, exportation, and management of the waters of the Basin are often referred to as the "Law of the River." There is no single, universally agreed-upon definition of the "Law of the River," but it is useful as a shorthand reference to describe this longstanding and complex body of legal agreements governing the Colorado River.

[9] 42 USC § 4321 *et seq.*

1.2 Proposed Federal Action

Reclamation, acting on behalf of the Secretary, proposes to adopt guidelines and coordinated reservoir management strategies to address operations of Lake Powell and Lake Mead through their full operating ranges. This action would improve predictability to all water users and managers in the Basin by developing and adopting objective guidelines for the operation of Glen Canyon Dam and Hoover Dam to take effect when the current operating guidelines expire in 2026. This action is designed to provide for the sustainable management of the Colorado River system and its resources under a wide range of potential future system conditions.

The proposed federal action considers the following operational elements that are collectively designed to address the purpose and need for the proposed federal action:

1) Identification of circumstances under which the Secretary would allocate, reduce, or increase the annual amount of water available for consumptive use from Lake Mead to the Lower Division States (Arizona, California, and Nevada) at, below, or above 7.5 million acre-feet (maf), pursuant to the Supreme Court Decree in *Arizona* v. *California*, 376 U.S. 340 (1964) (Final Decree entered in 2006).
2) Coordinated operations of Lake Powell and Lake Mead, particularly under low reservoir conditions.
3) Storage and delivery of conserved water in Lake Powell and/or Lake Mead to increase the flexibility to meet water use needs from both reservoirs, including the storage and delivery of non-system water; exchanges; and water conserved through extraordinary measures by or for tribal, agricultural, or municipal entities.

The proposed federal action allows for development of robust operating guidelines for Lake Powell and Lake Mead without precluding upstream or downstream actions needed to protect critical reservoir elevations at Lake Powell and Lake Mead, such as the following:

- Approaches that consider total system storage in all major Colorado River reservoirs and/or actual inflows to determine coordinated operations of Lake Powell and Lake Mead.
- Approaches that include opportunities for conservation, augmentation, demand management, or other water management strategies (such as exchanges or transfers).
- Modified operations at upstream CRSP Upper Initial Units to release additional water if needed to protect critical infrastructure at Glen Canyon Dam.

The Secretary intends that the guidelines be interim in nature and extend for the same duration as the 2007 Interim Guidelines (approximately 20 years). Adoption of new guidelines for an interim (or limited) period provides the opportunity to gain additional experience for operating the reservoirs, thereby informing future operational and water management decisions.

Recognizing additional authorities may be developed, the Department intends to adopt and implement the guidelines in a manner consistent with the Law of the River. The Department also intends that the guidelines be used to implement the LROC and applicable federal law through the issuance of the AOP.

1.3 Purpose of and Need for Action

The proposed federal action is needed for the following reasons:

- *The Secretary is legally required to coordinate operations of Colorado River reservoirs:* The CRBPA directs the Secretary to adopt criteria for the coordinated long-range operation of Colorado River reservoirs. In compliance with this obligation, the LROC were developed and adopted by the Secretary in 1970. The LROC provide general narrative guidance regarding Lake Powell and Lake Mead operations but does not contain specific, objective criteria to guide annual operations. To address this inadequacy, the 2007 Interim Guidelines were developed to provide objective criteria used by the Department to implement the LROC. The 2007 Interim Guidelines have provided the predictability needed by the entities that receive Colorado River water to better plan for and manage available water supplies from the Colorado River and other sources.
- The *2007 Interim Guidelines are expiring:* Current operational guidelines expire during the 2026 operating year. The Department has determined that specific, objective operational guidelines are important to provide improved predictability and should be established for another interim period beyond 2026. Most of the federal and non-federal agreements associated with implementing provisions of the 2007 Interim Guidelines also expire after the 2026 operating year.
- *The 2007 Interim Guidelines have not sufficiently reduced risk:* Based on operational experience since 2007, the current guidelines are not robust enough to manage the system in a way that is sufficiently protective of the resources dependent on the Colorado River. Despite near-continuous drought-response actions in recent years, low reservoir conditions have persisted, and new infrastructure risks at Glen Canyon Dam have arisen. More robust and adaptive guidelines are needed for the efficient and sustainable management of the major mainstream Colorado River reservoirs and system resources.
- *Imbalance between water supply and demand will be exacerbated by increasingly likely low-runoff conditions:* The Basin is experiencing increased aridity due to climate variability, and long-term drought and low-runoff conditions are expected in the future. These conditions will exacerbate the now widely recognized imbalance between water supply and demand in the Basin. Robust and flexible guidelines are needed to manage the Colorado River system and its resources under a broad range of potential future hydrologic conditions.
- *Expanded and innovative use of conservation is needed:* Recognizing the anticipated future low-runoff conditions in the Basin, the Department has also determined a need for guidelines that provide Colorado River water users, including Basin Tribes, expanded opportunities to conserve, store, exchange, and take subsequent delivery of water in and from Lake Powell and/or Lake Mead. The guidelines should also support and integrate future efficiency improvements and opportunities for augmentation.
- *Addressing tribal concerns regarding Basin management is needed:* Basin Tribes have expressed concern that the current approach to Colorado River water management is insufficient to address the range of interests, needs, and fundamental rights of the Basin Tribes. The Department has determined a need for guidelines that provide flexibility and predictability for Basin Tribes to

remain able to benefit from their water rights and have opportunities to participate in voluntary conservation programs.

The purpose of the proposed federal action is to:

- Update and expand management guidelines for Colorado River reservoirs, particularly for the coordinated operation of Lake Powell and Lake Mead
- Provide Colorado River water users a greater degree of predictability with respect to annual water availability in future years under anticipated increasing variability, low runoff, and low reservoir conditions
- Provide additional mechanisms for the conservation, exchange, storage, and delivery of water supplies in Colorado River reservoirs to increase the flexibility to meet water use needs
- Provide new or enhanced opportunities for Basin Tribes to benefit from their water rights
- Provide flexibility to build resilience and accommodate future needs and growth that are supported by Colorado River water supplies including the integration of unquantified tribal water rights once they are resolved

1.4 Lead and Cooperating Agencies

The Secretary is responsible for operating Glen Canyon Dam and Hoover Dam, as well as managing the mainstream waters of the lower Colorado River in accordance with federal law. These responsibilities are carried out consistent with the Law of the River. Reclamation, as the agency that is designated to act on the Secretary's behalf with respect to these matters, is the lead federal agency for the purposes of NEPA compliance and for the development and implementation of the proposed interim guidelines.

The following federal agencies are cooperating in the environmental analysis and preparation of this Final EIS:

- Bureau of Indian Affairs (BIA)
- National Park Service (NPS)
- U.S. Fish and Wildlife Service (FWS)
- U.S. Section of the International Boundary and Water Commission (USIBWC)
- Western Area Power Administration (WAPA)

1.5 Scope of the EIS

The scope of this Final EIS was informed by applicable federal law, Reclamation's operating experience under the 2007 Interim Guidelines, documentation of that experience,[10] and efforts conducted by Reclamation to gather public input on the scope of post-2026 guidelines. Before

[10] In 2020, Reclamation completed a retrospective evaluation (Reclamation 2020) to document the effectiveness of the 2007 Interim Guidelines with respect to the purpose stated in the 2007 ROD.

formally initiating the NEPA process, in June 2022, Reclamation conducted a public "pre-scoping" effort requesting input on suggested mechanisms to ensure a wide range of stakeholder participation in the process and potential substantive elements to be considered for post-2026 operations.[11] Using the input received, on June 16, 2023, Reclamation published a Notice of Intent (NOI) to prepare an environmental impact statement (EIS) in the *Federal Register* (88 *Federal Register* 39455), formally initiating the public scoping process. A Notice of Availability (NOA) for the Scoping Report (Reclamation 2023b) was published in October 2023 in the *Federal Register* (88 *Federal Register* 72535), summarizing all public comments received during the scoping period (June 16, 2023, to August 15, 2023). Over the 60-day scoping period, Reclamation engaged with stakeholders through public webinars, tribal consultations, and technical education sessions. During the scoping public comment period, Reclamation received a total of 24,290 comment submissions from a wide range of interested parties, including federal, state, and local entities; tribes; nongovernmental organizations; other stakeholder groups; and individuals. Reclamation considered the comments in developing the proposed federal action, purpose and need, and scope of the environmental analysis (see **Section 1.2**). A number of related efforts and parallel processes outside the scope of this federal action will continue independently of this Final EIS but may inform the development and implementation of new guidelines. Specifically, the Department acknowledges the importance of ongoing tribal water rights settlements and associated negotiations in the Basin. The alternatives in this Final EIS do not weigh in on or assume specific settlement terms, and the new guidelines are intended to be flexible enough to integrate tribal water rights once resolved.

The alternatives in this Final EIS are designed to cover a wide range of potential outcomes with respect to post-2026 operations; accordingly, they incorporate components that are within existing authorities along with components that would require new authorities and/or new agreements among Basin water users to fully implement. Reclamation has determined that, based on public input received during the scoping and alternative development phases of the NEPA process, analysis of these operations presents a reasonable and broad range of Colorado River operations that capture an appropriate range of potential environmental impacts. Recognizing that additional authorities and agreements may be developed, the Secretary intends to adopt and implement new guidelines in a manner consistent with the Law of the River.

1.5.1 Geographic Scope of the Proposed Federal Action and Affected Regions and Interests

Consistent with the geographic scope analyzed in the 2007 Interim Guidelines Final EIS, the geographic scope that would be affected by the proposed federal action begins at full pool of Lake Powell and extends downstream along the mainstream Colorado River floodplain to the Southerly International Boundary (SIB) with Mexico. While portions of northwestern Mexico are part of the Basin, these areas are not within the geographic scope of analysis for this EIS. This EIS does not address water deliveries to Mexico; however, in order to assess the potential effects of the proposed federal action, certain modeling assumptions regarding water deliveries to Mexico are used in this Final EIS.

[11] The pre-scoping period began with a Federal Register notice on June 24, 2022 (87 *Federal Register* 37884). The Department received substantial feedback from Basin States, Basin Tribes, water users, non-governmental organizations, and the public, which Reclamation summarized in a Pre-Scoping Summary Report (Reclamation 2023a).

This proposed federal action would also potentially affect interests of water users in the Lower Division States in service areas that extend beyond the Colorado River floodplain. Additionally, numerous tribes hold Colorado River water entitlements and could be affected by water supply availability. General operations and facilities outside the mainstream Colorado River may fall within separate Records of Decision (RODs) and authorities that are outside the scope of the proposed interim guidelines.

Although the proposed federal action is focused on Lake Powell and Lake Mead operations, management strategies that include activities upstream of Lake Powell are being analyzed in this Final EIS. These activities include Upper Basin conservation and, if warranted to protect critical reservoir elevations, coordinated operations of the CRSP Upper Initial Units (see **Map 1-1**) to release additional water within their respective Records of Decision (RODs) to increase the elevation at Lake Powell. Operations at the CRSP Upper Initial Units specifically contemplated in this Final EIS are intended to remain within the scope of the existing RODs (Reclamation 2006a, 2006b, 2012).[12] Since those RODs are covered by their own NEPA, this Final EIS does not need to expand the geographic scope of analysis upstream of Lake Powell. With respect to Upper Basin conservation, the nexus to the proposed federal action is the storage and delivery of that conserved water in Lake Powell. The effects of this storage in and delivery from Lake Powell are within the scope of the EIS (see **Section 3.3**, Hydrologic Resources, and **TA 3**, Hydrologic Resources), while specific activities that may be undertaken in the Upper Basin to generate the conserved water are not within the scope of this EIS. Any such activities are unknown at this time and will not necessarily require federal decision making. Any federal decisions associated with these conservation activities will be assessed outside of this EIS.

1.6 Application of NEPA Rules and Policy

As of April 11, 2025, the Council on Environmental Quality (CEQ) repealed its NEPA implementing regulations through a notice published in the *Federal Register* (90 FR 10610, Feb. 25, 2025), in accordance with Executive Order 14154, Unleashing American Energy (90 FR 8353; January 29, 2025), and directed agencies to revise their NEPA implementing procedures. On July 3, 2025, the Department issued an interim final rule partially rescinding its prior NEPA implementing regulations[13] and making necessary targeted updates to its remaining regulations (2025 Interim Final Rule). The Draft EIS was prepared under the 2025 Interim Final Rule. On February 24, 2026, the Department published the final rule along with 516 Department Manual 1 - U.S. Department of the Interior Handbook of National Environmental Policy Act Implementing Procedures (DOI NEPA Handbook). The Final EIS complies with Executive Orders and Department regulations and guidance for NEPA compliance.

[12] While the Secretary will consider and prioritize operations at these facilities that are consistent with existing RODs, the Secretary retains the authority to operate outside those RODs if necessary. The modeling assumptions regarding operation of the CRSP Upper Initial Units presented in this Final EIS are not intended to, and do not, limit the Secretary's ability to operate these facilities as necessary to respond to hydrologic conditions in accordance with applicable federal law, including operations for the authorized purposes as stated in the 1956 Colorado River Storage Project Act.

[13] NEPA Implementing Regulations, Interim Final Rule, Request for Comment, 43 Code of Federal Regulations (CFR) Part 46; the Department has retained and updated specific regulatory provisions regarding emergency response procedures, categorical exclusions and document preparation by applicants and contractors.

The 2025 Interim Final Rule and current implementing procedures allow for discretionary opportunities for public participation. Reclamation is using these discretionary opportunities, such as issuing the Draft EIS with a public comment period, to enhance public participation on the important topic of Colorado River operations.

This NEPA process applies to Reclamation's operation of Colorado River facilities, and those operations are inherently ongoing and cannot be suspended, including pending the development of new operating guidelines.[14] Reclamation's operations involve continuous adjustment to variable hydrologic conditions to maintain infrastructure integrity, deliver, and release water to Basin users consistent with the Law of the River. Even when operations may elicit objections, particularly under challenging hydrologic regimes, Reclamation cannot stop operating facilities until such time in the future as objections are resolved. Reclamation will continue to operate within the framework of applicable federal law, established authorities, and operational judgment aligned with any updated guidelines as necessary to respond to current and projected system conditions (see **Section 1.8.2.1** for further description).

1.7 Summary of Contents of this Final EIS

Following is a brief description of the topics presented in the four volumes that comprise this Final EIS.

Volume I of this Final EIS (this volume) describes the proposed federal action, the alternatives considered, and the analysis of the potential effects of these alternatives on Colorado River operations and associated resources. The contents of the chapters in this volume are as follows:

- **Chapter 1, Purpose and Need,** includes the following: identification of the purpose of and need for Lower Basin shortage guidelines and coordinated reservoir management strategies of Lake Powell and Lake Mead being considered in the proposed federal action; background information concerning the apportionment of Colorado River waters and the physical facilities associated with the Basin; and discussion of the institutional framework within which the Basin is managed. Chapter 1 also discusses previous and ongoing actions that have a relationship to the proposed federal action.
- **Chapter 2, Description of Alternatives,** describes the process of formulating alternatives, describes the Preferred Alternative, and presents a range of reservoir operation strategies and guidelines considered under each alternative. A summary of the performance tradeoffs between alternatives is provided at the end of Chapter 2.
- **Chapter 3, Affected Environment and Environmental Consequences,** describes the affected environment for the proposed federal action and evaluates potential impacts that could result from implementation of the alternatives. The discussion also addresses environmental consequences, i.e., potential effects of the action alternatives that could occur as compared to the No Action Alternative.

[14] See, e.g., Boulder Canyon Project Act of 1928 (BCPA), 45. Stat. 1057 (Dec. 21, 1928), sections 5 and 6; Consolidated Decree, Sections II-III.

- **Chapter 4, Consultation and Coordination,** describes the public involvement process, including public notices, scoping meetings, and hearings. This chapter also describes the coordination with federal and state agencies, Basin Tribes, and Mexico (through the USIBWC) during the preparation of this document and any permitting or approvals that may be necessary for implementation of the proposed federal action.

In addition to the above, Volume I includes a list of acronyms used throughout this document.

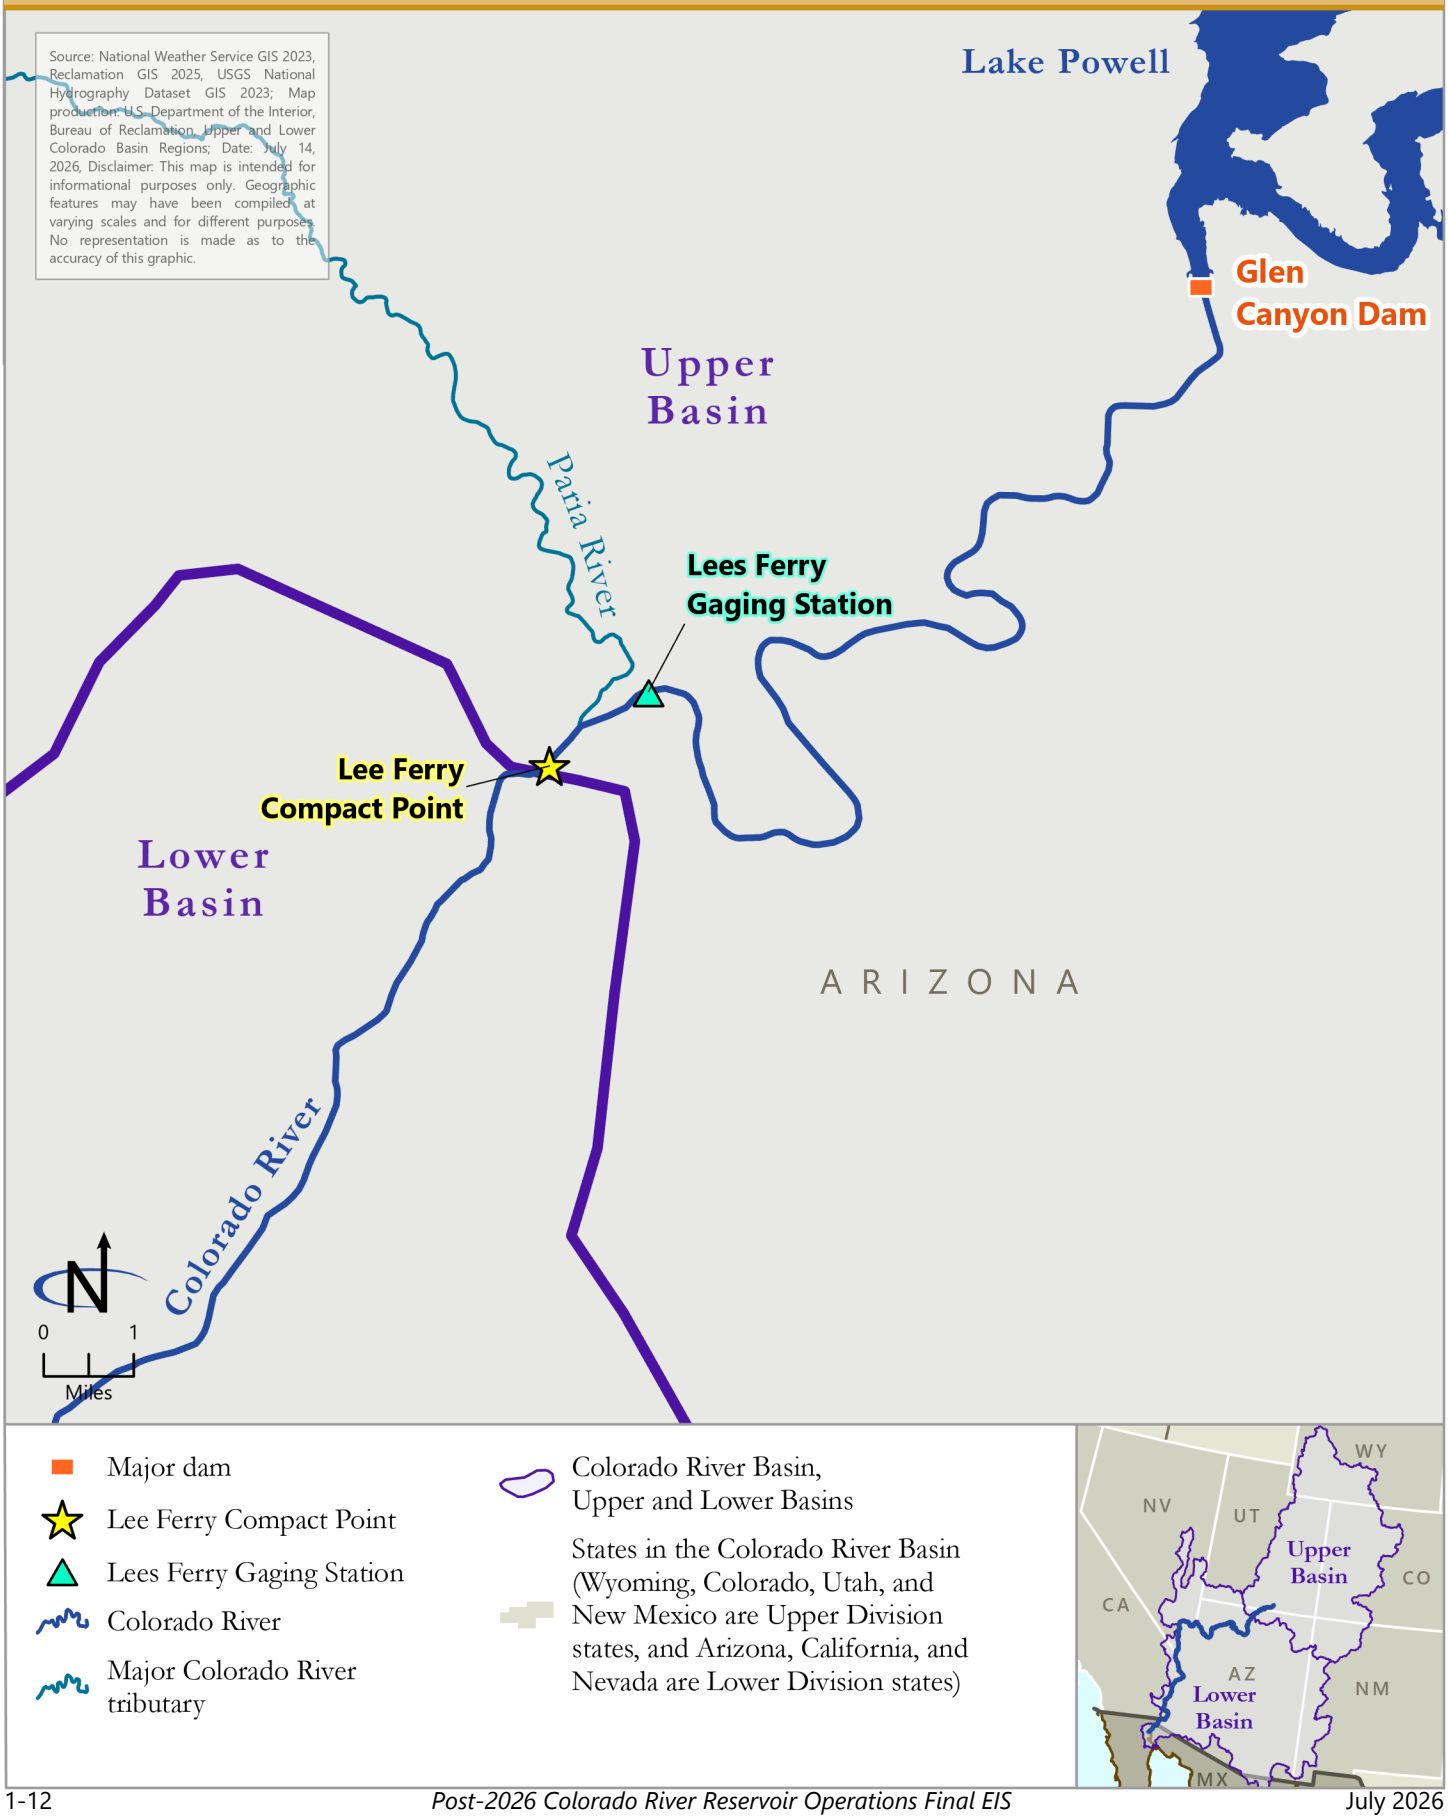
Volumes II and III contain appendices that are comprised of documents and other supporting material that provide detailed historical background and/or technical information concerning the proposed federal action. Volume IV contains a list of persons contributing to the preparation of the Final EIS, a list of references cited in this Final EIS, glossary of commonly used terms, and an index.

1.8 Water Supply Management and Allocation

1.8.1 Colorado River System Water Supply

The Basin includes broad areas of the southwestern U.S. and northwestern Mexico, as shown on **Map 1-1**, and occupies an area of approximately 250,000 square miles. The Colorado River is approximately 1,400 miles in length and originates along the Continental Divide in Rocky Mountain National Park in Colorado. Elevations in the Basin range from sea level to over 14,000 feet above mean sea level[15] in the mountainous headwaters.

Climate varies significantly throughout the Basin. Most of the Basin is arid and semi-arid, defined as receiving less than 10 and less than 20 inches of precipitation per year, respectively. In contrast, many of the mountainous areas that rim the northern portion, making up about 15 percent of the Basin, average over 40 inches of precipitation per year.



Most of the total annual flow in the Basin is a result of natural runoff from mountain snowmelt. Because of this, flow is highest in the late spring and early summer, diminishing rapidly by mid-summer. While flows in late summer through autumn sometimes increase following rain events, flow in the late summer through winter is generally low. Major tributaries to the Colorado River include the Green River, San Juan River, Yampa River, Gunnison River, and Gila River.

The annual flow of the Colorado River and its tributaries varies considerably from year to year. The natural flow at the Lees Ferry Gaging Station in Arizona (**Map 1-2**), located 15.9 river miles (RMs) downstream of Glen Canyon Dam, has varied annually from 5.0 maf to 23.0 maf. Natural flow represents an estimate of flows that would exist without human intervention (that is, without consumptive use or reservoir storage). Natural flow at Lees Ferry Gaging Station (Lees Ferry natural flow) represents the supply generated in the Upper Basin, which typically makes up approximately 92 percent of the total natural flow in the Basin as measured at Imperial Dam.

[15] Reservoir elevations are described in height above mean sea level.

— BUREAU OF —
RECLAMATION

Map 1-2
Lees Ferry Gaging Station and Lee Ferry Compact Point

The average annual Lees Ferry natural flow from 1906 to 2025 is approximately 14.6[16] maf; for the 21st Century, the average flow from 2000 to 2025 is 12.3 maf. In the Lower Basin, the average annual natural flow below Lees Ferry (including inflow from the Little Colorado River, Virgin River, and Bill Williams River) from 1906 to 2025 is approximately 0.630 maf,[17] and the average flow from 2000 to 2025 is approximately 0.479 maf.[18] For more context on the current drought in the Basin, see **Sections 1.1**, Introduction, and **3.3.1**, Hydrologic Resources.

1.8.2 Apportionment of Water Supply

This section summarizes the Law of the River, Colorado River apportionments of the Colorado River Basin States (Basin States), and the allotment to Mexico pursuant to the 1944 Water Treaty (IBWC 1944).

1.8.2.1. The Law of the River

The Secretary is vested with the responsibility to manage facilities throughout the Basin and the mainstream waters of the Lower Basin pursuant to applicable federal law. These responsibilities are carried out consistent with a body of documents referred to as the Law of the River. The Law of the River comprises numerous operating criteria, regulations, and administrative decisions included in federal and state statutes, interstate compacts, court decisions and decrees, an international treaty, and contracts with the Secretary.

Particularly notable among these documents are:

1. The Colorado River Compact of 1922, which apportioned beneficial consumptive use of water between the Upper Basin and Lower Basin
2. The Boulder Canyon Project Act of 1928 (BCPA), which authorized construction of Hoover Dam and the All-American Canal (AAC), required that water users in the Lower Basin have a contract with the Secretary in order to receive water from Lake Mead, and established the responsibilities of the Secretary to direct, manage, and coordinate the operation of Colorado River dams and related works in the Lower Basin
3. The California Seven Party Agreement of 1931, which, through regulations adopted by the Secretary, established the relative priorities of rights among major users of Colorado River water in California
4. The 1944 Water Treaty (and subsequent minutes of the IBWC) related to the quantity and quality of Colorado River water delivered to Mexico
5. The Upper Colorado River Basin Compact of 1948, which apportioned the Upper Basin water supply among the Upper Division States

[16] Calendar year (cy) values. 1906-2020 natural flow data can be found here: https://www.usbr.gov/lc/region/g4000/NaturalFlow/current.html. Preliminary 2021-2025 natural flow provided by Bureau of Reclamation staff and available upon request.
[17] In 2022, Reclamation revised how natural flow is calculated in the Lower Basin; the previous method added back in estimated losses due to phreatophytes, and the current method does not.
[18] Intervening flows between Lees Ferry and Imperial Dam for 2021 through 2025 are from the Lower Basin Gain/Loss Model.

6. The Colorado River Storage Project Act of 1956 (CRSPA), which authorized a comprehensive water development plan for the Upper Basin that included the construction of Glen Canyon Dam and other facilities
7. The 1963 U.S. Supreme Court Decision in *Arizona v. California* which confirmed the BCPA's Lower Basin mainstream apportionments of 2.8 maf for use in Arizona, 4.4 maf for use in California, and 0.3 maf for use in Nevada, not including tributaries which remain for the exclusive use of each state; provided water for American Indian (Indian) reservations and other federal reservations in Arizona, California, and Nevada; and confirmed the significant role of the Secretary in managing the mainstream Colorado River within the Lower Basin
8. The 1964 U.S. Supreme Court Decree (Decree) in *Arizona v. California* which implemented the Supreme Court's 1963 decision; the Decree was supplemented over time after its adoption and the Supreme Court entered a Consolidated Decree in 2006 which incorporates all applicable provisions of the earlier-issued decrees
9. The Colorado River Basin Project Act of 1968 (CRBPA; Public Law 90-537, 82 Stat. 885), which authorized construction of a number of water development projects including the Central Arizona Project (CAP) and required the Secretary to develop the LROC and issue an AOP for mainstream reservoirs
10. The Colorado River Basin Salinity Control Act of 1974 (Public Law 93-320, 88 Stat. 266), which authorized a number of salinity control projects and provided a framework to improve and meet salinity standards for the Colorado River in the U.S. and Mexico
11. The Grand Canyon Protection Act of 1992 (Public Law 102-575, 106 Stat. 4669), which addressed the protection of resources in Grand Canyon National Park (GCNP) and in Glen Canyon National Recreation Area, consistent with applicable federal law

Other documents which are generally considered as part of the Law of the River include, but are not limited to, those listed in **Table 1-1**. Among other provisions of applicable federal law, NEPA and the Endangered Species Act of 1973 (ESA; Public Law 93-205, 87 Stat. 884), as amended, provide a statutory overlay on certain actions taken by the Secretary. For example, as noted in **Section 1.1**, preparation of this Final EIS has been undertaken pursuant to NEPA.

Table 1-1
Selected Documents Included in the Law of the River

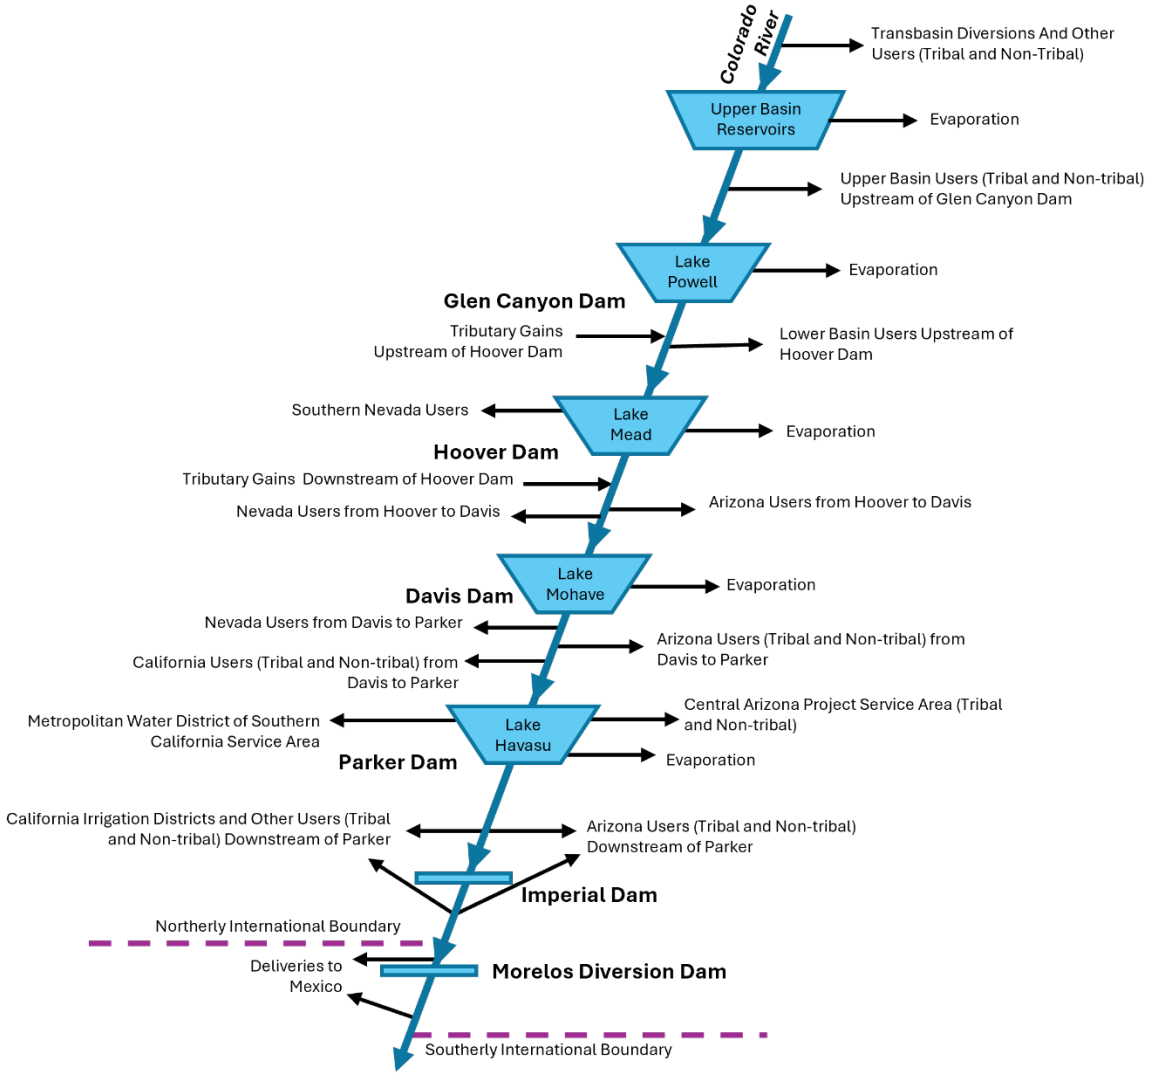
▪ The Rivers and Harbors Act of March 3, 1899 ▪ The Reclamation Act of June 17, 1902 ▪ Reclamation of Indian Lands in Yuma, Colorado River and Pyramid Lake Indian Reservations Act of April 21, 1904 ▪ Yuma Project authorized by the Secretary on May 10, 1904, pursuant to Section 4 of the Reclamation Act of June 17, 1902 ▪ Warren Act of February 21, 1910 ▪ Protection of Property Along the Colorado River Act of June 25, 1910	▪ International Flood Control Measures, Lower Colorado River Act of August 10, 1964 ▪ Southern Nevada (Robert B. Griffith) Water Project Act of October 22, 1965 ▪ The Colorado River Basin Project Act of September 30, 1968 ▪ Criteria for the Coordinated Long-Range Operation of Colorado River Reservoirs, June 8, 1970, amended March 21, 2005 ▪ Supplemental Irrigation Facilities, Yuma Division Act of September 25, 1970

- Patents and Water-Right Certificates Acts of August 9, 1912, and August 26, 1912
- Yuma Auxiliary Project Act of January 25, 1917
- Availability of Money for Yuma Auxiliary Project Act of February 11, 1918
- Sale of Water for Miscellaneous Purposes Act of February 25, 1920
- Federal Power Act of June 10, 1920
- The Colorado River Compact of November 24, 1922
- The Colorado River Front Work and Levee System Acts of March 3, 1925, and January 21, 1927–June 28, 1946
- The Boulder Canyon Project Act of December 21, 1928
- The California Limitation Act of March 4, 1929
- The California Seven Party Agreement of August 18, 1931
- The Parker and Grand Coulee Dams Authorization of August 30, 1935
- The Parker Dam Power Project Appropriation Act of May 2, 1939
- The Reclamation Project Act of August 4, 1939
- The Boulder Canyon Project Adjustment Act of July 19, 1940
- The Flood Control Act of December 22, 1944
- Water Treaty between the United States and Mexico Relating to the Utilization of the Waters of the Colorado and Tijuana Rivers and of the Rio Grande of February 3, 1944
- Gila Project Act of July 30, 1947
- The Upper Colorado River Basin Compact of October 11, 1948
- The Consolidated Parker Dam Power Project and Davis Dam Project Act of May 28, 1954
- The Palo Verde Diversion Dam Act of August 31, 1954
- Change Boundaries, Yuma Auxiliary Project Act of February 15, 1956
- The CRSPA of April 11, 1956
- The Water Supply Act of July 3, 1958
- The Boulder City Act of September 2, 1958
- Report of the Special Master, Simon H. Rifkind, *Arizona v. California*, et al., December 5, 1960
- The Consolidated Decree entered by the United States Supreme Court in the case of *Arizona v. California*, 547 U.S. 150 (2006)
- 43 CFR 417, Lower Basin Water Conservation Measures, September 7, 1972
- Minute 218, March 22, 1965; Minute 241, July 14, 1972 (replaced Minute 218); Minute 242, August 30, 1973 (replaced Minute 241); Minute 306, December 12, 2000; Minute 317, June 27, 2010; Minute 318, December 17, 2010; Minute 319, November 20, 2012; Minute 323, September 21, 2017; and Minute 330, March 21, 2024, of the 1944 Water Treaty
- The Colorado River Basin Salinity Control Act of June 24, 1974
- The Hoover Power Plant Act of August 17, 1984
- Numerous Colorado River Water Delivery and Project Repayment Contracts with the States of Arizona and Nevada, cities, water districts, and individuals
- Hoover and Parker-Davis Power Marketing Contracts
- The Reclamation States Emergency Drought Relief Act of 1991
- The Grand Canyon Protection Act of October 30, 1992
- Operation of Glen Canyon Dam, ROD (1996)
- Interim Surplus Guidelines ROD, January 17, 2001 (66 *Federal Register* 7772)
- Interim 602(a) Storage Guideline, May 19, 2004 (69 *Federal Register* 28945)
- The Colorado River Water Delivery Agreement of October 10, 2003 (69 *Federal Register* 12202)
- Colorado River Interim Guidelines for Lower Basin Shortages and Coordinated Operations for Lake Powell and Lake Mead ROD, December 13, 2007 (73 *Federal Register* 19873)
- Hoover Power Allocation Act of December 20, 2011
- Glen Canyon Dam Long-Term Experimental and Management Plan (LTEMP) ROD, December 2016
- Colorado River Drought Contingency Authorization Act (Public Law 116-14) - Colorado River Basin DCP
- Supplement to the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead ROD, May 6, 2024
- Supplement to the 2016 Glen Canyon Dam LTEMP ROD, July 3, 2024

1.8.2.2. Apportionment to the Basin States

The initial apportionment of water from the Colorado River was determined as part of the Compact, which divided the Colorado River system into two sub-basins, the Upper Basin and the Lower Basin. The Upper Basin includes those parts of the states of Arizona, Colorado, New Mexico, Utah, and Wyoming within and from which waters drain naturally into the Colorado River above the Lee Ferry Compact Point in Arizona. The Lower Basin includes those parts of the states of Arizona, California, Nevada, New Mexico, and Utah within and from which waters drain naturally into the Colorado River below the Lee Ferry Compact Point. The Compact also divided the seven Basin States into the Upper Division and the Lower Division States (**Map 1-1**). The Upper Division States are Colorado, New Mexico, Utah, and Wyoming. The Lower Division States are Arizona, California, and Nevada.

The Compact apportioned to the Lower Basin and the Upper Basin, in perpetuity, the exclusive beneficial consumptive use of 7.5 maf of water per year (mafy). In addition to this apportionment, Article III(b) of the Compact gives the Lower Basin the right to increase their beneficial consumptive use by 1.0 mafy. The Compact also stipulates in Article III(d) that the Upper Division States will not cause the flow of the river at the Lee Ferry Compact Point to be depleted below an aggregate of 75.0 maf for any period of ten consecutive years. Article III(c) reflects the intent that any future water deliveries to Mexico be supplied first from surplus Colorado River water and, if surplus is insufficient, that the resulting deficiency be shared equally between the Upper and Lower Basins.



The Compact, in Article VII, states that nothing in the Compact shall be construed as affecting the obligations of the U.S. to Indian tribes. Tribal rights to mainstream Colorado River water were subsequently adjudicated in the Consolidated Decree. To the extent that Indian tribes consumptively use water from the mainstream Colorado River, such uses are included in the apportionment of the appropriate Basin State.

Upper Division State Apportionments. Upper Division State apportionments were established by the Upper Colorado River Basin Compact of 1948. These apportionments allocate the Upper Division States' consumptive use after deduction of up to 50 thousand acre-feet per year (kafy) for Arizona as follows: Colorado, 51.75 percent; New Mexico, 11.25 percent; Utah, 23.00 percent; and Wyoming, 14.00 percent. The Upper Basin State apportionments have not yet been fully developed.

Lower Division State Apportionments. Lower Division State apportionments were established by Congress in the BCPA and by the Secretary's water delivery contracts under the BCPA. These apportionments are: Arizona, 2.8 maf; California, 4.4 maf; and Nevada, 0.3 maf; totaling 7.5 maf, subject to annual increases or reductions pursuant to Secretarial determinations of a Surplus or a Shortage Condition. Under Article II(B)(2) of the Consolidated Decree, when the Secretary determines that there is a Surplus Condition, 46 percent of the available water supply in excess of 7.5 maf may be apportioned for use in Arizona; 50 percent for use in California; and 4 percent for use in Nevada.

Figure 1-1 presents a schematic of the operation of the Colorado River. The Consolidated Decree confirms the apportionments to the Lower Division States established by the BCPA and guides the Secretary's operation of facilities, including Hoover Dam, on the lower Colorado River. Under the Consolidated Decree, if water apportioned for use in a Lower Division State is not consumed by that state in any year, the Secretary may release the unused water for use in another Lower Division State. Water that is stored off-stream by a Lower Division State (for future use by that state or by another Lower Division State) is accounted as consumptive use to the state that stored the water in the year it was stored.

Figure 1-1
Colorado River Reservoirs and Diversions

All mainstream Colorado River waters apportioned to the Lower Basin, except for a few kaf apportioned for use in Arizona, have been fully allocated to specific entities for permanent irrigation or domestic[19] use entitlements. These entities include irrigation districts, water districts, municipalities, Indian tribes, public institutions, private water companies, and individuals. Federal establishments with federal reserved rights established pursuant to Article II(D) of the Consolidated Decree are not required to have a contract with the Secretary, but the water allocated to a federal establishment is included within the apportionment of the Lower Division State in which the federal establishment is located; e.g., Fort Mojave Indian Reservation in California and the Havasu National Wildlife Refuge (NWR) in Arizona.

The highest priority lower Colorado River water rights are present perfected rights (PPRs), which the Consolidated Decree defines as those perfected rights existing on June 25, 1929, the effective date of the BCPA.[20] The Consolidated Decree quantified PPRs including federal Indian reserved rights on five Indian reservations along the lower Colorado River. PPRs are important because in any year in which less than 7.5 maf of Colorado River water is available for consumptive use in the Lower Division States, PPRs will be satisfied first, in the order of their priority without regard to state lines.

Waters available to a Lower Division State within its apportionment, but having a priority date later than June 25, 1929, have been allocated by the Secretary through execution of water delivery contracts to water users within that state as required by Section 5 of the BCPA. The Lower Division States have intrastate priority systems in accordance with those contracts.

1.8.2.3. Allotment to Mexico (Pursuant to the 1944 Water Treaty)

Allocation of Colorado River water to Mexico is governed by the 1944 Water Treaty. Article 10(a) of the 1944 Water Treaty states:

> "(a) A guaranteed annual quantity of 1,500,000 acre-feet (af; 1,850,234,000 cubic meters) to be delivered in accordance with the provisions of Article 15 of this Treaty"

Further, Article 10(b) of the 1944 Water Treaty provides:

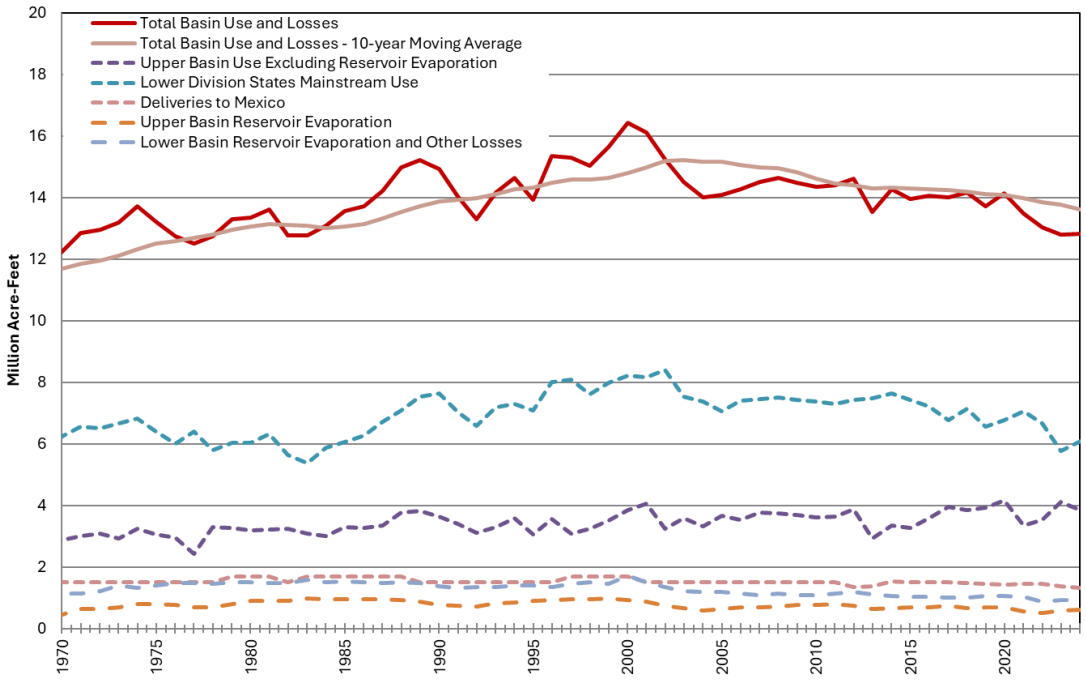
> "(b) Any other quantities arriving at the Mexican points of diversion, with the understanding that in any year in which, as determined by the United States Section, there exists a surplus of waters of the Colorado River in excess of the amount necessary to supply uses in the United States and the guaranteed quantity of 1,500,000 acre-feet (1,850,234,000 cubic meters) annually to Mexico, the United States undertakes to deliver to Mexico, in the manner set out in Article 15 of this Treaty, additional waters of the Colorado River system to provide a total quantity not to exceed 1,700,000 acre-feet (2,096,931,000 cubic meters) a year. Mexico shall acquire no right beyond that provided by this subparagraph by the use of waters of the Colorado River system, for any purpose whatsoever, in excess of 1,500,000 acre-feet (1,850,234,000 cubic meters) annually."

[19] The term "domestic use" shall include the use of water for household, stock, municipal, mining, milling, industrial, and other like purposes, but shall exclude the generation of electrical power (1922 Compact, Article II(h)).
[20] Priority is a ranking with respect to diversions of water relative to other water users.

Additionally, Article 10 of the 1944 Water Treaty provides:

> "In the event of extraordinary drought or serious accident to the irrigation system in the United States, thereby making it difficult for the United States to deliver the guaranteed quantity of 1,500,000 acre-feet (1,850,234,000 cubic meters) a year, the water allotted to Mexico under subparagraph (a) of this Article will be reduced in the same proportion as consumptive uses in the United States are reduced."

The proposed federal action is for the purpose of adopting additional operational guidelines to improve the Department's management and operation of key Colorado River reservoirs for an interim period. However, in order to assess the potential effects of the proposed federal action in this Final EIS, certain modeling assumptions (discussed in **Chapter 2** and **Appendix S**) are used that display projected water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico.



The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

1.8.3 Colorado River Basin Water Use

Total annual water "use" in the Basin is made up of diversions from the river, deliveries from reservoirs, and evaporation and other losses (e.g., seepage into the ground and usage by riparian vegetation). **Figure 1-2**, Historical Annual Colorado River Basin Use, shows Basin uses and losses from 1970 to 2024 as total Basin use and also shows use separated geographically and by category (use or evaporation and losses).

From 1970 to 2001, Upper Basin use varied between approximately 2.4 maf and approximately 4.1 maf, with a general upward trend over time. Since 2001, Upper Division States' use has varied within a similar range of volumes. Lower Division States' mainstream use increased from approximately 5.4 maf to approximately 8.4 maf from 1970 to 2002, and deliveries to Mexico were steady around 1.5 maf. Shortly after the onset of the ongoing drought in 2000, use began to decline. In the Lower Division States, the decline began after adoption of the Interim Surplus Guidelines in 2001, which brought California's water use to within its apportionment. After adoption of the 2007 Interim Guidelines, Lower Division States began significant conservation efforts, and drought-response activities since their adoption have resulted in continued reductions in use. The first year of shortages under the 2007 Interim Guidelines occurred in 2022. Evaporation and other losses declined between 2000 and 2024 because evaporation decreases as Lake Powell and Lake Mead elevations decline.

Figure 1-2
Historical Annual Colorado River Basin Use

Note: Use and losses includes consumptive use by the U.S. Colorado River Basin States and Mexico, reservoir evaporation, and other losses; use data from Upper Colorado River System Consumptive Uses and Losses Reports and Lower Colorado River Basin Water Accounting Reports.

1.8.4 System Reservoirs and Diversion Facilities

The Colorado River System contains numerous reservoirs that provide an aggregate of approximately 60.0 maf of storage (or roughly 4 years of average flow of the Colorado River). Of these reservoirs, Lake Powell and Lake Mead provide approximately 85 percent of this storage. Lake Powell, formed by Glen Canyon Dam, provides 23.3 maf of this storage.

The Lower Basin dams and reservoirs include Hoover Dam, Davis Dam, and Parker Dam (**Map 1-3**). Lake Mead, formed by Hoover Dam, can store up to 26.1 maf (27.6 maf at full pool less 1.5 maf of exclusive Flood Control space). Davis Dam was constructed by Reclamation to re-regulate Hoover Dam's releases and to aid in the annual delivery of 1.5 maf to Mexico. Davis Dam created Lake Mohave and provides 1.8 maf of storage. Parker Dam formed Lake Havasu (0.65 maf of storage) from which water is pumped by both Metropolitan Water District of Southern California (MWD) and the CAP. Parker Dam re-regulates releases from Davis Dam and from the U.S. Army Corps of Engineers' (USACE's) Alamo Dam on the Bill Williams River, and in turn releases water for downstream use in the U.S. and Mexico. Other Lower Basin mainstream reservoirs, shown on **Map 1-3**, are operated primarily for the purpose of river flow regulation to facilitate diversion of water to Arizona, California, and Mexico. Diversion facilities of the Lower Division States typically serve multiple entities.

Upper Basin
Lower Basin

There are several points of diversion in Arizona. Arizona can use up to 50 kafy of water under its Upper Basin apportionment. In the Lower Basin, the largest diversion for Arizona is the CAP pumping plant on Lake Havasu downstream of the confluence of the Bill Williams River. Irrigation water for the Fort Mojave Indian Reservation, near Needles, California, is pumped from both wells and pumps along the river channel. There are also several other municipal, industrial, and agricultural water users located along the Colorado River that pump their water from wells. Irrigation water for the Colorado River Indian Reservation near Parker, Arizona, is diverted at Headgate Rock Dam, which was constructed for that purpose. A river pumping plant in the Cibola area provides water to irrigate lands adjacent to the Colorado River. The last major diversion for Arizona occurs at Imperial Dam, where water is diverted into the Gila Gravity Main Canal for irrigation for the Gila and Wellton-Mohawk projects and into the AAC for subsequent release into the Yuma Main Canal for the Yuma Project and the City of Yuma.

California receives most of its Colorado River water at three diversion points: MWD's pumping plant on Lake Havasu; the Palo Verde Irrigation District's diversion at the Palo Verde Diversion Dam near Blythe, California; and the AAC diversion at Imperial Dam (**Map 1-3**).

In Nevada, the state's consumptive use apportionment of Colorado River water is used almost exclusively for municipal and industrial (M&I) purposes. About 90 percent of this water is diverted from Lake Mead at a point approximately 5 miles northwest of Hoover Dam at Saddle Island by the Southern Nevada Water Authority (SNWA) facilities. The remainder of Nevada's diversion occurs downstream of Davis Dam in the Laughlin, Nevada area and on the Fort Mojave Indian Reservation.

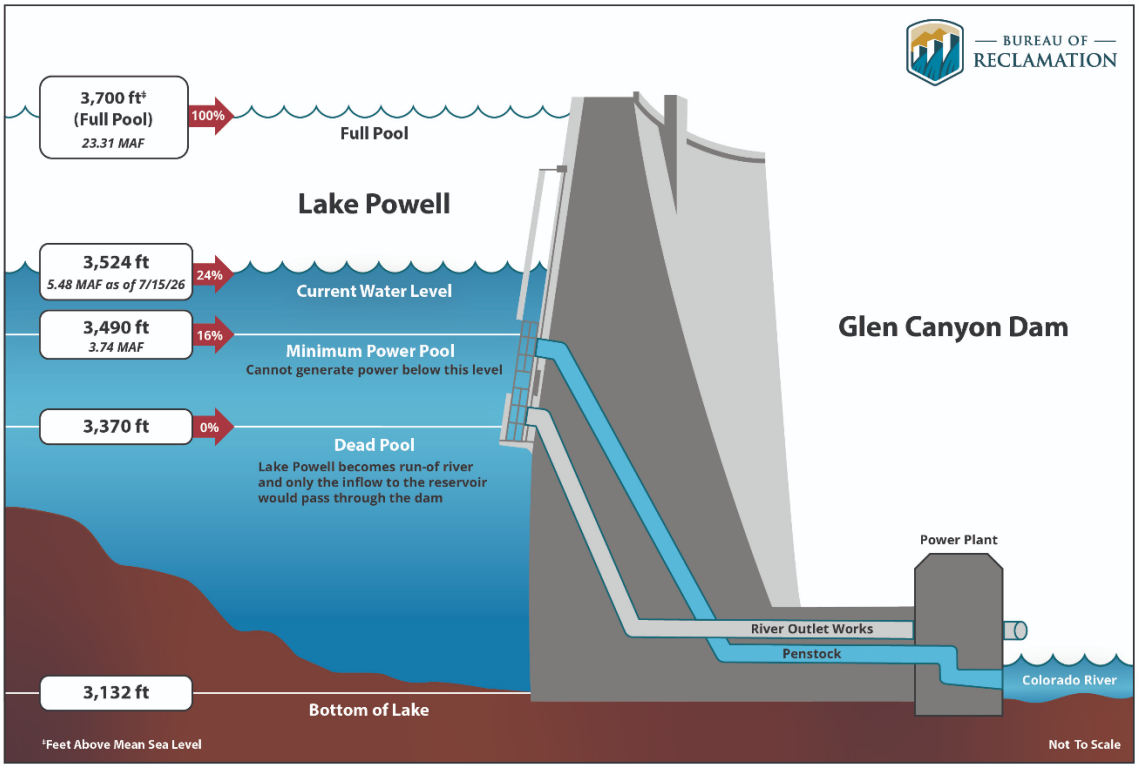
1.8.4.1. Critical Infrastructure Considerations at Glen Canyon Dam

Glen Canyon Dam is a National Critical Infrastructure site. Full pool is at elevation 3,700 feet, and dead pool is at elevation 3,370 feet (see **Figure 1-3**). There are three mechanisms for releasing water through the dam (see **Figure 1-4**): the spillways, the penstocks, and the river outlet works. The penstocks route water through turbines in the hydropower generating plant, and the river outlet works route water through four jet tubes. Water can be released through the spillways from full pool down to elevation 3,648 feet. Water can be released through the penstocks down to elevation 3,490 feet, which is minimum power pool. Water can be released from the river outlet works down to elevation 3,370 feet, which is the dead pool elevation.[21]

On March 26, 2024, Reclamation released a technical decision memorandum to guide operations at Glen Canyon Dam during low reservoir elevations (Reclamation 2024a). Glen Canyon Dam was not intended to operate for an extended period of time below minimum power pool (elevation 3,490 feet). Below this elevation, water cannot be released through the penstocks and must instead be released through the river outlet works. Infrastructure concerns associated with the uncertainty of extended operations through the river outlet works as the sole means of sustained water releases from Glen Canyon Dam include potential cavitation damage to the outlet works pipes at low reservoir elevations, tailrace scour and sediment deposition at the downstream base of the dam, and the potential for additional unknown issues from operating the outlet works for extended periods. Any one of these

[21] Emergency and other operations are further described in **Section 2.3**, footnote 7.

Figure 1-3
Glen Canyon Dam Key Elevations



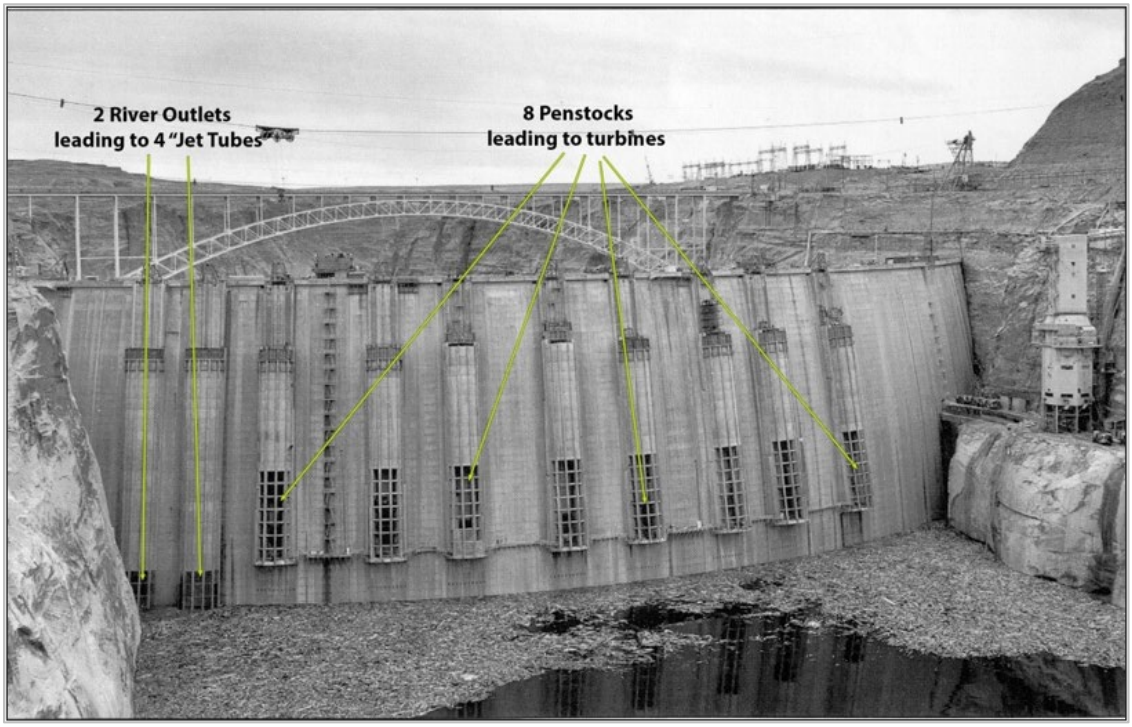


Figure 1-4
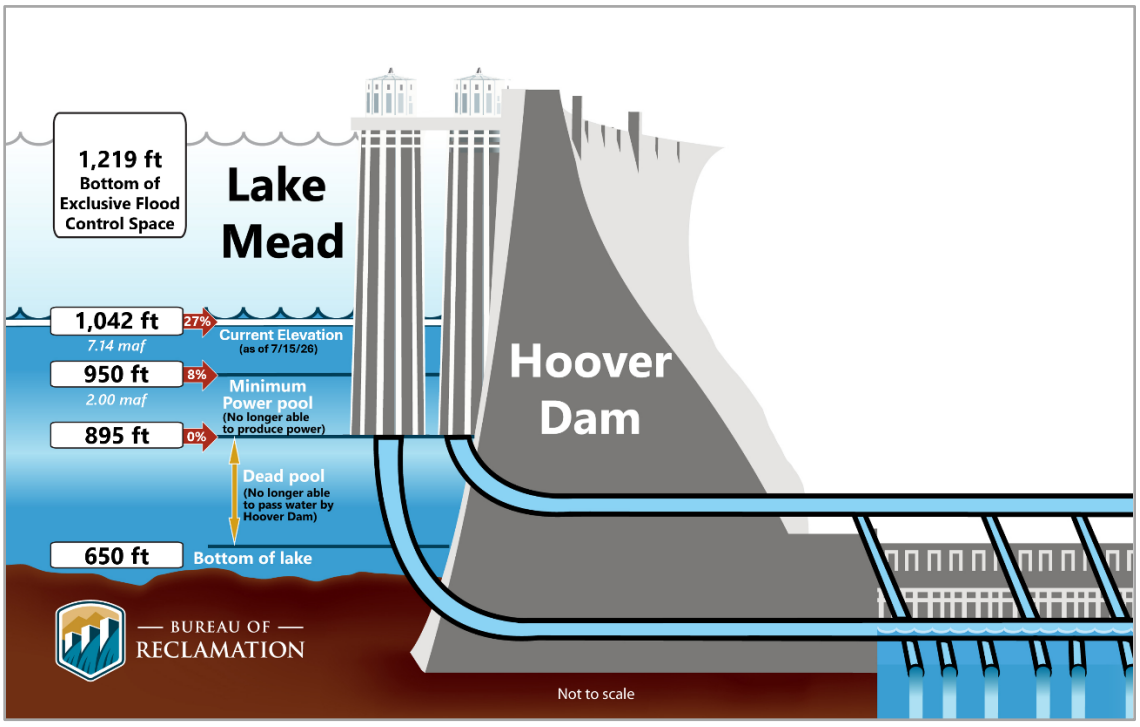
Glen Canyon Dam in 1963 (Before Filling)

factors could compromise the reliability and operational flexibility of Glen Canyon Dam and affect the ability to meet critical downstream water supply needs. The foregoing concerns informed the design of the Preferred Alternative to reduce the likelihood of having to rely on the river outlet works as the sole means of sustained water releases from Glen Canyon Dam. Alterations to the dam to reduce some of these risks and uncertainties are being contemplated but are outside the scope of this EIS and speculative; therefore, they are not analyzed in this document.

1.8.4.2. Critical Infrastructure Concerns at Hoover Dam

Hoover Dam is a National Critical Infrastructure site. Maximum pool elevation is elevation 1,229 feet, and dead pool is elevation 895 feet (see **Figure 1-5**). There are two mechanisms for releasing water through the dam (see **Figure 1-6**). There are four intake towers, two on each side of the dam, that draw water to four penstocks. These penstocks route water through the turbines in the hydropower generating plant and can also route water to two sets of river outlet works. If the reservoir is above elevation 1,205 feet, water can also be moved through two spillways, one on each side of the dam. However, normal operating practice is to not pass water through the spillways until the reservoir is at the top of the raised spillway (at elevation 1,221 feet) for flood control purposes. Minimum power pool elevation is estimated to be 950 feet and the bottom of the intake towers for the penstocks is elevation 895 feet (dead pool). Below elevation 950 feet, water can no longer be passed through the turbines and can only be passed through the river outlet works, resulting in release constraints at low elevations. The Hoover Dam hydropower plant has 17 total hydropower turbines including five wide-head turbines. All 17 turbines can generate power down to elevation 1,035 feet, but only the five wide-head turbines can continue to produce power below 1,035 feet to 950 feet. It is estimated that there would be a 70-percent loss of total generation capacity below elevation 1,035 feet.

Figure 1-5
Hoover Dam Key Elevations



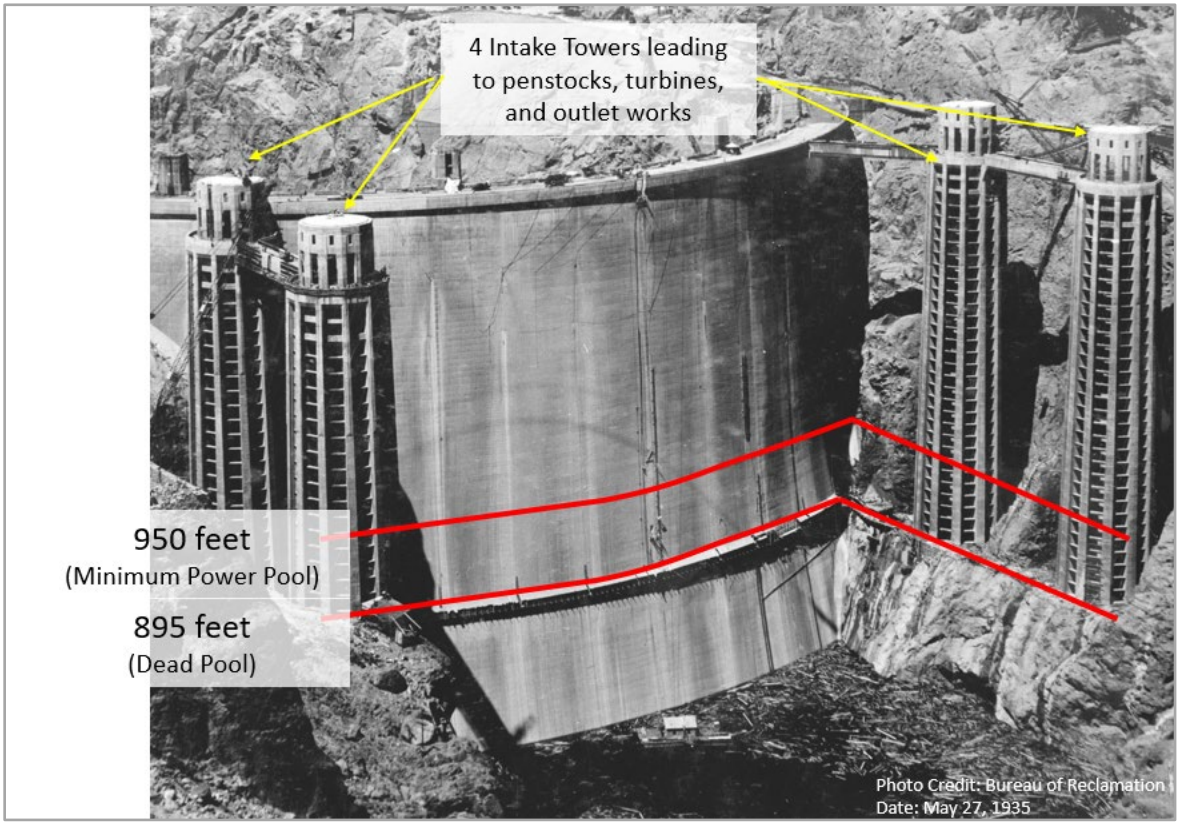


Figure 1-6
Hoover Dam in 1935 (before filling)

1.8.5 Flood Control Operation

Under the BCPA, flood control is specified as the project purpose having first priority for the operation of Hoover Dam. Subsequently, Section 7 of the Flood Control Act of 1944 established that the Secretary of War (now the USACE) will prescribe regulations for Flood Control for projects authorized wholly or partially for such purposes.

The Los Angeles District of the USACE published the current Flood Control regulations in its Water Control Manual for Flood Control, Hoover Dam and Lake Mead, Colorado River, Nevada and Arizona (Water Control Manual) dated December 1982. The Field Working Agreement between the USACE and Reclamation for the Flood Control operation of Hoover Dam and Lake Mead, as prescribed by the Water Control Manual, was signed on February 8, 1984. The Flood Control plan is the result of a coordinated effort between the USACE and Reclamation; however, the USACE is responsible for providing the Flood Control regulations and has authority for final approval. The Secretary is responsible for operating Hoover Dam in accordance with these regulations. Deviation from the Flood Control operating criteria must be authorized by the USACE.

1.8.6 Hydropower Generation

Reclamation is authorized by legislation to produce electric power at Glen Canyon Dam, Hoover Dam, Davis Dam, Parker Dam, and other smaller facilities. While Reclamation is the federal agency authorized to produce power at the major Colorado River system dams, WAPA is the federal agency

authorized to market and deliver this power. WAPA enters into electric service contracts on behalf of the U.S. with public and private utility systems for distribution of hydroelectric power produced at Reclamation facilities in excess of project demand. Glen Canyon, Hoover, Davis, and Parker Dams have a maximum combined capacity of approximately 3,769 megawatts (MW), which WAPA markets to more than 182 customers across Arizona, California, Colorado, Nebraska, Nevada, New Mexico, Utah, and Wyoming.

1.8.7 Long Range Operating Criteria and AOP

The CRBPA required the Secretary to consult with the Governors of the Basin States to adopt operating criteria for the Colorado River by July 1, 1970. The LROC, adopted in June 1970 by the Secretary (*35 Federal Register* 8951), address operation of the Colorado River reservoirs in compliance with requirements set forth in the Compact, the CRSPA, the BCPA, the 1944 Water Treaty, and other applicable federal laws. The CRBPA also provided that beginning on January 1, 1972, and annually thereafter, the Secretary "shall transmit to the Congress and to the Governors of the Colorado River Basin States a report describing the actual operation under the [LROC] for the preceding compact water year and the projected operation for the current year." This annual transmittal is known as the AOP.

Section 602 of the CRBPA, as amended, provides that the LROC can only be modified after correspondence with the governors of the Basin States and appropriate consultation with such state representatives as each governor may designate.

1.8.7.1. LROC Provisions

Under the applicable provisions of the CRBPA, the Secretary makes annual determinations in the AOP regarding the availability of Colorado River water for deliveries to the Lower Division States. A requirement to equalize storage between Lake Powell and Lake Mead when there is sufficient storage in the Upper Basin is also included in the LROC, as required by the CRBPA. Equalization releases are made if: 1) the end of the water year (WY) storage projection for Lake Powell is greater than that of Lake Mead; and 2) the storage projection for the end of the WY in the Upper Basin reservoirs is greater than the quantity of storage required by Section 602(a) of the CRBPA (602(a) storage) for that same date.

The 602(a) storage quantity is the storage in the Upper Basin necessary to assure obligations to the Lower Basin without impairing consumptive use requirements in the Upper Basin. The LROC offers factors to be considered to determine 602(a) storage but does not present a set formula. The factors to be considered include the historical stream flows, the most critical period of record, probability of available waters, and estimated future depletions in the Upper Basin. In the event that the elevation of Lake Powell is below the 602(a) storage guideline, and equalization is not required, the LROC provide that "the objective shall be to maintain a minimum release of water from Lake Powell of 8.23 maf for that year." Reclamation recognizes that entities in the Basin have different legal positions regarding how this LROC statement incorporates other Law of the River elements to determine annual releases. The Secretary has expressly recognized that variation in releases of water above and below the minimum objective release of 8.23 maf can, in appropriate circumstances, be adopted (Norton 2005). The LROC expressly note that releases from Lake Powell pursuant to the LROC or any adopted

guidelines "shall not prejudice the position of either the Upper or Lower Basin interests with respect to the required deliveries at Lee Ferry pursuant to the Colorado River Compact."

In the AOP, the Secretary is required to report on the determination of when Normal, Surplus, or Shortage Conditions occur in the lower Colorado River, based on various factors including storage and hydrologic conditions in the Basin.

1.8.7.2. LROC Implementing Criteria and Guidelines

Beginning in 1999, the Department recognized the need for more specific and objective provisions to implement the LROC and solicited input from the Governors and the general public in the *Federal Register* (64 *Federal Register* 27009). Rather than modifying the content of the LROC, the Department chose to develop more specific, objective criteria to implement the LROC. *Federal Register* (64 *Federal Register* 68373 and 65 *Federal Register* 42028). Interim criteria and guidelines to implement the LROC were developed in 2001 and 2007, addressing both Glen Canyon and Hoover Dam operations (66 *Federal Register* 7772 and 73 *Federal Register* 19873).[22] This NEPA process will develop the next set of LROC implementing guidelines to succeed those adopted in 2007.[23]

Among other provisions described in **Section 1.8.7.1**, the LROC provide that "the objective shall be to maintain a minimum release of water from Lake Powell of 8.23 maf for that year." Despite the operational challenges due to prolonged drought, the release from Lake Powell over the term of the 2007 Interim Guidelines has met or exceeded the minimum objective release of 8.23 maf in 13 out of 19 years, and has averaged 8.5 maf over the 2008-2026 period. Going forward, the Department recognizes the continued importance of operating to achieve a minimum objective release of 8.23 maf, but meeting this objective release has been and will be increasingly difficult in a constrained system of low reservoir elevations, declining river flows, and the need to protect the operational reliability of Glen Canyon Dam.

1.8.7.3. Normal Water Supply Condition

A Normal Condition exists when the Secretary determines that sufficient mainstream water is available to satisfy 7.5 maf of annual consumptive use in the Lower Division States. Pursuant to the Consolidated Decree, if a state will not use all of its apportioned water for the year, the Secretary may allow other states of the Lower Division to use the unused apportionment, provided that the use is authorized by a water delivery contract with the Secretary.

[22] Additionally, in 2004, Reclamation adopted an interim 602(a) storage guideline, in effect through 2026, which established that Lake Powell's elevation must be above 3,630 feet (which corresponds to storage of approximately 14.85 maf) for equalization releases to occur (Reclamation 2004). The 2007 Interim Guidelines included an Equalization Tier defined by an elevation schedule that would be used in determining when equalization releases would be made from Lake Powell (generally called the "Equalization Line").

[23] Prior to 2007, the Department conducted 5-year periodic reviews of the LROC. Implementation of the 2007 Guidelines included objective consultation provisions and a review conducted in 2020 (Reclamation 2020) that served the same function as the previous period reviews. The adaptive nature of the Preferred Alternative will require at a minimum biennial reconsideration of operations and is anticipated to serve the same purpose as the formal 5-year periodic reviews during the term of the action proposed in this NEPA process.

1.8.7.4. Surplus Water Supply Condition

A Surplus Condition exists when the Secretary determines that sufficient mainstream water is available for release to satisfy consumptive use in the Lower Division States in excess of 7.5 maf annually. This excess consumptive use is surplus and is distributed for use in Arizona, California, and Nevada pursuant to the terms and conditions provided in the Interim Surplus Guidelines (ISG), adopted in 2001, as modified by the 2007 Interim Guidelines. Other than 70(R) and Flood Control surplus determinations, surplus guidelines expire with the expiration of the 2007 Interim Guidelines.

In general terms, under the 2007 Interim Guidelines, the availability of surplus water is determined by the elevation of Lake Mead. When Lake Mead is full and Reclamation is making Flood Control releases, surplus supplies are unlimited. As Lake Mead's elevation drops, surplus water amounts are reduced and ultimately eliminated.

Pursuant to the Consolidated Decree, if a state does not use all of its apportioned water for the year, the Secretary may allow other Lower Division States to use the unused apportionment, provided that the use is authorized by a water delivery contract with the Secretary.

1.8.7.5. Shortage Water Supply Condition

A Shortage Condition exists when the Secretary determines that insufficient mainstream water is available to satisfy 7.5 maf of annual consumptive use in the Lower Division States. The Secretary is authorized to determine both the timing of the initiation of a Shortage Condition and the volume of any shortage. When making a shortage determination, the Secretary must consult with various parties as set forth in the Consolidated Decree and consider all relevant factors as specified in the LROC, including 1944 Water Treaty obligations, the priorities set forth in the Consolidated Decree, and the reasonable consumptive use requirements of mainstream water users in the Lower Division States. Under the 2007 Interim Guidelines, the 2019 Lower Basin Drought Contingency Plan Agreement, and related intrastate agreements, distribution of reductions were agreed to among the Lower Division States, tribes, and water entitlement holders prior to implementation. Without these agreements, the Secretary follows the Law of the River, which includes applicable priorities, as described below, to distribute reductions.

In the Lower Basin, PPRs, generally those established before June 25, 1929, must be addressed first and in priority-date order across state lines under the *Arizona v. California* Consolidated Decree. The CRBPA also requires junior, post-1968 supplies, including much of the Central Arizona Project supply, to be limited before uses in California are reduced. Within these legal constraints, the Secretary retains discretion over how any remaining shortage volume is apportioned among Arizona, California, and Nevada (see **Appendix C** for further discussion).

In the absence of adoption of new, specific shortage criteria through this proposed action, a shortage determination would most likely be made on an annual basis through the AOP process. This is a process by which the interests of the different stakeholders are addressed through consultation. In this consultation process, water users who rely on the Colorado River in the Lower Division States would not be able to identify in advance particular reservoir conditions under which the Secretary would reduce the annual amount of water available for consumptive use from Lake Mead, nor would they be able to understand the frequency or magnitude of any potential future annual reductions in their water deliveries.

1.9 Related Actions

The alternatives considered in this Final EIS address operation and storage of water in Lake Powell and Lake Mead. While there are many actions related to the operation of the Colorado River with respect to the proposed federal action analyzed in this Final EIS, Reclamation has identified seven primary documents that are related to, or would assist the reader in understanding the issues analyzed in this process:

- Off-stream Storage of Colorado River Water and Development and Release of Intentionally Created Unused Apportionment in the Lower Division States – 43 CFR pt. 414 (1999);
- Implementation Agreement, Inadvertent Overrun and Payback Policy, and Related Federal Actions - Final EIS (Reclamation 2002) and ROD - Colorado River Water Delivery Agreement (Reclamation 2003);
- Lower Colorado River Multi-Species Conservation Program (LCR MSCP) - Final Programmatic EIS/Environmental Impact Report (Reclamation 2004) and ROD - Lower Colorado River Multi-Species Conservation Plan (Reclamation 2005);
- CRSP Upper Initial Units RODs (Reclamation 2006a, 2006b, 2012);
- 2007 Interim Guidelines (Reclamation 2007a) and Near-term Colorado River Operations, Final Supplemental Environmental Impact Statement (SEIS) (Reclamation 2024b);
- LTEMP – Final EIS (Reclamation 2016) and LTEMP - Final SEIS (Reclamation 2024c) address sub-annual releases from Glen Canyon Dam; and
- 2019 Colorado River DCP (Reclamation 2019).

The actions documented in the references listed above are summarized below.

1.9.1 Off-stream Storage of Colorado River Water and Development and Release of Intentionally Created Unused Apportionment in the Lower Division States

In 1999, the Department adopted a rule to facilitate off-stream storage of Colorado River water and development and release of "Intentionally Created Unused Apportionment" for the Lower Division States. Reclamation prepared an Environmental Assessment to assess the environmental impacts of the rule, and a Finding of No Significant Impact was issued on October 1, 1999. The final rule was published in the Federal Register on November 1, 1999, and is codified at 43 CFR pt. 414.

This rule establishes a procedural framework within the Lower Basin States for an authorized entity in one state to enter into storage agreements with authorized entities in another state for the off-stream storage (and future recovery) of Colorado River water. Under the agreements, the storing state will use water it stores under an interstate agreement and, in return, at a future date, decrease its consumptive use of Colorado River water, thereby developing the ICUA that the Secretary will release for consumptive use in the consuming state. Under this rule, two Storage and Interstate Release Agreements (SIRAs) have been executed to date.[24]

[24] SIRA Contract No. 02-XX-30-W0406 was entered into on December 18, 2002, among Nevada, Arizona, and the U.S.; SIRA Contract No. 04-XX-30-W0430 was entered into on October 27, 2004, among Nevada, California, and the U.S.

1.9.2 Implementation Agreement, Inadvertent Overrun and Payback Policy and Related Federal Actions – Final EIS and ROD – Colorado River Water Delivery Agreement

California's Colorado River Water Use Plan called for conservation measures to be put in place that would reduce California's historical dependency on Colorado River water in excess of the state's 4.4 maf apportionment. The Colorado River Water Delivery Agreement, signed by the Secretary on October 10, 2003, provides for implementation of major components of California's Colorado River Water Use Plan and incorporates contractual agreements that facilitate California's sharing and distribution of Colorado River water within its 4.4 mafy entitlement.

The 2003 Colorado River Water Delivery Agreement is the Secretary's agreement to make those Colorado River water deliveries specified in the agreements with the relevant California entities for a period of up to 75 years. These agreements provide for the conservation and transfer of about 400 kaf of water annually among the Imperial Irrigation District (IID), Coachella Valley Water District (CVWD), MWD, and San Diego County Water Authority.

1.9.3 Lower Colorado River Multi-Species Conservation Program

The LCR MSCP is a 50-year cooperative effort between federal and non-federal entities, approved by the Secretary in April 2005. The LCR MSCP provides ESA compliance for specific covered federal actions and non-federal activities under ESA Sections 7 and 10. The LCR MSCP provides ESA coverage for non-federal actions that are related to the use and management of the lower Colorado River.

In addition to the covered activities of the non-federal LCR MSCP entities, specific present and potential future actions of six federal agencies on the lower Colorado River are also included in the LCR MSCP. Those federal agencies are Reclamation, BIA, NPS, Bureau of Land Management (BLM), WAPA, and FWS. These federal agencies and non-federal entities are collectively referred to as the LCR MSCP participants. The covered actions and activities for the LCR MSCP participants occur along the lower Colorado River in Imperial, Riverside, and San Bernardino counties, California; La Paz, Mohave, and Yuma counties, Arizona; and Clark County, Nevada. The duration of the Section 10 permit and the associated formal ESA Section 7 consultation for the federal agencies is 50 years (2005 to 2055).

The LCR MSCP is intended to avoid, minimize, and fully mitigate the incidental take of the covered species from the implementation of the covered activities to the maximum extent practicable. The EIS will evaluate operational interactions without altering LCR MSCP commitments. The LCR MSCP is being revisited in a separate process that will be finalized following the completion of this NEPA process.

1.9.4 Colorado River Storage Project Upper Initial Units RODs

The 1956 CRSPA authorized construction of the CRSP "to initiate the comprehensive development of the water resources of the Upper Basin, for the purposes, among others, of regulating flow of the Colorado River, storing water for beneficial consumptive use, making it possible for the States of the Upper Basin to utilize, consistently with the provisions of the Colorado River Compact, the apportionments made to and among them in the Colorado River Compact and the Upper Colorado

River Basin Compact, respectively, providing for the reclamation of arid and semiarid land, for the control of floods, and for the generation of hydroelectric power, as an incident of the foregoing purposes…"

There are four initial storage units built as part of the CRSP. The Glen Canyon Unit is the farthest downstream. The three upper initial units are Flaming Gorge Unit in Utah, Wayne N. Aspinall Unit in Colorado (Blue Mesa, Crystal, and Morrow Point Dams), and Navajo Unit in New Mexico (see **Map 1-1**). The current RODs governing operations of these units were signed in 2006, 2012, and 2006, respectively. Each ROD sets a range of releases from the unit with the goal of meeting flow and/or temperature recommendations.

With the adoption of the 2019 DCP, which included the Drought Response Operations Agreement (DROA), a specific operational mechanism was established for releases from the CRSP Upper Initial Units, if needed, to protect Lake Powell elevations and the ability of the Upper Division States to meet Compact compliance obligations while exercising their rights to develop and utilize Colorado River water. Releases from the CRSP Upper Initial Units implemented to date pursuant to the DROA have occurred within the scope of the existing RODs for the respective facilities, including the 2026 DROA release occurring during the final year of the agreement.

This Final EIS evaluates alternatives that contemplate the potential continued use of the CRSP Upper Initial Units to release additional water if needed to protect critical infrastructure at Glen Canyon Dam in a manner intended to remain within the scope of those existing RODs. While the Secretary will consider and prioritize operations at these facilities that are consistent with existing RODs, the Secretary retains the authority to operate outside those RODs if necessary. The modeling assumptions regarding operation of the CRSP Upper Initial Units presented in this Final EIS are not intended to, and do not, limit the Secretary's ability to operate these facilities as necessary to respond to hydrologic conditions in accordance with applicable federal law, including operations for the authorized purposes stated in the CRSPA.

1.9.5 2007 Interim Guidelines

Spurred by an ongoing multi-year drought, decreasing system storage, and growing demands for Colorado River water, in December 2007, the Secretary approved the ROD for the 2007 Interim Guidelines. The Guidelines, which are in place for an interim period through 2026, provide operating criteria for Lake Powell and Lake Mead including provisions designed to provide a greater degree of certainty to water users about timing and volumes of potential water delivery reductions, and additional operating flexibility to conserve and store water in the system. The interim nature of the Guidelines provided the opportunity to gain valuable experience for the management of Lake Powell and Lake Mead under modified operations and improve the basis for making future operational decisions, whether during the interim period or after.

The Guidelines are comprised of four operational elements collectively intended to address the purpose and need. These elements are as follows:

- **Shortage Guidelines:** Determines those conditions under which the Secretary would reduce the annual amount of water available for consumptive use from Lake Mead to the Lower Division States below 7.5 maf pursuant to the Consolidated Decree.

- **Coordinated Reservoir Operations:** Defines the coordinated operations of Lake Powell and Lake Mead to provide improved operation of these two reservoirs, particularly under low reservoir conditions. As described in Section XI.G.6. of the ROD, the objective of the operation of Lake Powell and Lake Mead is "to avoid curtailment of uses in the Upper Basin, minimize shortages in the Lower Basin and not adversely affect the yield for development available in the Upper Basin."
- **Storage and Delivery of Conserved Water**: Allows for the storage and delivery, pursuant to applicable federal law, of conserved Colorado River System and non-System water in Lake Mead to increase the flexibility of meeting water use needs from Lake Mead, particularly under drought and low reservoir conditions. Delivery of water previously conserved pursuant to the 2007 Interim Guidelines will continue beyond 2026 per the provisions of the 2007 Interim Guidelines and the DCP.
- **Surplus Guidelines:** Determines those conditions under which the Secretary may declare the availability of surplus water for use within the Lower Division States. Modifies the substance of the ISG existing at the time the Guidelines were adopted by extending the term from 2016 to 2026 and terminating the most permissive provision.

Except for the special provisions described in Section XI.G.8. of the ROD, the Guidelines remain in effect through December 31, 2025 (through preparation of the 2026 AOP).

1.9.6 Operation of Glen Canyon Dam – Long-Term Experimental and Management Plan

In contrast to the annual releases determined through the Interim Guidelines, LTEMP determines sub-annual releases from Glen Canyon Dam. LTEMP identifies specific options for dam operations (including hourly, daily, and monthly release patterns), non-flow actions, and appropriate experimental and management actions that meet the Grand Canyon Protection Act's requirements and maintain or improve hydropower production to the greatest extent practicable, consistent with improvement of downstream environmental and cultural resources, including those of importance to tribes. While the Post-2026 process will consider LTEMP's implications for Glen Canyon Dam management, it will not modify decisions made in the LTEMP ROD.

1.9.7 2019 Colorado River Drought Contingency Plans

Consistent with and pursuant to provisions in the 2007 Seven States' Agreement and the 2007 Interim Guidelines, Reclamation and the Basin States have regularly consulted regarding various issues that have arisen during implementation of the 2007 Interim Guidelines. In 2019, recognizing that those relying on water from the Colorado River system faced increased individual and collective risk of temporary or prolonged interruptions in water supplies, with associated adverse impacts on the society, environment, and economy of the Basin, the Basin States agreed that it was necessary and beneficial to pursue additional actions beyond those contemplated in the 2007 Interim Guidelines to reduce the likelihood of reaching critical elevation levels in Lake Powell and Lake Mead through 2026. Two DCPs were developed: the Upper Basin Drought Contingency Plan (Upper Basin DCP), which affects operations above Lee Ferry, and the Lower Basin Drought Contingency Plan (Lower Basin DCP), which affects operations below Lee Ferry. The Agreement Concerning Colorado River Drought Contingency Management and Operations is an overarching agreement between the Basin States and

the Department where the parties agree to consultative and cooperative processes during implementation of the Upper Basin DCP and the Lower Basin DCP, similar to the 2007 Seven States' Agreement. The 2019 DCP is supplemental to and in furtherance of the goals of the 2007 Interim Guidelines.

While most provisions of the 2019 DCP expire at the end of 2026, certain provisions related to intentionally created surplus (ICS) recovery, recovery of 2026 DROA release volumes, and Upper Basin demand management opportunities extend beyond 2026. These include provisions for the delivery of ICS in storage upon expiration of the DCP and continued authorization to make capacity in the CRSP Upper Initial Units available at no charge in accordance with the terms of the Upper Basin Demand Management Storage Agreement. The alternatives in this Final EIS contain modeling assumptions regarding the delivery of pre-2027 ICS that are in accordance with these provisions and provide additional flexibilities. Additionally, some alternatives contain general assumptions about Upper Basin conservation and storage that could potentially be realized through demand management-type programs.

1.10 Draft EIS Public Review, Comment Summary, and Changes Between Draft and Final EIS

A Notice of Availability of the Post-2026 Operational Guidelines and Strategies for Lake Powell and Lake Mead Draft EIS (see **Appendix Q**) was published in the *Federal Register* on January 16, 2026, which initiated a 45-day public review and comment period that ended March 2, 2026.

Reclamation received 18,153 submissions during the Draft EIS comment period. Of the submissions, 7 were from state government entities, 23 from tribes, 4 from federal agencies, 28 from non-government organizations, 76 from local entities, 3 from academic or research institutions, 5 from elected officials, 21 from resource sector or business interests, and the remainder were from individuals. Reclamation identified 23 form letters; 11,992 submittals had identical text to one of the 23 form letters and 5,298 had unique text in addition to the form text. Reclamation noted 52 submittals as duplicates and only reviewed them once. Unique submissions are available on the project website, and all public comments are retained in the project record.

All submissions received during the Draft EIS public review period were recorded and reviewed to identify substantive comments. Given the high number of substantive comments, and in accordance with Department guidance (DOI NEPA Handbook 2026, Appendix Section 1), substantive comments were entered into a database and organized into themes so that similar comments could be reviewed and addressed together. **Appendix R** describes these themes and Reclamation's response.

Based on public input and continued stakeholder coordination, Reclamation revised this Final EIS and incorporated a Preferred Alternative, which is carried throughout the Executive Summary, EIS, Appendices, and Technical Appendices. Notable changes include the following:

- Inclusion of quantitative analysis of hydropower economic rates and recreation visitation
- Revised initial reservoir condition assumptions in modeling to reflect the "Dry" initial condition assumptions only

- Improved consistency and clarity in Decision Making under Deep Uncertainty (DMDU) descriptions and use of modeling results, including clearer discussion of uncertainty
- Added emphasis on the first decade of potential resource impacts to align with the key period of performance of the Preferred Alternative
- Revised Chapter 3 resource sections to clarify assumptions, methods, and conclusions, and improve readability through clearer organization, plain language, and reduced repetition
- Updated figures, tables, and appendices to maintain internal consistency across volumes
- Statistical summary tables contained within resource technical appendices were moved to the end of the applicable appendix to improve readability and document flow

Additional updates were made to appendices and supporting information. **Appendix P** was added to summarize consultation and coordination efforts between Reclamation and Basin Tribes. **Appendix Q** was added to document all *Federal Register* notices issued for the process, and **Appendix R** was added to summarize comment themes and Reclamation's responses. **Appendix S** was added to provide descriptions of the alternatives analyzed in the Final EIS. **Appendix T** was added to include a preliminary description and analysis of the anticipated first operating interval covering 2027-2028. The List of Preparers was substantially updated to reflect cooperating agency participation and other revisions made during preparation of this Final EIS. Figures, tables, appendices, and supporting information were updated throughout the document to maintain internal consistency across volumes.

Chapter 2. Description of Alternatives

The alternatives analyzed in this Final EIS include a broad range of operational elements incorporating over 4 years of input provided by stakeholders and the public and received through consultations with the Basin States and tribes. During this timeframe, Reclamation and the Department have engaged extensively with the Basin States to facilitate an agreement among the seven Basin States and the Secretary on various aspects of post-2026 operations for consideration in this NEPA process. Despite this extensive engagement, a long-term consensus-based approach to Basin reservoir operations has not yet been achieved.

In the absence of a long-term consensus-based approach, Reclamation has developed a Preferred Alternative and analyzed it in this Final EIS. As described in **Section 2.4**, the Preferred Alternative is a 10-year decision framework. The decision framework does not establish specific reservoir operating guidelines; rather, it provides the structure within which operating guidelines would be developed, reviewed, and periodically updated through 2036.

The decision framework in the Preferred Alternative offers a vehicle for continued work toward sustainable water management in the Basin. It provides continuity following the expiration of the 2007 Interim Guidelines; establishes transparency and predictability for future decision making; preserves flexibility to respond to changing hydrology and evolving Basin circumstances; facilitates incorporation of future Basin consensus recommendations; and is consistent with applicable federal law.

This chapter summarizes the alternatives development process, describes the Preferred Alternative, provides a summary of all other alternatives analyzed in this Final EIS, and summarizes the performance tradeoffs between alternatives. Additional detail on these alternatives, including those considered but eliminated from detailed analysis is provided in **Appendix S**, Additional Description of Alternatives.

2.1 Development of Alternatives

The goal of the alternatives development phase for this Final EIS was to develop a reasonable and broad range of alternatives for managing the Colorado River system and its resources. The objectives associated with analyzing a sufficiently broad range of alternatives are two-fold:

1. Ensuring that decision-makers and the public are informed of all potential impacts and tradeoffs of different operational approaches
2. Providing analysis for the four operational elements that are the basis for operating guidelines that may eventually be developed under the Preferred Alternative

The process of developing the range of alternatives was informed by solicitation of input and extensive collaborative engagement with stakeholders throughout the Basin. This took place over a two-and-a-half-year period beginning with publication of the Scoping Report in October 2023 (as

described in **Section 1.5**) through publication of this Final EIS. To facilitate public input on and understanding of the alternatives, from December 2023 through March 2026 Reclamation supported access to the Post-2026 Operations Exploration Web Tool. This Web Tool was an online platform developed to allow stakeholders, interested parties and the public to independently or collaboratively design, model and explore a wide range of creative operational strategies. Use of the platform was not considered formal input to the Post-2026 Process, but insights from the 500-plus operational strategies entered into the platform were used to inform alternatives.

During the public involvement periods and the rest of the alternatives development process, Reclamation received considerable input from the Basin States, many Basin Tribes, conservation organizations, other federal agencies, other stakeholders, and members of the public. Input submitted ranged from detailed proposed alternatives to operational concepts and principles. Throughout the alternatives development phase, Reclamation met continuously with states, tribes, and other partners to review and discuss their input. For those proposals containing sufficient detail to be considered as a full alternative or a major component of an alternative, Reclamation worked extensively with these entities to not only understand and gather additional information, but also to model and perform preliminary analyses of their proposals to facilitate refinements.

Reclamation continued to inform the public on the status of alternatives development by conducting a public webinar in October 2024[1] and publishing an Alternatives Report (Reclamation 2025a) documenting the preliminary alternatives as of January 2025. On January 9, 2026, the EPA published a notice in the *Federal Register* (91 *Federal Register* 2131) announcing the availability of the Draft EIS and beginning a public comment period that ran through March 2, 2026. The Draft EIS analyzed five alternatives to capture a broad range of operational concepts and potential environmental impacts:

- No Action Alternative (discussed in **Section S.1**)
- Basic Coordination Alternative (discussed in **Section S.2**)
- Enhanced Coordination Alternative (discussed in **Section S.3**)
- Maximum Operational Flexibility Alternative (discussed in **Section S.4**)
- Supply Driven Alternative (discussed in **Section S.5**)

As discussed in more detail in **Section 2.4**, this Final EIS contains an additional alternative that the Department has identified as the Preferred Alternative.

The alternatives analyzed in the Draft EIS were informed by input from the Basin States, Basin Tribes, and other stakeholders referenced above, though they do not include all proposals submitted as standalone alternatives. Prior to the publication of the Draft EIS, Reclamation performed preliminary modeling of the initial (March 2024) and revised (December 2024 and January 2025) proposals submitted separately by the Upper Division States and Lower Division States and concluded that each lacked an appropriate basis for the comprehensive and coordinated operations of Lake Powell and Lake Mead. After continued work with all seven states throughout the spring and summer of 2025, the concept that became the Supply Driven Alternative was actively being considered by all states but had

[1] Webinar presentation material is available here: https://www.usbr.gov/ColoradoRiverBasin/documents/post2026/P26_Public_Status_Update_Webinar_10-10-24_508.pdf.

not achieved full agreement. Because there was no consensus-based alternative, the Draft EIS attempted to capture the state of discussions through inclusion of the Supply Driven Alternative but did not identify a preferred alternative. After publication of the Draft EIS, coordination with the States continued although the discussion had moved away from the concept of the Supply-Driven Alternative.

In addition to the individual state comments submitted on the Draft EIS that contained proposed operational strategies, the Upper Division States and Lower Division States submitted additional proposals in May 2026 after the publication of the Draft EIS. The proposal submitted by the Lower Division States described a 2-year set of operating guidelines through 2028 as a bridge to allow future opportunity to reach a consensus-based long-term solution. The Preferred Alternative identified in this Final EIS incorporates concepts from the States' proposals and tribal input and leaves open the opportunity for Basin entities to subsequently arrive at a consensus-based path forward. Should no consensus emerge, the Preferred Alternative ensures that the Secretary will have the flexibility to make necessary operational decisions.

2.2 The Four Operational Elements Included in Each Alternative

In consideration of the input received during pre-scoping and scoping, and to meet the purpose and need described in **Section 1.3**, Reclamation identified four operational elements that make up each alternative described below.[2] Each alternative represents a different option for implementing the proposed federal action described in **Section 1.2**. Descriptions of the alternatives will be based on their implementation of each element. For a summary of key features of each alternative, see **Section 2.5**, Summary Comparison of Alternatives. **Appendix A**, Colorado River Simulation System (CRSS) Model Documentation, describes detailed modeling assumptions for the alternatives.

Determination of deliveries to Mexico is not a part of the proposed federal action. Any such determination would be made in accordance with the 1944 Water Treaty. Nevertheless, modeling assumptions regarding water deliveries to Mexico are necessary in order to analyze the potential impacts on hydrologic and other environmental resources. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

2.2.1 Guidelines to Reduce or Increase Deliveries from Lake Mead

This element addresses the adoption of guidelines that would identify those circumstances under which the Secretary would reduce the annual amount of water available for consumptive use from Lake Mead to the Lower Division States below 7.5 maf, pursuant to the Consolidated Decree (*Arizona v. California*, 547 U.S. 150). It also addresses the definition of conditions under which the Secretary may declare the availability of surplus water for use within the Lower Division States. Article III of the

[2] The operational elements include modeling assumptions but do not necessarily describe all implementation details that would be developed should an alternative be finalized and adopted. Impacts are addressed in subsequent chapters.

LROC lists some relevant factors for determining available water, including storage in Lake Mead, expected inflows, and historical streamflow.

The primary purpose of this element is the distribution of water supplies during drought and low reservoir conditions. While Lake Powell and Lake Mead have large storage capacities, recent years have shown that careful management of available supply is key to ensure sufficient supplies are available to meet future water demands. The alternatives present a range of shortage guidelines, from aggressive shortages to reductions slightly higher than the maximum volumes included in current policies, different distributions in the Lower Division States (including priority-based and other approaches), and a variety of criteria to trigger reductions.

The specified shortage volumes in each alternative include modeling assumptions related to reductions in water deliveries to Mexico in order to analyze the potential impacts on hydrologic and other environmental resources. These modeling assumptions are identical under all alternatives.[3] **Appendix K**, Sensitivity Analysis – Effects of Modeling Assumptions with Regard to Future Water Deliveries to Mexico, compares the effects of varied assumptions.

This element also provides for the distribution of water above 7.5 maf when reservoir conditions support it.

2.2.2 Coordinated Reservoir Operations (Lake Powell and Lake Mead)

This element addresses adoption of guidelines for the coordinated operation of Lake Powell and Lake Mead to potentially improve operation of these two reservoirs. The LROC specify coordination at high elevations through the equalization of storage in Lake Powell and Lake Mead, as nearly as practicable.

Operations under the current guidelines have provided valuable experience related to the implications of coordinating Lake Powell and Lake Mead. The effects of coordination on each reservoir depend on other aspects of an alternative, for example, shortage triggers and volumes, so the degree to which coordination improves operations is context specific. The alternatives range from highly coordinated distribution of storage to minimal coordination.

2.2.3 Storage and Delivery of Conserved System and Non-System Water

This element addresses the adoption of guidelines for the storage and delivery of conserved Colorado River system and non-system water in Lake Powell and Lake Mead, pursuant to applicable law, to increase flexibility in meeting water use needs while maintaining reservoir storage above critical elevations.

Extended drought, low reservoirs, and hydrologic variability from year to year create challenges when trying to plan for water supply and protect critical elevations. Mechanisms that offer water users flexibility to conserve and/or augment water supplies can increase stability of the reservoirs, thereby reducing the need for and mitigating the impacts of large shortages. The alternatives represent a wide range of approaches to this element, including no new conservation mechanism, to moderately sized pools in Lake Powell and Lake Mead open to users within the Upper and Lower Basins, respectively, to

[3] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico.

large, inclusive pools that may be flexibly stored in either reservoir to maximize their benefit to the system.

While delivery of existing ICS is available after 2026 pursuant to existing and any new agreements, Reclamation may establish guidelines for administration of a new ICS program and/or storage mechanisms, including requirements for verification of the conservation action and water accounting procedures.

2.2.4 Additional Activities Above Lake Powell

This element addresses additional activities above Lake Powell including releases from the CRSP Upper Initial Units[4] within their respective RODs to increase elevations at Lake Powell and conservation by Upper Basin water users to support critical elevations at Lake Powell and other important system goals.

Since the adoption of the DCP, the Basin has recognized the importance of developing a framework to formally employ resources above Lake Powell to mitigate the potential for critical impacts on infrastructure. These alternatives represent various levels of within-ROD releases from CRSP Upper Initial Units (see **Section 1.9.4** and **Map 1-1**) and Upper Basin conservation, and different assumptions about consideration of these activities in broader operations.

2.3 Authorities to Implement Alternatives

The Secretary has the vested authority and responsibility to operate the System through coordinated operations, including the ability to respond to exigent and emergency conditions, pursuant to applicable federal law, the Decree, contractual obligations, and other elements of the Law of the River.[5] Since the late 1990s, management of the river has historically been based on Secretarial authority along with tools that are founded on agreements among Basin water users (e.g., interstate water banking, ICS and forbearance, etc.). In most cases, Reclamation's authority has been sufficient to fully implement the agreements. In contrast, however, specific operational mechanisms negotiated as part of the 2019 DCP required congressional legislation[6] to fully implement.

The alternatives in this Final EIS are designed to cover a wide range of potential outcomes with respect to post-2026 operations; accordingly, they incorporate components that are within existing authorities along with components that would require new authorities and/or new agreements among Basin water users to fully implement.

[4] Flaming Gorge, Blue Mesa (the most upstream facility of the Aspinall Unit, which serves as its primary storage reservoir), and Navajo reservoirs.

[5] This Final EIS analyzes potential operations to improve coordinated operations under dry hydrology that are designed to reduce the need for emergency operations. However, the need to perform emergency or other necessary operations remains, and the Department reserves its authorities to perform such operations, which could include operation of UIUs outside of RODs, reduction of Glen Canyon Dam releases, and greater Lower Basin shortages. Specific emergency, or other necessary operations, are not proposed in this document because the conditions around such potential operations are too speculative at this time. If such conditions arise, operational decisions and notifications would be made at that time based on the then-current conditions with appropriate levels of analysis.

[6] The Colorado River Drought Contingency Authorization Act was passed on April 16, 2019, directing the Secretary to implement the 2019 DCP.

2.4 Preferred Alternative

The Preferred Alternative is a 10-year decision framework through 2036. The decision framework establishes operational principles, sideboards (key thresholds and ranges for operational elements), and a process that would govern development and issuance of operating guidelines covering anticipated 2-year intervals, unless consensus-based agreements provide for a longer duration. The framework does not establish specific operating guidelines; rather, it provides the structure within which operating guidelines would be developed, reviewed, and periodically updated. The framework (principles, sideboards, and process) would remain constant through 2036, unless modified through future federal action and appropriate environmental compliance.

The choice of a 10-year period in the Preferred Alternative is a duration contemplated in the Draft EIS but shorter than the duration of recent operating guidelines. In 2023, the Proposed Federal Action contemplated adopting successor operating guidelines for approximately 20 years, which was identified as an appropriate length of time to gain operational experience and reflected the expectation that the Basin would reach consensus on a long-term operational approach. At the time the Draft EIS was published, that outcome was still being pursued. In the absence of such consensus, and given the uncertainty facing the Basin, the Department has determined that rather than imposing prescribed operating guidelines that would be in place for 20 years, a different approach was needed. Thus, the Department selected a 10-year decision framework that provides certainty regarding the decision process while preserving flexibility to adapt to changing conditions. A 10-year duration also provides sufficient time to gain operational experience, thereby informing future operational and water management decisions.

As of the date of this Final EIS, it is anticipated that the first operating interval would cover 2027–2028. Reclamation worked extensively with stakeholders to develop guidelines that align with the operational principles and sideboards. For the purpose of describing the potential upcoming operating guidelines and their associated impacts, a preliminary description and analysis of those anticipated operating guidelines is included in **Appendix T**.

2.4.1 Rationale for Selecting the Preferred Alternative

Since 2021, Colorado River operations have included a series of extraordinary operations designed to bolster reservoir elevations and protect the ability of infrastructure at Glen Canyon Dam to continue reliable operations in response to extremely low hydrologic conditions. Despite all of these measures, and compounded by uncertain future hydrologic conditions, the risk to the system has never been greater. The prevalence of extraordinary activities and the state of the system demonstrate the great need for flexibility and adaptation. At the same time, structure and transparency are needed to provide predictability for Basin stakeholders.

Consensus-based approaches have provided stability for the system for decades, including when extraordinary measures have been needed. The Department and Reclamation engaged extensively with the Basin States, Basin Tribes, and other interested parties in pursuit of developing consensus-based long-term operational guidelines. Unfortunately, as of the publication of this Final EIS, consensus on long-term operations has not been reached. Basin entities continue to work toward consensus and, given how important consensus-based agreements have been in the Basin, the Department is

committed to preserving the opportunity to implement potential future consensus agreements within the Preferred Alternative. Should no consensus emerge, the Preferred Alternative ensures that the Secretary will have the flexibility to make necessary operational decisions.

The Preferred Alternative strikes a balance between flexibility and predictability given unprecedented hydrologic and system conditions and the potential for considerable impacts on water users. It is a reasonable approach to meeting the purpose and need described in **Section 1.3**. Analysis of the operational sideboards in **Section 2.6** demonstrates that, while there are inherent performance tradeoffs among resources that benefit from different fundamental system elements—storage in each reservoir, dam releases, river flows, and water deliveries—the Preferred Alternative, as analyzed in the Representative Preferred Alternative (described in **Section 2.4.3**), appropriately balances the tradeoffs and achieves more robust performance than previous operations.

The decision framework establishes a transparent and structured process guided by operational principles that allows Reclamation and stakeholders to adapt and respond to uncertain future conditions and extremely low reservoir elevations. This flexibility allows for the recognition of evolving Basin circumstances and for more robust performance through development of innovative and adaptive operational mechanisms.

2.4.2 Operating Guidelines, Operational Principles, Operational Sideboards, and Process

2.4.2.1 Operating Guidelines

Operating guidelines are the objective criteria that determine the operations of Lake Powell and Lake Mead for the anticipated 2-year interval. For each interval, the framework process would be carried out to develop and issue operating guidelines in accordance with the principles and sideboards described below. The operating guidelines would be adopted through the issuance of a decision document published in the *Federal Register*. Once issued, the operating guidelines would be implemented through Annual Operating Plans.

During the implementation of each set of guidelines, the process to develop subsequent guidelines would begin. Each set of operating guidelines would be informed by the operational principles, consider the performance of the previous operating guidelines, and incorporate additional agreements that may be reached during the duration of the decision framework, such as consensus agreements among states and other parties and/or tribal water rights settlements. Before the issuance of new operating guidelines, a review would be conducted to ensure that the potential impacts of such operating guidelines are within the range of impacts analyzed in this NEPA process.

Throughout the period of the decision framework, it is the intent that the operating guidelines would implement the LROC by providing objective criteria for coordinated operations, while recognizing operations to respond to extraordinary circumstances due to hydrologic conditions may be warranted, consistent with applicable federal law.

As of the date of this Final EIS, the first set of operating guidelines are anticipated to be issued in July 2026 and are anticipated to cover 2027–2028.

2.4.2.2 Operational Principles

The decision framework's operational principles are fundamental objectives and considerations that reflect Reclamation's mandate to protect the Colorado River system infrastructure, acknowledge the Secretary's authority to operate the system and take protective actions when necessary, and promote reaching consensus operations whenever possible.

Elevating these principles ensures that operating guidelines adopted under the framework adhere to fundamental management priorities and provide a basis for review and reflection as new operating guidelines are developed.

The operational principles are listed below:

1. **Operations should be responsive to hydrology.** Annual operations and mid-year adjustments that account for evolving supply conditions should be adopted to ensure a flexible, adaptive approach to management.
2. **Critical federal infrastructure must be protected through practical and deliberate operations**. When Lake Powell is projected to fall below elevation 3,500 feet or when Lake Mead is projected to fall below elevation of 1,000 feet, processes and tools will be used to manage risks to infrastructure and prevent damage to federal facilities of regional and national importance. These elevations reflect current understanding of these facilities but do not preclude the identification of alternate or additional critical elevations.
3. **Operating guidelines should implement the LROC while also providing directions to address extraordinary circumstances**. Operating guidelines will provide objective criteria for operating under low reservoir conditions within the bounds of the LROC but may also provide for temporary operational actions that are not otherwise provided for under the LROC when necessary to protect critical federal infrastructure in accordance with applicable federal law.
4. **Operating guidelines should prioritize consensus-based recommendations**. The Department will support efforts to achieve consensus agreements that appropriately provide benefits to multiple parties, that offer innovative, inclusive solutions to operational and management challenges, and that are sufficiently protective of the system. Should such agreements arise, they will be prioritized as new operating guidelines are developed and adopted. In the absence of consensus-based arrangements, the Secretary will take necessary management actions, consistent with applicable federal law.

2.4.2.3 Operational Sideboards

The decision framework's operational sideboards are key thresholds and ranges for operational elements that create boundaries for the development of each set of operating guidelines and provide a basis for environmental compliance for the duration of the decision framework. The sideboards defined in **Table 2-1** were chosen to appropriately balance tradeoffs among resources and ensure that the Department would have the flexibility and environmental compliance to operate in accordance with the operational principles given future hydrologic uncertainty.

Table 2-1
Operational Sideboards for the Preferred Alternative

Operational Element	Operational Ranges
Lower Basin Shortage Guidelines	Up to 3.0 maf to provide protection of critical infrastructure at Hoover Dam in dry hydrologic conditions The allocation of shortages would be based on applicable law, including the Consolidated Decree. Deviation from applicable law would occur only if water entitlement holders have reached voluntary arrangements Consultation would occur if projected Lake Mead elevation < 1,000 ft to determine potential additional reductions to Lower Basin water deliveries
Coordinated Reservoir Operations	5.0 maf to 12.0 maf Lake Powell WY releases to provide protection for critical infrastructure at Glen Canyon Dam and sufficiently high releases necessary to prevent spill avoidance releases Consultation would occur if projected Lake Powell elevation < 3,500 ft to determine potential additional actions
Storage and Delivery of Conserved System and Non-system Water	Lake Powell: up to 3.0 maf Lake Mead: up to 8.0 maf (supports existing ICS, new ICS-type program, conservation pools, and exchange mechanisms)
Lower Basin Surplus Guidelines	Up to 500.0 kaf in addition to Flood Control and Quantified Surplus
Additional Activities Above Lake Powell	Potential for maximum use of CRSP Upper Initial Units within their respective RODs to release additional water if needed to protect critical infrastructure Voluntary Upper Basin contributions up to 200.0 kaf per year subject to hydrologic conditions

2.4.2.4 Process

Each set of operating guidelines would be implemented and evaluated through a process during which Reclamation would work with stakeholders to seek consensus, align with operational principles and sideboards, and account for system conditions, hydrology, and other Basin developments. This process is illustrated through an example schedule of activities and determinations during the potential 2027–2028 operating guidelines interval outlined in **Table 2-2**. Two years are anticipated to be appropriate due to the current drier hydrological conditions and low reservoir elevations of the system.

Table 2-2
Example Operating Guidelines Process, 2026-2028

Month and Year	Reclamation Actions or Activities by Water Year (WY)
July 2026	• Anticipated issuance of Operating Guidelines pursuant to ROD
August 2026	• Implement WY 1 operations through AOP
August 2027	• Implement WY 2 operations through AOP

Month and Year	Reclamation Actions or Activities by Water Year (WY)
October 2027	• Review current Operating Guidelines and develop considerations for the next set of Operating Guidelines
November 2027	• Release review and considerations for the next set of Operating Guidelines
November 2027 – March 2028	• Engage and consult with stakeholders regarding the next set of Operating Guidelines • Develop preliminary proposed Operating Guidelines, applying operational principles and sideboards
March 2028	• Release preliminary Operating Guidelines
May 2028	• Consensus recommendations on Operating Guidelines due
May – June 2028	• Finalize Operating Guidelines, perform analysis and necessary consultations
June 2028	• Release upcoming Operating Guidelines • Initial AOP consultation on next WY's operations (per upcoming Operating Guidelines)
July 2028	• Conduct compliance checks on upcoming Operating Guidelines • Issue Federal Register Notice with Operating Guidelines
August 2028	• Implement WY 3 operations through AOP

Subsequent periods would follow the same process of implementing, reviewing, engaging, and issuing new operating guidelines.

2.4.3 Representation of the Four Operational Elements

In contrast to the specified operations under the other alternatives in this chapter, the Preferred Alternative is designed to create the opportunity for subsequent decision making; because of this distinction, it is appropriate to include a modeling representation of operating guidelines that may be developed under the Preferred Alternative. The sideboards provide a basis for understanding the range of potential impacts, and analyzing these potential impacts provides a necessary and instructive comparison to the other alternatives included in this Final EIS. Taken together, the representation of the operational elements described below is referred to and analyzed in this Final EIS as the "Representative Preferred Alternative." The Representative Preferred Alternative is a set of modeling assumptions designed around the Preferred Alternative sideboards to approximate the range of operating guidelines that may be adopted for each interval during the 10-year framework. The specifications in the operational elements below reflect how the Representative Preferred Alternative was modeled; exact operations would be subject to the guidelines in place during each interval and would adhere to consultation triggers as described in **Table 2-1**. The modeling assumptions do not represent implementation details (e.g., use of projections) that would be identified as specific operating guidelines are developed through the decision framework process.

Modeling in this Final EIS that captures the sideboards, and the analysis of the potential impacts, provides environmental compliance for decisions made consistent with the decision framework.

2.4.3.1 Guidelines to Reduce or Increase Deliveries from Lake Mead

2.4.3.1.1 Shortage Conditions

This alternative models shortages of up to 3.6 maf (including assumptions about reductions to Mexico) and two different approaches to distributing shortages are applied. Two different approaches for distributing shortage are modeled in order to analyze the impacts of the proposal received on May 1, 2026, from the Lower Division States regarding the distribution of shortage in 2027 and 2028.

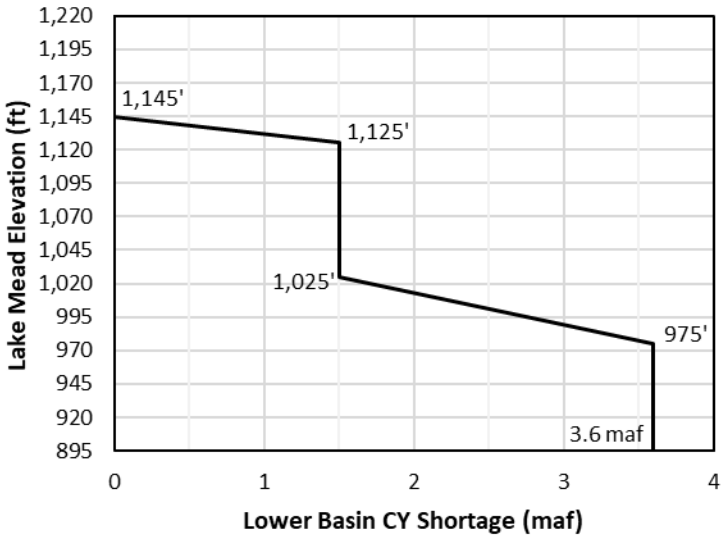
In 2027 and 2028 shortage volumes up to 1.5 maf are distributed using the approach developed by the Lower Division States and shortage volumes above 1.5 maf up to 3.6 maf are distributed using the priority system.[7] In 2029 through 2060, all volumes of shortage are distributed using the priority system. **Table 2-3** and **Table 2-4** show how shortage volumes are divided among the states and Mexico for each time period.

The shortage guidelines are summarized below and shown in **Figure 2-1**.

Table 2-3
2027–2028 Shortage Distribution,
Representative Preferred Alternative

Entity	Shortage (%) from 0 to 300 kaf	Shortage (%) from 300 to 1,500 kaf	Total Shortage (kaf) when Lower Basin-wide Shortage is 1,500 kaf	Shortage (%) 1,500 kaf to 2,344 kaf	Shortage (%) 2,345 kaf to 3,600 kaf
Arizona	80.00	43.33	760	76.26	31.10
California	0	36.67	440	0	45.16
Nevada	3.33	3.33	50	7.08	7.08
Mexico	16.67	16.67	250	16.67	16.67

Note: Shortage distributions include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.



[7] As noted in **Section 2.4**, the anticipated guidelines for the first operating interval as of publication of this Final EIS are preliminary. Modeling assumptions for 2027–2028 regarding shortage distribution reflect the May 1, 2026, Lower Division States proposal. As described in **Table 2-1**, Operational Sideboards for the Preferred Alternative, absent voluntary arrangements, the distribution of shortages would be based on applicable law (i.e., the priority system). This distribution is modeled in the Representative Preferred Alternative for years 2029 and beyond. Both distribution methods are documented and analyzed in **Appendix C**, Shortage Allocation Model, and **Chapter 3**. Regarding maximum shortage volume, modeling assumptions provide for reductions above the 1.25 maf maximum if needed to avoid critically low elevations at Lake Mead.

Table 2-4
2029-2060 Shortage Distribution, Representative Preferred Alternative

Entity	Shortage (%) from 0 to 1,814 kaf	Shortage (%) from 1,815 to 3,600 kaf
Arizona	77.40	25.77
California	0	51.63
Nevada	5.93	5.93
Mexico	16.67	16.67
Total	**100**	**100**

Note: Shortage distributions include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Figure 2-1
Shortage Guidelines to Reduce Deliveries from Lake Mead, Representative Preferred Alternative

Note: Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

2.4.3.1.2 Surplus Conditions

Volumes above normal apportionment are distributed when criteria are met in Lake Mead for a Domestic Surplus Condition, a 70R Surplus Condition or a Flood Control Surplus Condition.[8, 9] A Domestic Surplus is determined anytime the January 1 Lake Mead pool elevation is at or above 1,165 feet and Flood Control or 70R Surplus is not triggered. Depending on Lake Mead's physical pool elevation, up to 500.0 kaf of Domestic Surplus volume is distributed.

2.4.3.2 Coordinated Reservoir Operations (Lake Powell and Lake Mead)

The WY release volume from Lake Powell determined on October 1 ranges from 6.0 maf to 12.0 maf. If Lake Powell is projected to decline below elevation 3,500 feet, the WY release volume is reduced to as low as 5.0 maf to protect critical elevations at Lake Powell.

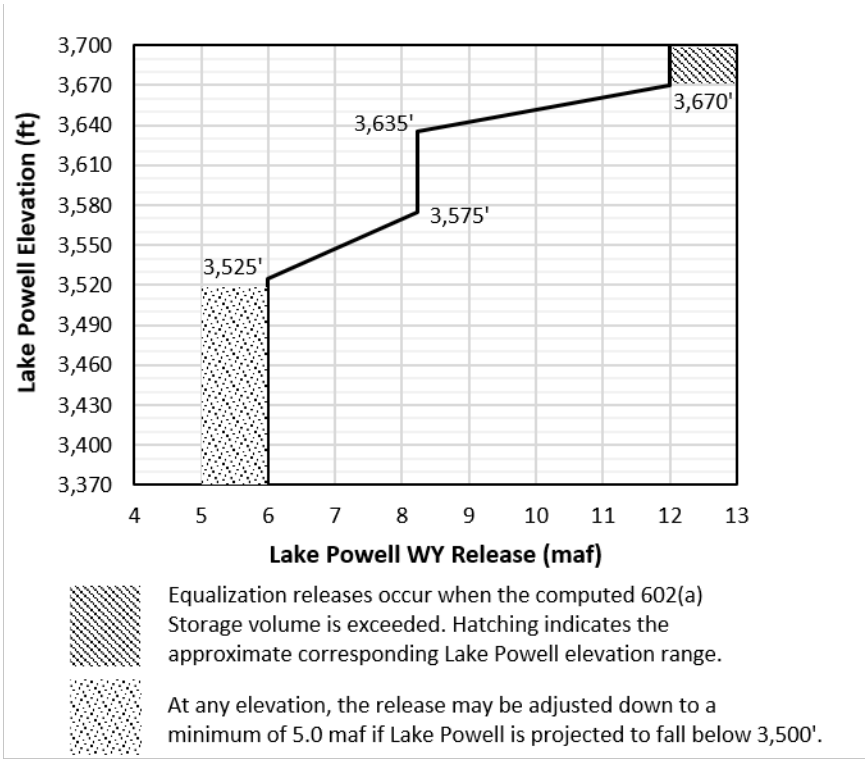
2.4.3.2.1 Primary Operations

WY releases from Lake Powell would be based on the observed October 1 elevation[10] as depicted in **Figure 2-2**.

2.4.3.2.2 Coordination at High Elevations

A determination to potentially increase releases for the purpose of equalizing storage between Lake Powell and Lake Mead is made for the upcoming year if, on October 1, the net storage of all CRSP reservoirs exceeds the 602(a) storage volume, computed using the parameters from the 2007 Final EIS. **Appendix J**, Sensitivity Analysis – Effects of Assumed Parameter Values on 602(a) Storage, describes the 602(a) storage calculation and documents the parameters used in the 2007 calculation, which are also used in this alternative. **Appendix J** also presents a comparison illustrating how different parameter assumptions would influence the resulting 602(a) storage values. Under Equalization, Lake Powell would release a minimum of 12.0 maf and may release more to balance storage with Lake Mead (see **Appendix A**, CRSS Model Documentation, for details).

2.4.3.2.3 Infrastructure Protection and Other Considerations



If Lake Powell is projected to fall below 3,500 feet within the WY, the WY release is reduced to prevent this from occurring, subject to a minimum WY release of 5.0 maf.

[8] The 70R Strategy is a modeling approach used by Reclamation since the 1980s to understand the need to distribute additional water, and it was documented in the 2007 Final EIS. Under the strategy, a Surplus Condition is based on the system space requirement at the beginning of each year. Based on the 70th percentile historical runoff, a normal 7.5 maf delivery to the Lower Division States, the Upper Basin scheduled use, and Lake Powell and Lake Mead volumes at the beginning of the year, the volume of water in excess of the system space requirement at the end of the year is estimated. If that volume is greater than zero, a Surplus is declared.

[9] If flood control releases are anticipated to be required given the current inflow forecast, the Secretary declares Flood Control Surplus conditions for that year.

[10] While a mid-year adjustment is included in the operational principles for the Preferred Alternative, it was not incorporated into the Representative Preferred Alternative modeling assumptions when they were finalized due to then-ongoing discussions about how such a mechanism should be used to adjust Lake Powell's WY release. The modeling of the Representative Preferred Alternative is still a reasonable representation of the operational principles and sideboards. Although the mid-year adjustment can shift the timing of release volumes, modestly increasing or decreasing a given WY release with a likely corresponding adjustment in the opposite direction the following year, it would not change the range of WY releases across the analysis, which would remain within the sideboards of 5.0 to 12.0 maf.

Figure 2-2
Coordinated Operations of Lake Powell and Lake Mead, Representative Preferred Alternative

2.4.3.3 Storage and Delivery of Conserved System and Non-System Water

This alternative incorporates specific elements that are designed to provide enhanced flexibility and predictability for water users via a storage and conversion mechanism in Lake Powell and storage and delivery mechanisms in Lake Mead. The storage, conversion and delivery mechanisms include assumptions for contributions of consumptively used tribal water, which may require additional authorities.

Three pools capture a range of opportunities to store, convert and deliver water for the benefit of water users and the system: the Lake Powell mechanism, the water user-controlled Lake Mead mechanism, and the Lake Mead Federally Managed Water Resources Pool, which was informed by a group of Basin Tribes and would be established by Reclamation for Lower Basin-wide benefits. The design of these mechanisms supports proactive conservation and water user flexibility.

2.4.3.3.1 Lake Powell Mechanism

Water conserved by Upper Basin users would be stored in a pool in Lake Powell that could reach a maximum volume of 3.0 maf. Upper Division States and Upper Basin Tribes would have equal access to contribute to the conservation pool and to use their conserved water in intra- and interstate transactions with other Upper Basin users. Upper Basin Tribes would receive credit for the contribution of conserved consumptive use stored in the pool. Water in the Lake Powell conservation pool can be released if needed to meet the determined WY volume. Assumptions related to contributions to the Lake Powell conservation pool are described in **Section 2.4.3.4.1**.

2.4.3.3.2 Lake Mead Mechanism

Water conserved by Lower Basin users would be stored in a pool in Lake Mead that can reach a maximum volume of 7.0 maf, which includes the storage of pre-2027 ICS. Annual total and state-based limits for conservation volumes and delivery of conserved water are presented in **Table 2-5**. All conserved water stored in Lake Mead would be included in determinations of equalization releases from Lake Powell and Lower Basin surplus and shortage volumes. Lower Colorado River entitlement holders, including Lower Basin Tribes, consistent with applicable implementation agreements, would be able to contribute to the conservation pool and to use their conserved water for delivery and/or in intra- and interstate transactions with other Lower Basin users.

Table 2-5
Volume Limitations of Storage and Delivery of Conserved Water, Representative Preferred Alternative

Entity	Maximum Annual Contribution (kaf)	Maximum Cumulative Storage (kaf)	Maximum Annual Conversion or Delivery[2] (kaf)
Arizona	880	2,300	430
California	880	2,300	430
Nevada	100	900	140
Mexico[1]	500	1,500	200[3]
Total	**2,360**	**7,000**	**1,200**

1) Volumes include modeling assumptions for Mexico's storage and delivery limits. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.
2) The Representative Preferred Alternative maintained the total U.S. annual delivery of 1.0 maf from the 2007 Interim Guidelines. For modeling purposes, to maximize reach impacts, and to integrate with other modeling assumptions, e.g., demand schedules, the state specific maximums were modified from those in the 2007 Interim Guidelines; this modeling assumption is not intended to determine any future state maximum delivery constraints.
3) The 1944 Water Treaty authorizes scheduled delivery of up to 200.0 kaf in excess of the 1.5 annual allotment to Mexico.

Water users could contribute and convert or deliver water previously stored under this new mechanism at their discretion within the annual volume constraints related to the pool. At the time the water is conserved, a one-time three percent system assessment would be applied, along with a one-time seven percent assessment allocated to the Federally Managed Water Resources Pool, for a total assessment of 10 percent.

Conversion and delivery of conserved water would be prohibited when Lake Mead begins the year with a physical pool elevation below 1,000 feet and would be limited to 50 percent of the maximum annual delivery/conversion volume when Lake Mead begins the year with a physical pool elevation between 1,000 and 1,025 feet. Additionally, when Lake Mead begins the year with a physical pool elevation above 1,125 feet, delivery and conversion of stored water would not be subject to a state's annual apportionment or Mexico's annual allotment.

2.4.3.3.3 Lake Mead Mechanism (Federally Managed Water Resources Pool)

The Federally Managed Water Resources Pool is a pool of water in Lake Mead established by Reclamation that is anticipated to be around 450.0 kaf, but could reach a maximum volume of 1.0 maf[11]. It could acquire water through multiple mechanisms involving acquisition of conserved consumptive use water including but not limited to ICS. Contents of the Pool would be included in determinations of Lake Powell equalization releases and Lower Basin surplus and shortage volumes.

Depending on final formulation, the Pool could be used for a range of purposes, including meeting federal firming or other federal delivery obligations pursuant to Congressionally authorized Indian water rights settlements[12] and providing limited offsetting of tribal water shortages as well as protecting federal infrastructure. Modeling assumptions related to logic for creation and use of Pool volumes can be found in **Appendix B**, Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water. Delivery of water from the Pool would be prohibited when Lake Mead's elevation is below 1,000 feet. Additionally, annual contribution and delivery/conversion constraints could be outside the limits outlined in **Section 2.4.3.3.2**.

2.4.3.3.4 Treatment of Pre-2027 Intentionally Created Surplus

ICS created under the 2007 Interim Guidelines and 2019 DCP that remains in Lake Mead in 2027 would be transferred to the Post-2026 Lake Mead water user-controlled mechanism immediately and would be subject to all provisions described in the previous section.

2.4.3.4 Additional Activities Above Lake Powell

2.4.3.4.1 Upper Basin Conservation

Exact volumes of Upper Basin conservation over time are uncertain, but for the purposes of modeling, conservation up to a maximum volume of 200.0 kaf per year is included, with variable annual volumes based on hydrologic conditions. Conservation is modeled as a single lumped volume; no assumptions are made with respect to contributions from different entities or via specific activities.

2.4.3.4.2 Releases to Protect Glen Canyon Dam

This alternative would allow for potentially maximum use of the CRSP Upper Initial Units within their respective RODs to release additional water if needed to protect critical infrastructure at Glen Canyon Dam. Additionally, if Lake Powell's elevation is projected to go below 3,525 feet, CRSP Upper Initial Units would increase their releases within their RODs, contingent on hydrologic conditions. Reclamation would identify triggers for when additional Upper Basin actions would be required to protect critical infrastructure. Any volumes released for the protection of Glen Canyon Dam would begin to be recovered when Lake Powell is no longer projected to go below 3,525 feet by assuming that the CRSP Upper Initial Units return to their normal annual operating targets The frequency and volumes of the assumed releases to protect Glen Canyon Dam are assessed in **Appendix O**, Analysis of Powell Infrastructure Protection Releases.

[11] This volume has been proposed to accommodate future water use arrangements, which could include but would not be limited to conservation programs, contracts, and potential Indian water rights settlements.

[12] The Secretary is obligated to firm certain volumes of CAP non-Indian agricultural water provided as part of Indian water rights settlements to specific tribes in Arizona, including under Section 105(a) of the Arizona Water Settlements Act of 2004, Pub. L. 108-451, 118 Stat. 3478.

2.5 Summary Comparison of Alternatives

Preferred Alternative (Including Representation of Operational Elements)	The Preferred Alternative is a multi-year decision framework that establishes the process and criteria that would govern development and adoption of operating guidelines through 2036. The decision framework is anticipated to be implemented in two-year operating intervals, unless consensus-based agreements provide for a longer duration. Unlike other alternatives, the operating guidelines for each interval are not specified in this Final EIS, and each set of guidelines would be developed based on operational principles and fit within the framework's defined operational sideboards (thresholds and ranges for operational elements). The sideboards provide a basis for assumptions included in the Representative Preferred Alternative summarized in this table, which captures the range of operating guidelines that may be adopted during each interval. Lake Powell releases range from 5.0 maf to 12.0 maf depending primarily on Lake Powell elevation. Lower Basin shortages up to 3.6 maf (including assumptions about reductions to Mexico) are distributed using a combination of LB Priority (up to 1.5 maf, 2027-2028) and priority.				
	Shortage Guidelines to Reduce Deliveries from Lake Mead[3, 4]	**Coordinated Reservoir Operations (Lake Powell and Lake Mead)**	**Storage and Delivery of Conserved System and Non-system Water[3]**	**Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]**	**Additional Activities Above Lake Powell**
	• Shortages up to 3.6 maf (including assumptions about reductions to Mexico) • In 2027-2028, shortages up to 1.5 maf are distributed based on the distribution developed by the Lower Division States and shortages exceeding 1.5 maf are distributed based on priority (Approach 1 of the Supply Driven Alternative) • After 2028, shortages are distributed based on priority, unless agreements are reached • Consultation to determine additional reductions if projected Lake Mead elevation is less than 1,000 feet	• Lake Powell releases determined based on Lake Powell elevation unless equalization releases are required • Releases range from 5.0 to 12.0 maf, unless more is required for equalization releases • Consultation to determine additional actions if projected Lake Powell elevation is less than 3,500 feet	• Storage up to 7.0 maf in Lake Mead with additional 1.0 maf Federally Managed Water Resources Pool; included for purposes of determining Lower Basin surplus and Shortage Conditions, as well as equalization releases from Lake Powell • Storage up to 3.0 maf at Lake Powell; included for purposes of determining Lake Powell releases • Existing ICS converted to new mechanism immediately • Expanded flexibilities: interstate exchanges within each basin, new tribal mechanism	• Surplus determinations based on Lake Mead elevation at or above 1,165 feet, 70R (spill avoidance strategy) or Flood Control conditions	• Potential maximum use of CRSP Upper Initial Units within their respective RODs to release additional water if needed to protect critical infrastructure at Glen Canyon Dam contingent on hydrologic conditions • Trigger additional releases when projected Lake Powell elevation is less than 3,525 feet • Voluntary Upper Basin contributions up to 200.0 kaf per year subject to hydrologic conditions

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

[4] As noted in **Section 2.4**, the anticipated guidelines for the first operating interval as of publication of this Final EIS are preliminary. Modeling assumptions for 2027-2028 regarding shortage distribution reflect the May 1, 2026, Lower Division States proposal. As described in **Table 2-1**, Operational Sideboards, absent voluntary arrangements, the distribution of shortages would be based on applicable law (i.e., the priority system). This distribution is modeled in the Representative Preferred Alternative for years 2029 and beyond. Both distribution methods are documented and analyzed in **Appendix C**, Shortage Allocation Model, and **Chapter 3**. Regarding maximum shortage volume, modeling assumptions provide for reductions above the 1.25 maf maximum if needed to avoid critically low elevations at Lake Mead.

<table>
<tr><td>No Action Alternative</td><td colspan="5">The No Action Alternative is included as a requirement of NEPA. Operations would revert to annual determinations announced through the Annual Operating Plan. Pursuant to the LROC, the objective is to maintain a minimum release of water from Lake Powell of 8.23 maf, therefore Lake Powell releases are assumed to be 8.23 maf[1] unless a higher release is required for equalization or a lower release occurs due to Glen Canyon Dam infrastructure limitations.[2] Shortages to the Lower Basin would be based on priority and reach a maximum of 600.0 thousand acre-feet (kaf). This would not represent a continuation of current operations but is generally based on the operating guidance that was in place before the adoption of the 2007 Interim Guidelines. While the authority to use CRSP Upper Initial Units to respond to exigent and emergency conditions was recognized at that time, no specific framework for such activities had been developed, so no defined activities are included in this alternative. Existing Intentionally Created Surplus (ICS) would be delivered in accordance with existing agreements, but there would be no new storage and delivery mechanisms.</td></tr>
<tr><td></td><td>Shortage Guidelines to Reduce Deliveries from Lake Mead[3]</td><td>Coordinated Reservoir Operations (Lake Powell and Lake Mead)</td><td>Storage and Delivery of Conserved System and Non-system Water[3]</td><td>Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]</td><td>Additional Activities Above Lake Powell</td></tr>
<tr><td></td><td>• Shortages determined based on Lake Mead elevation
• Shortage volume of 400.0, 500.0, and 600.0 kaf at elevations 1,075, 1,050, and 1,025 feet, respectively
• Shortages distributed based on priority</td><td>• Lake Powell release of 8.23 maf unless more is required for equalization releases
• Releases less than 8.23 maf below elevation 3,490 feet due to Glen Canyon Dam infrastructure limitations</td><td>• No new storage and delivery mechanism to replace ICS
• Delivery of existing ICS in accordance with existing agreements</td><td>• Surplus determinations limited to 70R (spill avoidance strategy) and Flood Control conditions</td><td>• No specific additional activities above Lake Powell defined</td></tr>
</table>

[1] Article II(2) of the LROC states the "objective shall be to maintain a minimum release of water from Lake Powell of 8.23 [maf]." Reclamation recognizes that entities in the Basin have different legal positions regarding how this LROC statement incorporates other Law of the River elements to determine annual releases. Reclamation also recognizes that variation in releases of water above and below the minimum objective release of 8.23 maf can, in appropriate circumstances, be adopted.

[2] Releases from Glen Canyon Dam may be unable to achieve the specified annual release volume when Lake Powell is below elevation 3,490 feet due to infrastructure constraints. Modeling assumptions for all alternatives reflect this constraint (see **Appendix A**).

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

<table>
<tr><td>Basic Coordination Alternative</td><td colspan="5">This alternative is designed to be implementable absent new agreements among Basin water users. Lake Powell releases would primarily be 8.23 maf, with some releases above and below 8.23 maf, and minimum releases of 7.0 maf. Lake Powell elevations could be increased by releases from CRSP Upper Initial Units within their respective RODs to protect infrastructure at Glen Canyon Dam. Reclamation would identify triggers for when additional Upper Basin actions are needed to protect critical infrastructure. Lower Basin shortages up to 1.48 maf would be triggered based on Lake Mead elevation and distributed consistent with priority system. Existing ICS would be delivered in accordance with existing agreements, but there would be no new delivery and storage mechanisms.</td></tr>
<tr><td></td><td>Shortage Guidelines to Reduce Deliveries from Lake Mead[3]</td><td>Coordinated Reservoir Operations (Lake Powell and Lake Mead)</td><td>Storage and Delivery of Conserved System and Non-system Water[3]</td><td>Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]</td><td>Additional Activities Above Lake Powell</td></tr>
<tr><td></td><td>• Shortages based on Lake Mead elevation up to 1.48 maf
• Shortages distributed based on priority
• Identify conditions when additional reductions may be needed to avoid reaching critically low elevations</td><td>• Lake Powell releases are determined based on Lake Powell elevation unless equalization releases are required
• Releases range from 7.0 to 9.5 maf, unless more is required for equalization releases
• Identify conditions when additional action may be needed for infrastructure protection</td><td>• No new storage and delivery mechanism to replace ICS
• Delivery of existing ICS in accordance with existing agreements</td><td>• Surplus determinations limited to 70R (spill avoidance strategy) and Flood Control conditions</td><td>• Releases from CRSP Upper Initial Units within their respective RODs and contingent on hydrologic conditions to protect infrastructure at Glen Canyon Dam
• Identify conditions when additional Upper Basin actions may be needed for infrastructure protection</td></tr>
</table>

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Enhanced Coordination Alternative

This alternative is based on concepts from Basin Tribes, federal agencies, and other stakeholders to achieve protection of critical infrastructure while benefitting key resources (e.g., natural, hydropower and recreation) through an approach to distributing storage between Lake Powell and Lake Mead. Lake Powell releases would be determined based on a combination of Lake Powell and Lake Mead elevations, 10-year running-average hydrology, and Lower Basin deliveries. This alternative would include storage and delivery mechanisms for Lake Powell and Lake Mead and extensive flexibilities for all users. The operations incorporate Basin-wide shared contributions to the system, including Upper Basin conservation that would be stored in Lake Powell and Lower Basin shortages starting at 1.3 maf, approximately the average annual evaporative and system losses at and below Lake Mead, and reaching a maximum of 3.0 maf. Shortages would be triggered based on combined storage in Lake Powell and Lake Mead and distributed pro rata.

Shortage Guidelines to Reduce Deliveries from Lake Mead[3]	**Coordinated Reservoir Operations (Lake Powell and Lake Mead)**	**Storage and Delivery of Conserved System and Non-system Water[3]**	**Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]**	**Additional Activities Above Lake Powell**
• Shortages determined based on combined storage in Lake Powell and Lake Mead • Shortages begin at 60% full at a volume of 1.3 maf, then increase linearly, reaching a maximum of 3.0 maf at 30% full and below • Shortages distributed pro rata	• Lake Powell releases determined based on a combination of Lake Powell and Lake Mead elevations, 10-year running-average hydrology, and Lower Basin deliveries • Releases range from 4.7 to 10.8 maf	• Storage up to 5.0 maf in Lake Mead with additional 2.0 maf Protection Pool; included for purposes of determining Lake Powell releases and shortages • Storage up to 2.0 maf in Lake Powell; included for purposes of determining Lake Powell releases but excluded from shortage determinations • Existing ICS converted to new mechanism immediately • Extensive flexibilities for all users: intra- and interstate transactions within each basin • Tribal water (both conserved consumptive use and unused) including in Lake Powell conservation pool and Lake Mead Protection Pool	• Surplus determinations limited to 70R (spill avoidance strategy) and Flood Control conditions	• Upper Basin conservation contributed to the Lake Powell conservation pool based on hydrologic conditions: up to 200.0 kaf per year for first 5 years, up to 275.0 kaf per year for second 5 years, up to 350.0 kaf starting in year 11

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Maximum Operational Flexibility Alternative

This alternative is informed by a proposal submitted by a consortium of conservation organizations and incorporates proactive responses, targeted reservoir management strategies, and innovative and flexible tools to address an increasingly variable set of future hydrologic conditions. Lake Powell releases would range from 5.0 to 11.0 maf and would be determined by total CRSP system storage and recent hydrology. Releases would switch to "run-of-river" when Lake Powell is at 3,510 feet or lower. The operations incorporate Basin-wide shared contributions, including up to 4.0 maf of shortages in the Lower Basin triggered by combined seven-reservoir storage (CRSP Upper Initial Units, Lake Mead, Lake Mohave, and Lake Havasu) and recent hydrology and voluntary water contributions from both basins.

Shortage Guidelines to Reduce Deliveries from Lake Mead[3]	**Coordinated Reservoir Operations (Lake Powell and Lake Mead)[3]**	**Storage and Delivery of Conserved System and Non-system Water**	**Surplus Guidelines to Increase Deliveries/ Releases from Lake Mead[3]**	**Additional Activities Above Lake Powell**
• Shortages determined based on combined seven-reservoir storage and recent hydrology • Shortages start at 80% full and increase linearly, subject to upward adjustment based on hydrology, reaching a maximum of 4.0 maf • Shortages distributed based on priority, as described in Approach 1 of the Supply Driven Alternative	• Lake Powell releases determined based on total Upper Basin system storage and recent hydrology • Releases subject to downward adjustment based on hydrology and range from 5.0 to 11.0 maf • Releases switch to "run-of-river" when Lake Powell is at elevation 3,510 feet or lower	• Storage up to 8.0 maf in either Lake Powell or Lake Mead; excluded for purposes of determining Lake Powell releases and shortages • Existing ICS converted to new mechanism over 5 years • Extensive flexibilities for all users: transactions within and across basins, including interstate and inter-basin	• Surplus determinations limited to Flood Control conditions	• Average of 200.0 kaf of Upper Basin annual conservation based on hydrologic conditions contributed to the Lake Powell conservation pool

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

<table>
<tr><td>Supply Driven Alternative</td><td colspan="5">Annual Lake Powell releases are determined based on a 65 percent of 3-year-average natural flow at Lees Ferry. Lake Powell elevations could be increased by releases from CRSP Upper Initial Units within their respective RODs to protect infrastructure at Glen Canyon Dam. This alternative would include new delivery and storage mechanisms for Lake Powell and Lake Mead. Lower Basin shortages up to 2.1 maf would be triggered based on Lake Mead elevation. This alternative analyzes two approaches to shortage distribution: state-based combined with Lower Basin-wide priority and state-based combined with Lower Basin-wide pro rata.</td></tr>
<tr><td></td><td>Shortage Guidelines to Reduce Deliveries from Lake Mead[3]</td><td>Coordinated Reservoir Operations (Lake Powell and Lake Mead)</td><td>Storage and Delivery of Conserved System and Non-system Water[3]</td><td>Surplus Guidelines to Increase Deliveries/Releases from Lake Mead[3]</td><td>Additional Activities Above Lake Powell</td></tr>
<tr><td></td><td>• Shortages determined based on Lake Mead elevation
• Shortages start at 1,145 feet and reach a maximum of 2.1 maf at 1,000 feet and below
• Shortages distributed using two approaches: LB Priority and LB Pro Rata</td><td>• Lake Powell releases determined primarily based on 65% of 3-year natural flows at Lees Ferry
• Releases range from 4.7 to 12.0 maf</td><td>• Storage up to 8.0 maf in Lake Mead; excluded for purposes of determining shortages
• Storage up to 3.0 maf at Lake Powell; included for purposes of determining Lake Powell releases
• Existing ICS converted to new mechanism over 10 years
• Expanded flexibilities: interstate exchanges within each basin</td><td>• Surplus determinations based on Lake Mead elevation at or above 1,165 feet, 70R (spill avoidance strategy) or Flood Control conditions</td><td>• Increased releases from CRSP Upper Initial Units by up to 500.0 kaf per year within their respective RODs and contingent on hydrologic conditions to protect infrastructure at Glen Canyon Dam
• Up to 200.0 kaf of Upper Basin annual conservation based on hydrologic conditions contributed to the Lake Powell conservation pool
• In years when Lake Powell cannot meet its required water year release because of low elevation, additional “gap water” is introduced into the system and tracked to be released in subsequent years</td></tr>
</table>

[3] These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico. **Appendix A** provides additional detail. Reclamation’s modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

2.6 Summary of Tradeoffs between Alternatives

Operations at Lake Powell and Lake Mead inherently involve tradeoffs among resources that benefit from different fundamental system elements: storage in each reservoir, dam releases, river flows, and water deliveries. For example, it is not possible for a set of operating guidelines to have the most robust performance with respect to maximizing protection of critical elevations, minimizing reductions in water deliveries, and maximizing hydropower generation all at once. With the extended period of dry hydrologic conditions since 2000 and the resulting depletion of storage, these tradeoffs have become more stark, and achieving a broadly acceptable balance between resources is now more difficult than ever before.

Based on the analysis in this Final EIS and the key tradeoffs shown below, the Preferred Alternative, as analyzed in the Representative Preferred Alternative, appropriately balances the inherent system tradeoffs: it is a practical approach to robust protection of critical infrastructure while considering adverse impacts to water users and avoiding unnecessary impacts to other resources.

2.6.1 Tradeoffs Analysis

While there are many important metrics across Basin resources, it is instructive to summarize the high-level system impacts through five metrics related to Lake Powell and Lake Mead elevations, Lower Basin deliveries, and releases from Glen Canyon Dam. Analyzing tradeoffs among the metrics described in **Table 2-6** also provides important insight into the tradeoffs among other resources.

Table 2-6
High Level Performance Metrics Included in Figure 2-3

Metric Name	Description
Percent of months in which Lake Powell stays above elevation 3,500 feet	Elevation 3,500 feet provides a buffer above 3,490 feet, below which the reliability of infrastructure to meet critical downstream water supply needs may be critically impacted and hydropower cannot be produced at Glen Canyon Dam
Percent of months in which Lake Mead stays above elevation 975 feet	Elevation 975 feet provides a buffer above 950 feet, below which infrastructure may be critically impacted and hydropower cannot be produced at Hoover Dam
Percent of years in which Lake Mead dead pool-related reductions[13] are avoided	Delivery reductions due to Lake Mead being near dead pool (elevation 895 feet) resulting in large magnitudes of reductions to Lower Basin water users
Average annual shortage	The average annual shortage that occurs under each alternative provides important summary information for Lower Basin water users and context for reservoir-based performance

[13] Dead pool and Hoover Dam infrastructure can start to impact Lake Mead's ability to make deliveries to the Lower Basin at elevation 950 feet. Restrictions on water deliveries would occur when Lake Mead is near dead pool, resulting in large reductions (referred to as "dead pool-related reductions"). Although not considered an operational element of the alternatives, accounting for such reductions is an important performance metric.

Metric Name	Description
Average water year releases from Glen Canyon Dam	The average water year release from Glen Canyon Dam that occurs under each alternative provides important context for reservoir-based performance

The elevations described in **Table 2-6** have operational relevance, and comparing alternative performance relative to these elevations provides meaningful insight. In practice, operational implementation would include identifying elevations above critical thresholds (i.e., 3,490 feet and 950 feet) at which additional responsive actions could be taken in advance to avoid reaching those critical elevations. The "buffer" elevations shown in **Table 2-6** (i.e., 3,500 feet and 975 feet) may or may not represent correspond to operational decision for actual implementation; here, they are used for analytical purposes in this Final EIS.

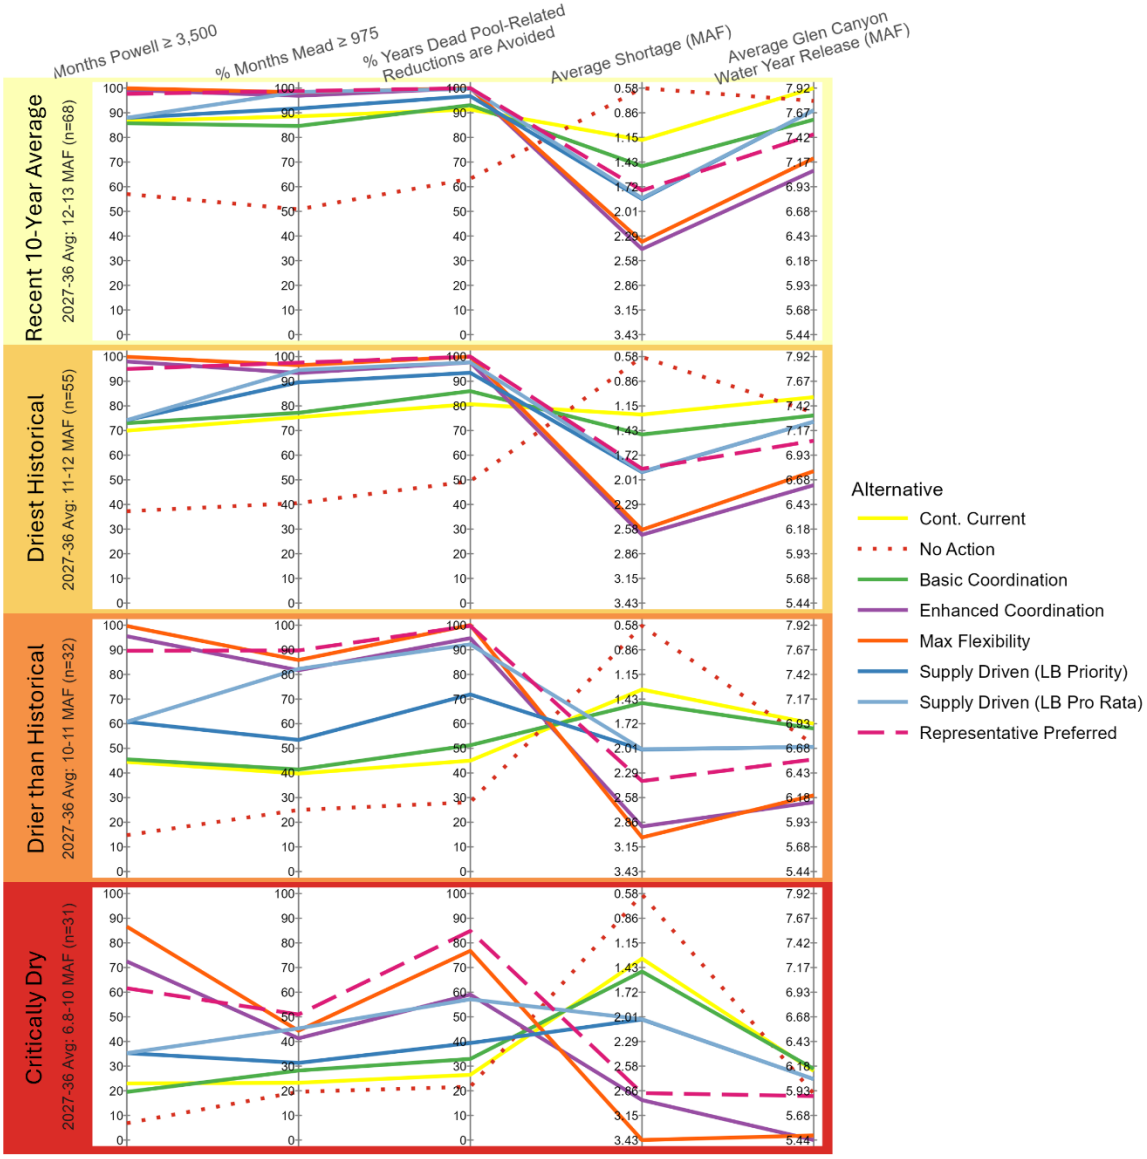


Figure 2-3 summarizes how the alternatives and the Continued Current Strategies Comparative Baseline[14] (labeled "Cont. Current") perform over the next 10 years in five vertical axes that correspond to the five key metrics described in **Table 2-6**. The performance of each alternative is captured by a colored, segmented line that crosses the axes at different vertical positions, where the height denotes performance. Crossing lines are a visual cue that there is a tradeoff between different performance metrics. The five-metric performance summary is divided into four categories of potential 2027-2036 future hydrologic conditions that get increasingly dry from top to bottom.[15] The hydrologic categories are summarized in **Table 2-7**. Results are divided into these categories to demonstrate how the alternatives respond under different assumptions about future hydrologic conditions and to explore the impacts of hydrology on performance tradeoffs.

A key performance tradeoff demonstrated by **Figure 2-3** is the tradeoff between percent of time in which critical reservoir elevations and dead pool-related reductions are avoided (first three axes from left) and average shortage (fourth axis from left). In the Recent 10-Year Average hydrologic category, this stands out as a difference between the No Action Alternative and the action alternatives, but in the drier hydrologic categories (especially Drier than Historical and Critically Dry), the performance differences between the action alternatives becomes clearer and the tradeoffs (indicated by the crossing lines) become steeper: the Maximum Operational Flexibility and Enhanced Coordination Alternatives incorporate large shortages and better protect the reservoirs; the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and the Basic Coordination Alternative have lower volumes of shortage and lower reservoir protection; and the No Action Alternative provides minimal protection and results in a high frequency of dead pool-related reductions while imposing minimal shortage. Across hydrologic categories, the Representative Preferred Alternative balances tradeoffs differently than other action alternatives. This is evident beginning in the Driest Historical hydrologic category, where it provides protection of Lake Powell and Lake Mead elevations similar to the most protective alternatives, while the average shortage volumes are similar to the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches).

[14] This scenario represents no changes from current operations and relies on strategies and agreements that expire in 2026. It is provided as a comparative baseline to inform an understanding of how the alternatives perform relative to current operations.

[15] Wetter futures were also tested and are included in the impact analysis; however, for this analysis the hydrologic categories shown are most informative.

Figure 2-3
Key Performance Tradeoffs in Different Hydrologic Conditions

Note: Differences in Lake Mead performance between Supply Driven (Lower Basin [LB] Priority approach) and the Supply Driven (LB Pro Rata approach) Alternatives reflect how different shortage distributions interact with assumptions regarding the use of the storage and delivery mechanism for conserved water.

Table 2-7
Hydrologic Categories Included in Figure 2-3

Hydrologic Category	Average Annual Simulated Lees Ferry Flow, 2027-2036 (maf)	Description
Recent 10-Year Average	12-13	Hydrologic conditions in this category are similar to the historical average from 2016-2025 (12.1 maf)[16]
Driest Historical	11-12	Hydrologic conditions in this category are similar to the driest 10-year period in the historical record (11.8 maf, 2012-2021)
Drier than Historical	10-11	Hydrologic conditions in this category are 7-15% (0.8 to 1.8 maf) drier than the driest 10-year period in the historical record
Critically Dry	<10	Hydrologic conditions in this category are 15-42% (1.8-5.0 maf) drier than the driest 10-year period in the historical record

In Drier than Historical hydrologic futures, the Maximum Operational Flexibility and Enhanced Coordination Alternatives show that lower WY releases from Glen Canyon Dam provide more protection to keep Lake Powell above 3,500 feet, while the higher water year releases in the Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives result in significantly higher frequencies of Lake Powell falling below 3,500 feet. The Representative Preferred Alternative falls in between the Supply Driven (both LB Priority and LB Pro Rata approaches) and Enhanced Coordination Alternatives: it releases less from Glen Canyon on average than the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and better protects elevation 3,500 feet, but it releases more and offers less protection compared to the Enhanced Coordination Alternative. In the Critically Dry hydrologic category, water year releases are low across all alternatives, but only the Representative Preferred (62 percent of months), Enhanced Coordination (72 percent of months) and Maximum Operational Flexibility (87 percent of months) Alternatives protect 3,500 feet more than half of the time. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and Basic Coordination Alternative maintain elevations above 3,500 feet in 35 percent and 20 percent of months, respectively.

The effectiveness of large shortages at preventing dead pool-related delivery reductions is clearest in the Critically Dry hydrologic category, where the Representative Preferred, Maximum Operational Flexibility, and Enhanced Coordination Alternatives rely on large average shortages to significantly outperform the other alternatives in avoiding dead pool-related reductions. However, in Critically Dry conditions, even these more protective alternatives result in Lake Mead elevations below 975 feet in 49, 56, and 59 percent of months, respectively.

Figure 2-3 is a quantitative representation of system tradeoffs and shows how those tradeoffs are exacerbated by drying hydrologic conditions. The analysis in this figure demonstrates how the sideboards of the Preferred Alternative, as analyzed in the Representative Preferred Alternative,

[16] The 10-year average for 2014-2023 (12.8 maf), 2015-2024 (12.6 maf), and 2016-2025 (12.1 maf) are all between 12.0 and 13.0 maf.

appropriately balance the tradeoffs across key system metrics and provide protection in conditions drier than the ongoing, unprecedented drought. The Representative Preferred Alternative achieves good performance across key system metrics related to critical infrastructure in the driest hydrologic conditions the Basin has experienced (Driest Observed Hydrology) but imposes lower average shortages and enables higher Glen Canyon Dam releases than other similarly protective alternatives. In conditions that are slightly drier than observed history (Drier than Historical Hydrology), the Representative Preferred Alternative maintains this moderate balance of performance between reservoir elevations, shortages, and Glen Canyon Dam releases. In the driest hydrologic conditions modeled (Critically Dry Hydrology), the ability of any set of operations to achieve good performance in these metrics is significantly diminished, but the Representative Preferred Alternative shows that the Preferred Alternative sideboards can protect critical infrastructure in the majority of these conditions while considering adverse impacts to Lower Basin water users.

2.6.2 Conclusions

This Final EIS analyzes a reasonable and broad range of alternatives for the operational elements identified in the proposed federal action. These alternatives were developed through extensive engagement with a wide range of partners and stakeholders as well as the public during a timeframe of over 4 years. In the absence of a consensus long-term agreement, Reclamation has included a Preferred Alternative decision framework in this Final EIS that establishes the operational principles, sideboards, and process that would govern development and adoption of operating guidelines through 2036.

The sideboards of the Preferred Alternative were analyzed through the Representative Preferred Alternative, and the analysis of the potential impacts of these sideboards provides environmental compliance for decisions made consistent with the decision framework. Based on the analysis in this Final EIS and the key tradeoffs shown above, the Preferred Alternative, as analyzed in the Representative Preferred Alternative, appropriately balances the inherent system tradeoffs: it is a practical approach to robust protection of critical infrastructure while considering adverse impacts to water users and avoiding unnecessary impacts to other resources.

Chapter 3. Affected Environment and Environmental Consequences

3.1 Introduction

This chapter describes the existing conditions of the environmental resources (e.g., hydrologic, biologic, and socioeconomic) of the Basin, followed by an analysis of the extent and magnitude of potential effects on each resource from the alternatives described in **Chapter 2**. Only resources that could potentially be significantly affected by the alternatives are analyzed. Resources considered for analysis but determined not to be significantly affected include the following:

- **Transportation** – No impacts on transportation are anticipated in the analysis area, as the proposed changes are operational in nature. Impacts to the Lake Powell ferry are analyzed in the recreation section.
- **Minerals** – No impacts on minerals or mineral rights are anticipated because all proposed Lake Powell and Lake Mead operational changes and their associated releases and elevations would not affect minerals or mineral rights.
- **Noise** – No impacts on noise are anticipated in the analysis area, as existing noise conditions are expected to continue at the same level under all proposed Lake Powell and Lake Mead operational changes.
- **Light** – No impacts on light are anticipated in the analysis area, as existing light conditions are expected to remain unchanged under all proposed Lake Powell and Lake Mead operational changes.

Section 3.2, Analysis Methods, describes the approach used for assessing the environmental consequences, including the geographic and temporal scope, alternatives and a comparative baseline, and modeling. This is followed by the individual resource sections, which represent a summarized overview of the affected environment and environmental consequences. Further information for each resource section can be found in the corresponding technical appendices identified in each section.

3.2 Analysis Methods

3.2.1 Geographic Scope

Consistent with the geographic scope analyzed in the 2007 Interim Guidelines Final EIS, the geographic scope that would be affected by the proposed federal action begins at full pool of Lake Powell and extends downstream along the mainstream Colorado River floodplain to the SIB with Mexico. This proposed federal action would also potentially affect interests of water users in the Lower Division States in service areas that extend beyond the Colorado River floodplain. Additionally,

numerous tribes hold Colorado River water entitlements and could be affected by water supply availability.

Although the proposed federal action is focused on Lake Powell and Lake Mead operations, management strategies that include activities upstream of Lake Powell are being analyzed in this Final EIS. These activities include Upper Basin conservation and, if warranted to protect critical reservoir elevations, operations at the CRSP Upper Initial Units (see **Map 1-1**). Operations at the CRSP Upper Initial Units specifically contemplated in the Final EIS alternatives are intended to remain within the scope of the existing Records of Decision (Reclamation 2006a, 2006b, 2012).[1] [2] Accordingly, the Final EIS does not expand the geographic scope of analysis upstream of Lake Powell. With respect to Upper Basin conservation, the nexus to the proposed federal action is the storage and delivery of that conserved water in Lake Powell. The effects of this storage in and delivery from Lake Powell are within the scope of the EIS (see **Section 3.3**, Hydrologic Resources, and **TA 3**, Hydrologic Resources), while specific activities that may be undertaken in the Upper Basin to generate the conserved water are not within the scope of this EIS. Any such activities are unknown at this time and will not necessarily require federal decision making. Any federal decisions associated with these conservation activities will be assessed outside of this EIS.

For ease of discussion with respect to the geographic scope of this Final EIS and the affected areas and potential effects, the Colorado River has been divided into nine reaches, as shown on **Table 3-1** and **Map 3-1**. The geographic scope described in this section is a standard area of analysis; for some resource topics, the impact analysis area differs from this scope to account for the impacts on that specific resource. When different, the impact analysis area is defined in the resource's specific methodology section.

3.2.2 Temporal Scope

For purposes of analysis, the temporal scope of this EIS extends from 2027 through 2060, providing a framework for assessing short-term to long-term effects.

3.2.3 Alternatives Analyzed and Comparative Baseline

The analysis for each resource section focuses on specific issues identified during internal and public scoping (Reclamation 2023b). Impact analysis is provided for the Preferred Alternative, as represented by the Representative Alternative, described in **Chapter 2**, and all the "action alternatives" described in **Appendix S,** Additional Description of Alternatives (Basic Coordination Alternative, Enhanced Coordination Alternative, Maximum Operational Flexibility Alternative, and Supply Driven Alternative [both LB Priority and LB Pro Rata approaches]), along with the No Action Alternative. A No Action Alternative typically serves as an extension of current operations to provide a benchmark to

[1] RODs for CRSP Upper Initial Units include those for Flaming Gorge, Blue Mesa (a component of the Aspinall Unit), and Navajo reservoirs.

[2] While the Secretary will consider and prioritize operations at these facilities that are consistent with existing RODs, the Secretary retains the authority to operate outside those RODs if necessary. The modeling assumptions regarding operation of the CRSP Upper Initial Units presented in this Final EIS are not intended to, and do not, limit the Secretary's ability to operate these facilities as necessary to respond to hydrologic conditions in accordance with applicable federal law, including operations for the authorized purposes as stated in the 1956 Colorado River Storage Project Act. See additional information regarding the modeling assumptions of the CRSP Upper Initial Units in **Appendix A,** CRSS Modeling Documentation **Section A.5.11**.

[1] For purposes of this EIS, RMs are measured differently along the length of the Colorado River in the Upper and Lower Basins. RMs in the Upper Basin begin at Glen Canyon Dam and increase from north to south. The Lower Basin RMs increase upstream (south to north), beginning at RM 0.0 at the SIB with Mexico and increasing to RM 342.2 at Hoover Dam. This system of identifying RMs is consistent with common practices within each Basin. Dam locations, reach limits, and other features are identified at their respective RM.

compare the extent and magnitude of the impacts from each action alternative. However, as described in **Chapter 2**, the expiration of current domestic and international implementing agreements means that the No Action Alternative represents a change in operations. As a result, the No Action Alternative does not serve as an appropriate baseline to compare impacts. Therefore, a CCS Comparative Baseline scenario is provided to assess the impacts if operations were to continue under the current direction and strategies.[3] While the CCS Comparative Baseline is not an action alternative, it is a contemporary set of operations that stakeholders are familiar with that can be used to comparatively evaluate the performance of the alternatives (including the No Action Alternative).

As discussed in **Chapter 2**, the Preferred Alternative is a multi-year decision framework that establishes the process and criteria that would govern development and adoption of operating guidelines through 2036. The decision framework is anticipated to be implemented in two-year operating intervals. Unlike other alternatives, the operating guidelines for each interval are not specified in this Final EIS. The sideboards provide a basis for assumptions included in the Representative

[3] This framework relies on strategies and agreements that expire in 2026, including the 2007 Interim Guidelines (as amended), the 2019 DCP, Minute 323 of the 1944 Water Treaty, and other agreements.

Preferred Alternative which captures the range of operating guidelines that may be adopted during each interval, but exact operations would be subject to the guidelines in place during each interval.

The key modeling assumptions for the CCS Comparative Baseline are summarized in **Table 3-2** and additional details are included in **Appendix A**, CRSS Model Documentation. These modeling assumptions were designed to reflect a continuation of the primary existing agreements for Colorado River management including the 2007 Interim Guidelines, the 2019 DCP, and Minute 323 of the 1944 Water Treaty.

3.2.4 Hydrologic Modeling

Hydrologic modeling of the Colorado River system was conducted to determine the potential hydrologic effects of the alternatives considered in this Final EIS. The hydrologic modeling provides projections of potential future Colorado River system conditions (such as reservoir elevations, reservoir releases, and river flows) under the No Action Alternative (and the CCS Comparative Baseline) for comparison with conditions simulated for the action alternatives. Due to uncertainties associated with future inflows, which are the largest driver of system outcomes under any given operation, hundreds of simulations were performed for each alternative to explore how each responds to a range of plausible future conditions. The simulations and analysis framework were designed to avoid reliance on narrow hydrologic assumptions, ensure meaningful comparison between alternatives, and provide reliable information about how the system would respond under each alternative. Hydrologic modeling is the driver for various resource impacts and is therefore the basis for analyzing potential effects on other environmental resources (e.g., recreation, biological resources, and energy). The potential effects on specific resource issues are identified for each alternative and compared with those under the No Action Alternative and CCS Comparative Baseline.

Hydrologic Model Description

Future Colorado River system conditions under the No Action Alternative, CCS Comparative Baseline, and the action alternatives were simulated using CRSS. CRSS, implemented through RiverWare™, is the core simulation tool, providing monthly and annual outputs of key variables, including reservoir storage, reservoir elevations, dam releases, and river flows. The simulation is based on a mass-balance calculation that accounts for water entering the system, water uses (diversions and consumptive use), water losses (evaporation), intervening gains and losses, and water movement through the system.

Input data for the model include monthly natural inflows, physical process parameters (e.g., evaporation rates for reservoirs), initial reservoir conditions, and future diversion and depletion schedules for the Basin States and for Mexico. The operating rules for the Colorado River system reservoirs (including Lake Powell and Lake Mead) are also considered inputs to the model. Detailed descriptions of CRSS and the hydrologic model process are included in **Appendix A**, CRSS Model Documentation.

Table 3-2
Summary of the CCS Comparative Baseline

Shortage Guidelines to Reduce Deliveries from Lake Mead[1]	Coordinated Reservoir Operations (Lake Powell and Lake Mead)	Storage and Delivery of Conserved System and Non-system Water (Lake Mead and/or Lake Powell)[1]	Surplus Guidelines to Increase Deliveries/Releases from Lake Mead[1]	Additional Activities Above Lake Powell
• Shortages determined based on Lake Mead elevation • Shortage volume of 400, 500, and 600 kaf at elevations 1,075, 1,050, and 1,025 feet, respectively • DCP and BWSCP contributions ranging from 241 kaf at elevation 1,090 feet to 750 kaf at elevation 1,025 feet • Shortages and DCP contributions distributed based on existing agreements	• Lake Powell releases are determined based on Lake Powell and Lake Mead elevations • 3 tiers of releases ranging from 9.5 to 7.0 maf with potential adjustments down to 6.0 maf for infrastructure protection • Equalization tier with higher releases possible at higher Lake Powell elevations	• Storage up to 4.2 maf in Lake Mead • Delivery of existing ICS assumed to continue through the analysis period (2027-2060) in accordance with existing agreements designed to reflect the historical range of use of the ICS mechanism • Creation of ICS assumed to continue through the analysis period (2027-2060) in accordance with existing agreements designed to reflect the historical range of use of the ICS mechanism	• Surplus determinations based on Lake Mead Elevation at or above 1,145 feet: Domestic Surplus, 70R (spill avoidance strategy), Flood Control Conditions, and increases in deliveries to Mexico per Minute 323	• Releases from CRSP Upper Initial Units within their respective RODs and contingent on hydrologic conditions to protect infrastructure at Glen Canyon Dam

[1]These operational elements contain modeling assumptions for water deliveries to Mexico. Shortage volumes include assumptions related to reductions in water deliveries to Mexico based on Minute 323. Lake Mead storage volumes for the Storage and Delivery of Conserved System and Non-system Water include assumptions related to storage available to Mexico. Surplus Guidelines include assumptions related to increased deliveries to Mexico based on Minute 323. **Appendix A** provides additional detail. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Assumptions

In addition to the specific operating rules necessary to model each alternative (discussed in **Chapter 2** and the associated appendices) and the CCS Comparative Baseline, modeling of Colorado River system operations requires assumptions about various aspects of inflows, water delivery, and system operations that are common to all alternatives and the CCS Comparative Baseline. These assumptions include:

- **Input Data Consistency:** All simulations use a common set of input data to isolate the effects of alternative operational guidelines.
- **Hydrologic Variability:** Simulations use 400 different hydrologic traces to capture the variability inherent in natural flows.
- **Initial Conditions:** In the Draft EIS, three sets of 2027 reservoir elevations were used to capture hydrologic uncertainty between 2025 and 2027. Since the Draft EIS was developed, the observed hydrology supports using the Low initial conditions only because they are similar to the likely starting point at the end of 2026.
- **Future Water Demands:** Upper Basin depletion schedules were developed from the Upper Colorado River Commission's updated 2016 Depletion Demand Schedule (**Appendix L**, Upper Division Depletion Schedules). The modeled Upper Basin use varies due to hydrologic conditions and alternative specific conservation assumptions. Lower Basin depletion schedules were developed by Reclamation (**Appendix M**, Lower Division Depletion Schedules). Lower Basin depletion schedules start at full apportionment and modeled use varies by alternative specific shortage, surplus, and conservation assumptions.
- **Physical Process Parameters:** Assumptions regarding evaporation, bank storage, and other processes are based on the most current measurements and modeling studies.
- **Infrastructure Constraints:** Modeled limitations on operations at high and very low reservoir elevations.

Detailed modeling assumptions and other aspects of the simulation are documented in **Appendix A**, CRSS Model Documentation. All results in **Chapter 3**, and the supporting technical appendices in **Volume III** are based on the single Upper Basin demand assumptions described above. **Appendix I**, Sensitivity Analysis – Effects of Alternate Upper Basin Demand Scenarios on Operations at Lake Powell and Lake Mead, presents a sensitivity analysis that evaluates how future Upper Basin demands assumptions influence modeled system conditions and vulnerabilities for select hydrologic and water delivery impact indicators.

3.2.5 Resource Model Description

In addition to CRSS, a suite of resource-specific models was used to evaluate potential effects of the alternatives on individual resource areas. These models build on CRSS outputs and provide finer-scale or specialized analyses tailored to individual resource areas. **Table 3-3** lists the primary models and the resources they support.

Table 3-3
Models and Supported Resources

Model/Owner	Primary Purpose	Resource Areas Supported
CRSS/RiverWare™ (Reclamation)	Core system operations model; simulates reservoir elevations, releases, river flows, and salinity.	Hydrologic Resources; Water Deliveries; Dams and Electrical Resources, Water Quality; Visual Resources; Vegetation; Terrestrial Wildlife; Geomorphology and Sediment; Air Quality; Fish and other Aquatic Species; Tribal; Recreation; Population and Land Use; Indian Trus Assets
SAM / Alternative Distribution Model(s) (ADM) (Reclamation)	Emulates a distribution of Colorado River water shortage among entitlement holders under shortage tiers and allocation assumptions; translates tiers into volumes for specific users/jurisdictions.	Water Deliveries; Socioeconomics; Indian Trust Assets (ITAs); Lands and Population
High-Flow Experiment (HFE) / Sediment models (Grand Canyon Monitoring and Research Center [GCMRC] / U.S. Geological Survey [USGS])	Simulates sediment transport and geomorphic response to HFEs (sand mobilization, sandbar building, channel budgets). Evaluates whether and how often HFEs rebuild sandbars.	Geomorphology and Sediment
CRSP Python model (CRiSPPy)/WAPA	An advanced hydropower scheduling tool that projects annual electricity production and powerplant firm capacity. The hourly release data generated by this model is used as an input for many of the GCMRC models listed below.	Dams and Electrical Power Resources
GCMRC Dissolved Oxygen and Temperature Models for Glen Canyon, Lees Ferry and Grand Canyon (Reclamation/ GCMRC/USGS)	Evaluates thermal stratification, interflows, and downstream release water temperatures and dissolved oxygen conditions, especially important for aquatic resource (humpback chub, trout) impacts and selective withdrawal scenarios.	Water Quality; Fish and Aquatic

Model/Owner	Primary Purpose	Resource Areas Supported
Glen Canyon National Recreation Area (NRA) Exposed Shoreline Model (Lake Powell) (subaerially exposed sand model) (USGS/GCMRC/ Southwest Biological Science Center)	Predicts exposed sand and shoreline area as reservoir levels change; used to estimate aeolian sand availability and cultural/paleo exposure.	Air Quality; Cultural Resources; Paleontological Resources
Lake Mead Dust Model (USGS/GCMRC)	Predicts potential dust emissions from newly exposed shoreline and estimates human-health/air-quality impacts under drawdown scenarios.	Air Quality
Preservation Risk Model (USGS/GCMRC)	Ranks Lake Powell and Lake Mead (1–5) based on the potential for cultural and paleontological resource preservation to be affected by reservoir levels. Combines a resource distribution model with a preservation hazard model.	Cultural Resources; Paleontological Resources
Joint Cultural/Paleo Models (Sand Area, Vegetation, and Sandbar Models) (USGS/GCMRC)	Integrates the aeolian sand availability model, vegetation habitat suitability model, and sandbar volume model. Together, these evaluate sand supply, vegetation cover, and sandbar dynamics as key drivers of cultural and paleontological resource preservation in the Grand Canyon.	Cultural Resources; Paleontological Resources
Smallmouth Bass Model (entrainment and population growth proxies) (GCMRC)	Estimates entrainment rates of smallmouth bass through Glen Canyon Dam, thermal suitability downstream, and consequent population establishment/growth (λ proxies).	Fish and Aquatic
Whitewater and Angling Economic Model (USGS/GCMRC)	Estimates changes in recreation value (rafting in Grand Canyon, angling in Glen Canyon) under varying flow and condition scenarios.	Recreation
Socioeconomic IMPLAN (Impact Analysis for Planning) commercial regional input-output model	Assesses community-level socioeconomic outcomes (employment, income, tax base, social vulnerability) from water delivery and recreation/hydropower impacts. Additional specialty models that add layers of analysis to the above models are introduced in their respective resource sections.

3.2.6 Decision Making under Deep Uncertainty

To help inform the impact analysis, a DMDU approach, drawn from a well-established branch of decision science, was implemented to evaluate how each alternative performs across a wide range of plausible future hydrologic and operational conditions. As described in Smith et al. (2022), this approach is appropriate because of extreme uncertainty in future hydrology, the inability to accurately assess the probability distribution of future inflows, and the desire to avoid overconfidence in probabilistic predictions that will vary depending on model inputs.

The DMDU approach is a non-probabilistic evaluation framework that compares alternatives based on their ability to meet specific performance criteria in many potential future conditions and analyzes how the alternatives respond to specific hydrologic conditions. Importantly, the DMDU approach does not assume the likelihood of any future conditions *before* the quantitative analysis is performed. Instead, it first evaluates a broad range of future conditions and then, *after the analysis is presented*, it provides the opportunity to consider whether specific impacts are reasonably foreseeable based on individual and/or expert judgment. Essentially, since there is no way to confidently state the probabilities of different conditions or outcomes occurring, DMDU focuses on applying knowledge and experience at the end of the analysis to assess whether it is reasonable to plan for the specific conditions that result in negative consequences.

Additional background and technical details about the DMDU framework are provided in **Appendix E**, DMDU Overview and Approach.

Note, certain analysis thresholds, such as historic minimum elevations and minimum average flows, were based on observations through June 2026.

Overview of the DMDU Analysis Framework

The key to successful DMDU-style analysis is structured model inputs that capture a range and variety of conditions related to the key factors that drive the uncertainties in the model outputs. For this EIS process, the most impactful uncertainty is future hydrology. Four hundred hydrology sequences (traces) were selected from a suite of data sources that include observed flows, reconstructions of historical flows based on tree ring analysis, statistical models that combine information about recent trends, historical patterns, projected variability, and projections derived from climate models. The traces capture a wide range of potential future conditions and a variety of streamflow statistics. This ensures that the alternatives are thoroughly tested and enables targeted analysis to understand how each alternative responds to specific hydrologic conditions. In the Draft EIS, three sets of 2027 reservoir elevations (High, Mid and Low initial conditions) were used to capture hydrologic uncertainty between 2025 and 2027. Since the Draft EIS was developed, the observed hydrology supports using the Low initial conditions only since they are similar to the projected conditions at the end of 2026. The Low initial conditions are combined with the 400 different hydrology (streamflow) traces. Each alternative is simulated in all 400 futures using CRSS and subsequent resource-specific models. For more information about the hydrology used in this analysis, refer to **Appendix F**, Approach to Hydrologic Uncertainty, and for more information on the initial reservoir condition used in the analysis, refer to **Appendix G**, CRSS Initial Conditions.

Overview of DMDU Figures and Terminology Included in this Analysis

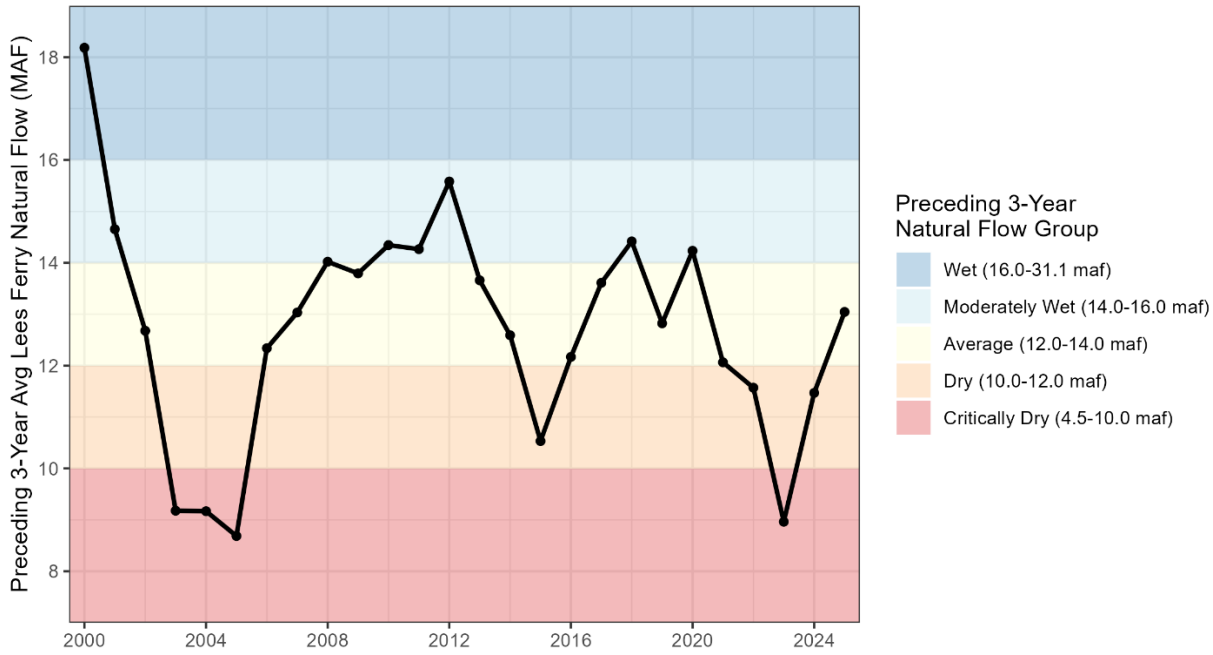
Throughout the resource analysis there are three standard figures: conditional boxplots, robustness heatmaps, and vulnerability bar plots. Each type of figure explains key information regarding performance. When taken together, the figures provide a full picture of how the alternatives compare and whether significant negative impacts are reasonably foreseeable under each alternative. The following sections introduce these figures and provide annotated examples to assist with understanding the resource analysis.

DMDU enables readers to apply individual judgment about the likelihood of specific impacts: The quantitative analysis underpinning this document tests alternatives in a wide range of conditions to identify relationships between hydrologic conditions and system impacts. The DMDU-oriented figures can be combined with historical hydrologic context and future projections to understand whether impacts of concern are reasonably foreseeable. These connections will be demonstrated as each figure is introduced.

Conditional Boxplots

The conditional boxplot figures show how the alternatives respond to different categories of preceding hydrology and enable a comparison of alternatives in specific hydrologic conditions (e.g., average conditions or dry conditions). To create these figures, all 34 years (2027–2060) from all 400 simulated futures (13,600 data points per alternative) are separated into five categories based on their preceding 3-year average Lees Ferry natural flow.[4,5] Then, the resource outcomes for each year are sorted into their respective categories, resulting in a range of potential system outcomes that could occur given the preceding hydrologic conditions. The range of values is presented as a boxplot to summarize the statistical distribution of outcomes.

The flow categories were defined based on how they compare to historical conditions and stakeholders' understanding of different historical periods, as presented in **Table 3-4**, Colorado River Flow Categories. **Figure 3-1**, Preceding 3-Year Average Lees Ferry Natural Flow, 2000 to 2024, shows how the preceding 3-year average Lees Ferry natural flow varied from 2000 to 2024 and demonstrates the relevance of these categories in recent history.



[4] Natural flow at Lees Ferry is a calculated estimate of the flow at that point in the river undepleted by human activities upstream (e.g., reservoir evaporation and regulation, consumptive use). Given that over 90 percent of the total water in the system originates upstream of Lees Ferry, it is a good proxy for the amount of water available to the system overall. This makes it a useful way to categorize hydrology traces.

[5] The 3-year average is used because it is long enough to show impacts from multiple years of moderately challenging hydrology yet short enough to capture the impacts of annual extremes.

Table 3-4
Colorado River Flow Categories

Flow Category Name	Range of Preceding 3-Year Average Lees Ferry Natural Flows (maf)	Percent of Modeled Years in Flow Category	Number of Observed Years in Flow Category, 2000–2025
Wet	16.0–31.1	17	1
Moderately Wet	14.0–16.0	20	7
Average	12.0–14.0	25	11
Dry	10.0–12.0	21	3
Critically Dry	4.5–10.0	17	4

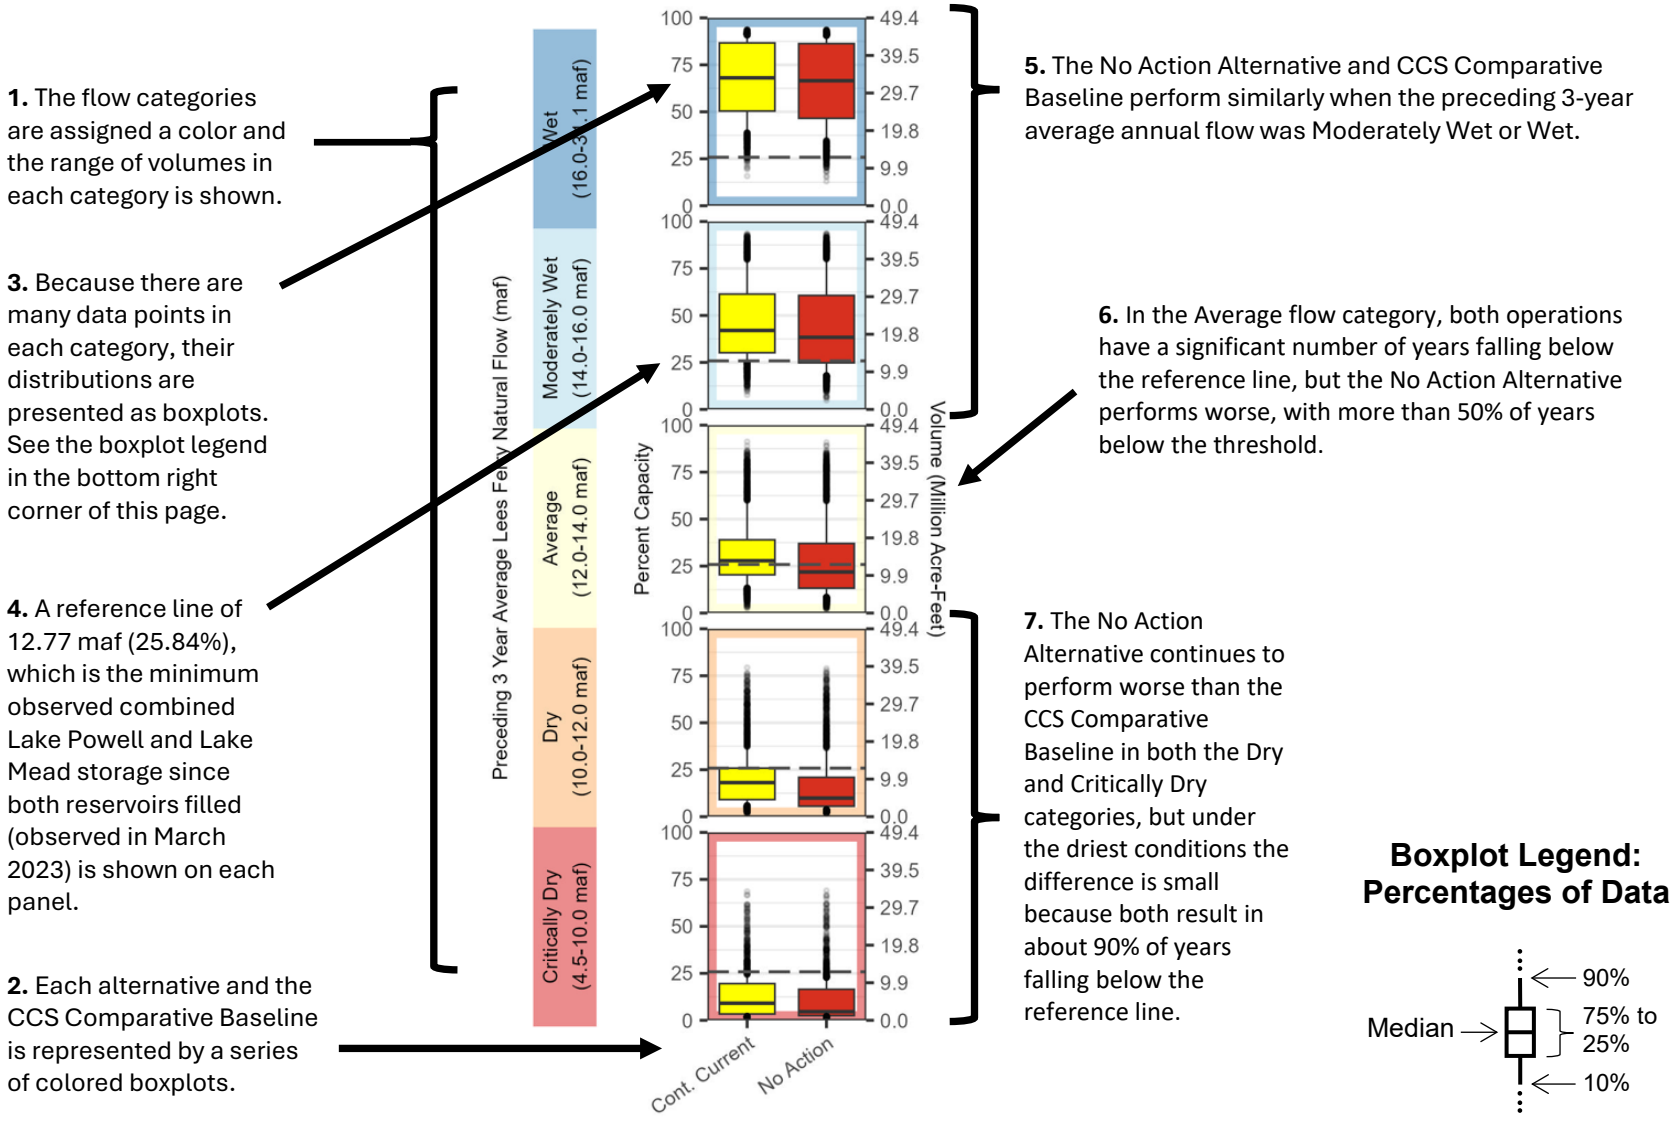


Figure 3-1
Preceding 3-Year Average Lees Ferry Natural Flow, 2000 to 2024

A sample conditional boxplot figure with annotations for guidance is provided in **Figure 3-2,** Sample Conditional Boxplot for WY Minimum Combined Storage of Lake Powell and Lake Mead. **Figure 3-2** has numbered annotations to describe the features of the figure and provide an example summary of what the figure shows about the comparison between the No Action Alternative and the CCS Comparative Baseline. Reading the text in numerical order will provide the clearest understanding.

Conditional boxplots in the impacts analysis will show these two operations alongside the action alternatives. Additionally, reference lines representing values of interest (e.g., historical values or critical thresholds) will be shown with dashed lines. Conditional boxplots will be accompanied by tables of values captured in the boxplots to ensure that precise statistics are communicated.

Figure 3-2
Sample Conditional Boxplot for WY Minimum Combined Storage of Lake Powell and Lake Mead

The connection between system outcomes and hydrologic conditions is clear in the conditional boxplots because the data is sorted by the preceding 3-year average hydrology. To determine which hydrologic categories to focus on and which impacts to contemplate as reasonably foreseeable, the recently observed conditions presented in **Figure 3-1** and **Table 3-4** offer useful context. The Average category is the most common since 2000, while the Wet category is the least common. There have been as many combined instances of Dry and Critically Dry conditions (seven) as there have been instances of Moderately Wet (though, notably, most of the Moderately Wet instances were close to being Average). Recent history combined with the increasing temperature trend, which is associated with lower streamflow, suggests that focusing more on the Average and Dry categories is warranted. However, Critically Dry conditions have been observed and could become more common.

Within each flow category, the distribution of data provides a connection to conditions that occurred before the 3 years used to sort the data into categories: the higher end of a distribution is likely the result of wetter conditions preceding the 3 years, and the lower end of a distribution is likely the result of drier conditions preceding the 3 years. Considering that 20 out of 24 years since 2000 have fallen in the Moderately Wet, Average, and Dry flow categories, it is prudent to focus on specific portions of the distribution within each flow category: the 25th to 75th percentiles (the colored portions of the boxes) are most relevant, since the high and low ends of the distributions are representative of extreme conditions occurring before the 3 years used to sort the data into the flow categories.

Robustness Heatmaps

A robust alternative achieves the preferred minimum performance level under a wide range of future conditions. Robustness heatmaps show the alternatives' ability to meet different levels of performance over one or more decades in the wide range of potential future conditions used in the analysis. Since there are many ways to analyze performance for each resource, there are many opportunities to define meaningful levels of performance. A definition for a single level of performance requires three components: the modeled outcome of a system variable over a time period (i.e., a timeseries), a threshold, and a frequency of meeting the threshold over the specified period.

When a simulated (or modeled) future meets the specified level of performance, it is considered a "successful future." Under each alternative, the percentage of futures (out of 400 modeled futures) that are successful provides information about how robust the alternative is. A large percentage of successful futures (i.e., a high robustness score) means that the alternative is robust (i.e., it performs well) with respect to the specified level of performance; a low percentage of successful futures means that the alternative is not robust with respect to the specified level of performance.

The data that was sorted into categories for the conditional boxplots in **Figure 3-2** can be used in an example robustness heatmap. Performance levels are defined using the annual timeseries of minimum WY combined storage in Lake Powell and Lake Mead (i.e., the minimum storage recorded in each WY from 2027 through 2060) and comparing the timeseries to the threshold of the minimum observed storage (12.77 maf), where staying above this value is better. The final component of defining a level of performance is the frequency of staying above the minimum observed combined storage (100 percent of years, 90 percent of years, etc.).

Figure 3-3 compares the robustness of the No Action Alternative to the CCS Comparative Baseline with respect to their ability to maintain different levels of performance in combined Lake Powell and

Lake Mead storage. It is annotated using numbered descriptions as a guide to the features of the figure and a summary of findings. Reading the text in numerical order will provide the clearest understanding.

In **Figure 3-3**, each row represents a different level of performance. This is useful because individuals can have different opinions about what level of performance is necessary for a given resource. In this case, they could focus on the row that best aligns with their preference. At the same time, it is useful for resource experts to identify a 'preferred minimum level of performance,' which is identified in **Figure 3-3** by the purple box. In this example, the preferred minimum performance level is for the combined storage of Lake Powell and Lake Mead to stay above 12.77 maf in at least 90 percent of years. The preferred minimum performance level is also the basis for vulnerability analysis, as described in the next section.

This type of figure is referred to as a "heatmap" because clusters of colors provide an easy way to identify regions of robustness or lack of robustness across the alternatives. Robustness heatmaps contain a large amount of information, but a quick scan of the rows and columns can reveal key conclusions about robustness. The analysis in this chapter and in the technical appendices uses heatmaps covering four different modeling periods: the full 34-year modeling period (2027-2060) and three approximately equal sub periods. This provides insight into how different alternatives perform in smaller timespans. Importantly, the early sub period (2027-2039) captures how the dry conditions leading up to 2027 affect robustness and corresponds approximately to the length of the Preferred Alternative.

Key visual tips to quickly interpret robustness heatmaps: Every column of colors represents the robustness of an alternative across different levels of performance in a given resource. The more blue there is in a column, and the darker the blue, the more robust an alternative is; a large amount of orange or red, and especially dark red, means an alternative is not robust with respect to a specific type of performance.

For all modeling periods (the full modeling period and individual sub periods), approximately 75 percent of the 400 hydrology traces had an average annual flow lower than the 1906–2025 average of 14.6 maf. Across all periods, approximately 50 percent of traces had an annual average flow lower than the 1988–2024 average, and more than 25 percent of traces had an average that is lower than the 2000–2024 average. Over the subperiods, the 25th percentiles, 10th percentiles, and the driest traces became drier.

The distributions of these statistics can be roughly mapped to robustness percentiles to understand the average conditions associated with unsuccessful futures. For example: over the full modeling period, if a resource is sensitive to drier conditions and an alternative has a robustness score of 90 percent, it is unsuccessful in 10 percent of futures and it is reasonable to map this unsuccessful percentage to the driest 10 percent of the average flows, meaning that the failures are most likely occurring in futures where the 34-year average flow is 11 maf or lower. Readers can determine whether these average conditions are reasonably likely to occur, in which case a 90 percent robustness score may not be adequate to avoid negative impacts on the resource. For resources that are sensitive to wet conditions, the higher end of the distribution of average flows should be referenced. Note that these comparisons are only approximations but are useful for providing context to robustness scores.

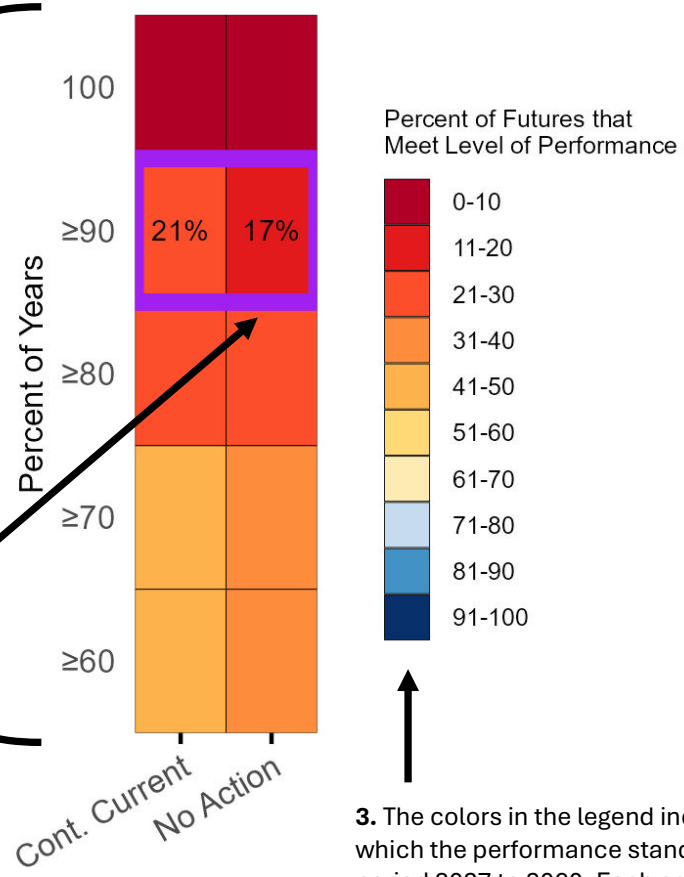

Figure 3-3
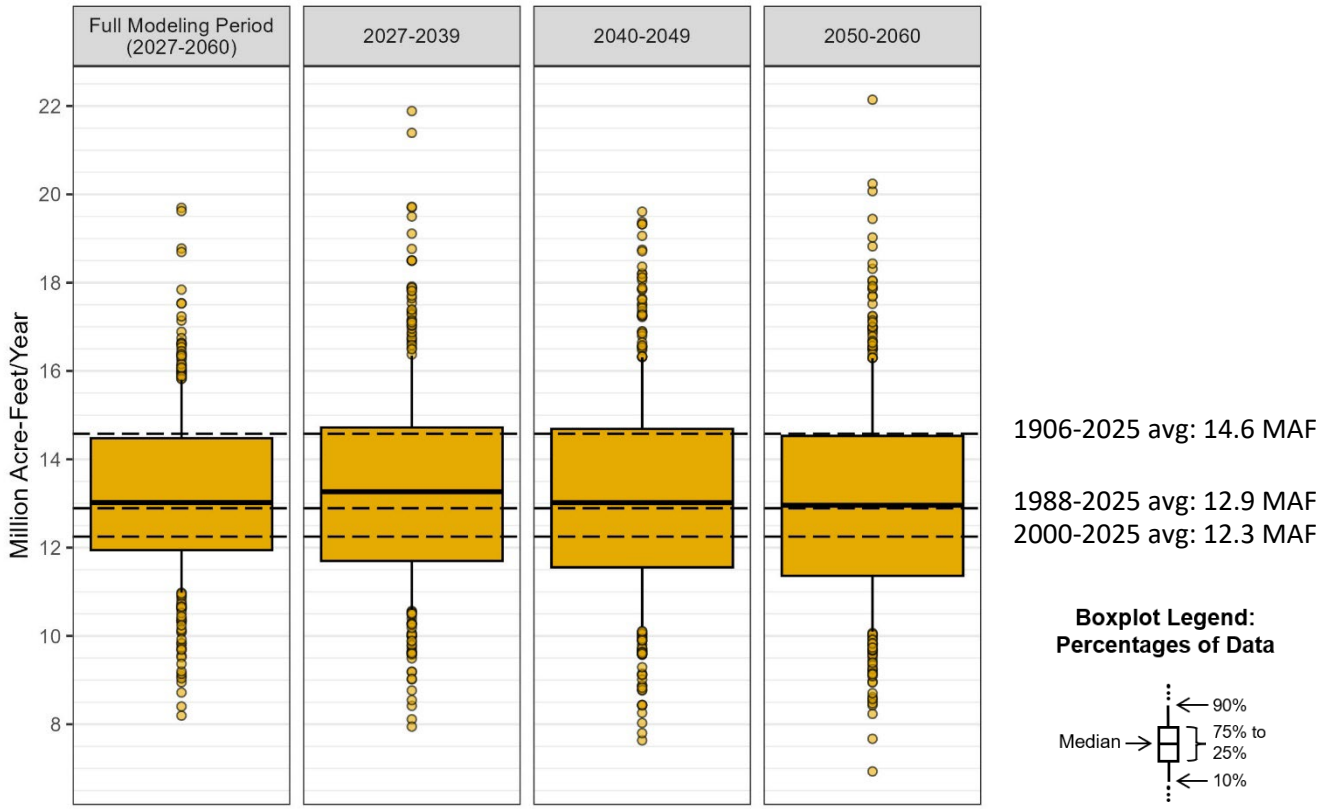
Sample Robustness Heatmap for WY Minimum Combined Storage of Lake Powell and Lake Mead.
Percent of futures in which the WY minimum combined storage stays above the historical minimum (12.77 maf) in the percent of years specified by each row

1. The subtitle describes the time-series, threshold, and frequency used to calculate *robustness* (i.e., the percentage of 400 futures that meet the performance requirement).

4. The rows in the heatmap capture different levels of performance. The highest row is the hardest level of performance to achieve (colors are more likely to be red, orange or yellow) and the lowest row is the easiest (colors are more likely to be blue). In this example, each row represents a frequency of keeping combined Lake Powell and Lake Mead storage above the observed minimum.

5. The purple highlighted row denotes the *preferred minimum performance*. This row is the focus for figure descriptions and is the performance level used in vulnerability bar plots.

2. Each alternative and the CCS Comparative Baseline has a column of "cells" that are colored based on the legend.



3. The colors in the legend indicate the percentage of futures out of 400 in which the performance standard in each row is met across the time period 2027 to 2060. Each cell in the heatmap has a color corresponding to the robustness of an alternative with respect to the performance standard in that row. Higher percentages (darker blues) indicate higher robustness.

6. The ability of different alternatives to maintain a reasonable minimum amount of storage in Lake Powell and Lake Mead is an important consideration when evaluating their performance. Here, the observed minimum volume of 12.77 maf is taken as a significant threshold, and the preferred minimum performance is to stay above that threshold in at least 90% of years across the 34-year simulation period (purple highlighted row). The CCS Comparative Baseline achieves this level of performance in 17% of futures, so it is slightly more robust than the No Action Alternative which only achieves it in 21% of futures. Both increase in robustness as the performance standard is lowered (looking down the rows), with CCS Comparative Baseline achieving above 40% robustness (light orange cell) when the frequency of staying above the observed minimum storage is relaxed to 60% of years (bottom row).

Assessing which alternatives are in shades of blue (generally robust) and which are in shades of yellow, orange, or red (generally not robust) for a given level of performance provides a basic level of information that is sufficient for comparison. To apply judgment about what robustness score is adequate, it is beneficial to understand the statistical distribution of the underlying hydrology.

Figure 3-4 shows annual average flows by trace for the full 400-trace hydrology ensemble over different time periods and compares them to historical averages. In the first subperiod (second panel from the left) the distribution is slightly higher at the median and 75th percentiles. This is a statistical artifact from several of the constituent ensembles, not a prediction that supply could increase between 2027 and 2039.

Figure 3-4
Average Annual Lees Ferry Natural Flow by Trace for 400-Trace Hydrology Ensemble over Different Time Periods

Vulnerability Bar Plots

Vulnerability bar plots provide complementary analysis to the robustness heatmaps by identifying the specific hydrologic conditions in which each alternative is likely to succeed or fail the preferred minimum performance level[6] (recall, the preferred minimum performance is shown by the purple-

[6] Vulnerability analysis considers if the performance levels are violated any time during the 34-year modeling period. Using the full modeling is preferred such that one hydrology statistic can accurately predict if an alternative will meet the performance level. A decadal-based analysis (like what is included in some robustness heatmaps) would require a multi-dimensional prediction accounting for reservoir storage at the start of each decade, which varies by alternative and hydrology, making it difficult to compare alternatives.

outlined row of the heatmap). For example, the heatmap in **Figure 3-3** shows that the CCS Comparative Baseline successfully meets the preferred minimum performance level in 21 percent of futures, meaning that the CCS Comparative Baseline is unsuccessful in the remainder of the futures (79 percent of futures). Vulnerability analysis uses information about both the successful and the unsuccessful futures to identify hydrologic conditions (via statistical characteristics) that are most skillful at predicting the different outcomes. The hydrologic statistical characteristics tested are:

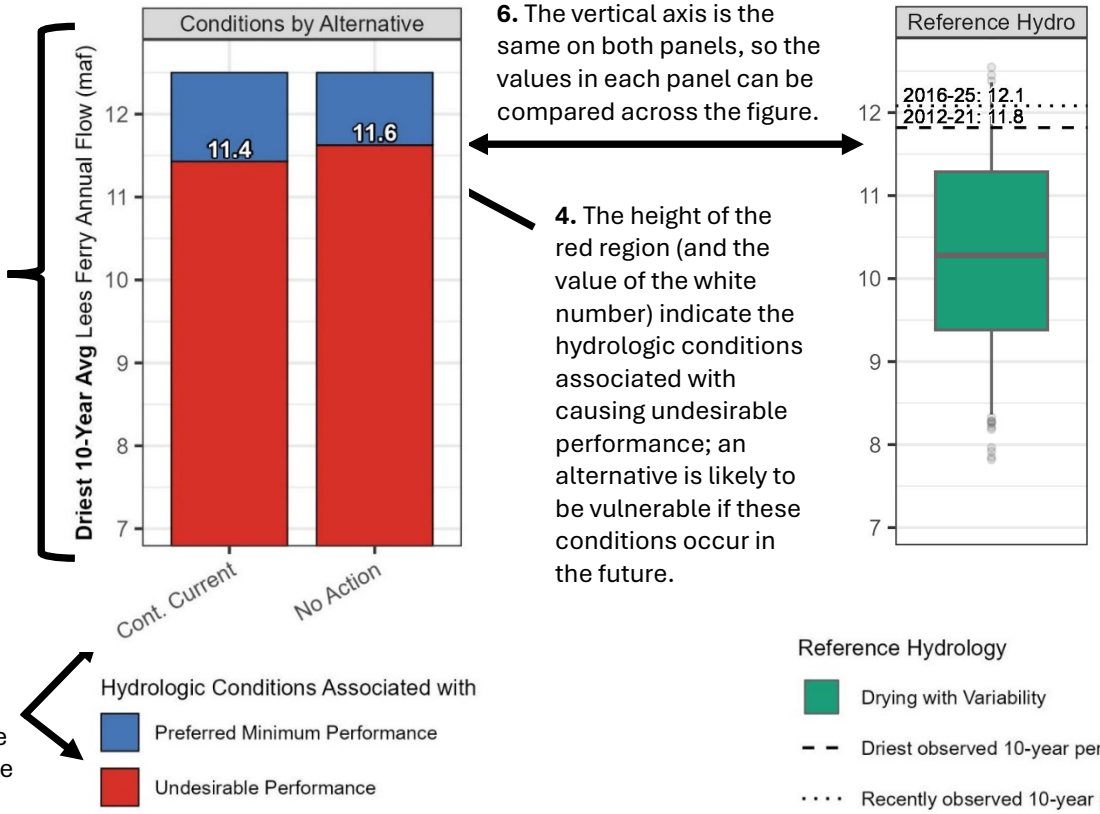
- the driest 10-year average Lees Ferry flow over a 34-year hydrology trace
- the median 10-year average Lees Ferry flow over a 34-year hydrology trace
- the wettest 10-year average Lees Ferry flow over a 34-year hydrology trace

Statistics based on 10-year averages were determined to be highly accurate at separating successful from unsuccessful futures and provide information on a time-scale relevant to the Preferred Alternative (which is a 10-year decision framework). The driest 10-year average is most frequently the most skillful predictor because it is highly correlated with the undesirable resource outcomes that occur due to dry hydrology. For information about other predictors and how they are tested, refer to **Appendix E**, DMDU Overview and Approach.

Once a skillful predictor is identified, the alternatives can be described in terms of the hydrology conditions associated with undesirable performance (i.e., the conditions in which an alternative is vulnerable). Alternatives will have different vulnerabilities because of their different approaches to operating the reservoirs. Conditions associated with vulnerability can then be compared to conditions that have occurred in the past and a range of conditions that could potentially occur in the future; if conditions that have already occurred are similar to those associated with vulnerability under an alternative, the conclusion is that the undesirable impacts are reasonably likely to occur in the future.

Figure 3-5 compares the vulnerability of the No Action Alternative and the CCS Comparative Baseline with respect to avoiding undesirable performance in combined Lake Powell and Lake Mead storage (i.e., falling below the historical minimum in more than 10 percent of years). The figure also shows how each alternative's vulnerability compares to conditions that have occurred in the past or could potentially occur in the future. It is annotated using numbered descriptions as a guide to the features of the figure and a summary of findings. Reading the text in numerical order will provide the clearest understanding.

Vulnerability bar plots capture complex information, but a brief visual inspection can provide the key conclusions about whether undesirable impacts could be reasonably expected under a given alternative.



Key visual tips to quickly interpret vulnerability bar plots: Every alternative is linked to a bar that is divided into blue and red; the larger the red portion, the wider the range of hydrology conditions in which the alternative is vulnerable. If the red portion of the bar encompasses, or is close to, conditions that have already occurred according to the reference hydrology panel, undesirable performance in that resource is likely to occur. (If a bar is completely blue, none of the conditions tested caused vulnerability and the alternative is robust.)

Figure 3-5
Sample Vulnerability Bar Plot for WY Minimum Combined Storage of Lake Powell and Lake Mead. Conditions that could cause Combined Lake Powell and Lake Mead storage to fall below the historical minimum in more than 10 percent of years

1. The subtitle provides a definition of undesirable performance adapted from the purple preferred minimum performance row in the heatmap.

3. The vertical axis is based on the streamflow statistic that is a skillful predictor of the alternatives' ability to meet the preferred minimum performance. In this case, the driest 10-year average Lees Ferry annual flow was a good predictor. The range of the axis captures the full range of worst 10-year droughts tested.

2. Each alternative and the CCS Comparative Baseline have a vertical bar divided into conditions associated with meeting the minimum preferred performance (blue region) and conditions that are associated with undesirable performance (red region).

6. The vertical axis is the same on both panels, so the values in each panel can be compared across the figure.

4. The height of the red region (and the value of the white number) indicate the hydrologic conditions associated with causing undesirable performance; an alternative is likely to be vulnerable if these conditions occur in the future.

5. The Reference Hydro panel provides two types of context for the height of the red region for each alternative. First, there are two historical reference lines: the statistics for the most recent period and the statistics for the worst observation in the relevant statistic. The second type of context shows the distribution of this streamflow statistic represented in the Drying-with-Variability ensemble, which is a set of 100 hydrology traces whose significance is described in Section 3.2.6 and Appendix F.

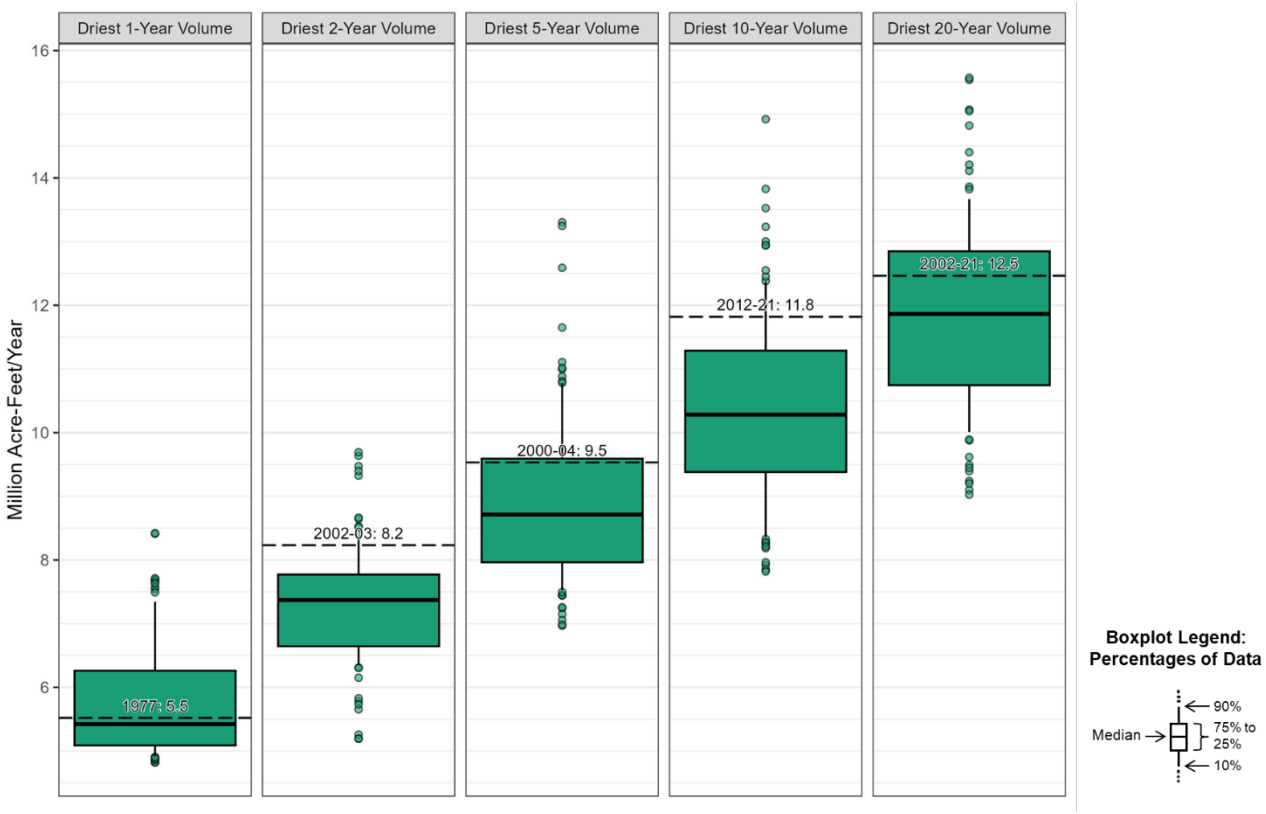
7. The No Action Alternative is likely to be vulnerable to undesirable performance if the future includes a 10-year drought averaging 11.6 maf or less; conditions similar to these have already occurred in the observed record. The CCS Comparative Baseline is likely to be vulnerable if the future includes a 10-year drought averaging 11.4 maf or lower, which is close to conditions that have already occurred. About 90 percent of the hydrology sequences in the Drying-with-Variability ensemble have drier droughts than those likely to cause vulnerability under these two operations.

The "reference hydrology" panel introduced in **Figure 3-5** is included in every vulnerability bar plot to provide context for interpreting the likelihood of the conditions associated with vulnerability. The historical reference lines are the first component of the context, and anytime an alternative is vulnerable to conditions that have already been observed, it is reasonable to assume these conditions can occur again.

The second component of the context is the boxplot that shows projections about potential future conditions. These projections are based on the "Drying-with-Variability" ensemble, which is a 100-trace statistically generated ensemble that represents conditions that may occur in the future.[7] Long-term planning in the Basin must consider the significant potential for a future with more frequent, sustained, and/or severe dry periods and a downward trend in average flows, but this does not preclude the occurrence of wet years. The Drying-with-Variability ensemble was designed to capture this by combining information about the observed temperature trend, temperature's impact on the translation of precipitation into streamflow, and the sequencing of wet and dry periods from paleo reconstructed data while preserving the potential for infrequent but significant wet years.

For every vulnerability bar plot, the two sources of hydrologic context – observed hydrology and the Drying with Variability ensemble – are used to make a summary statement about whether the Representative Preferred Alternative is reasonably likely or unlikely to be vulnerable absent additional action. This statement combines objective analysis of conditions likely to cause failure and Reclamation's expert judgment considering how those conditions compare to the past and to a reasonable expectation of future hydrology given current trends.

Figure 3-6 provides the distribution of statistics across the 100 traces in the Drying-with-Variability ensemble and compares them to the worst statistic in the observed record (1906–2025). For the driest 1-year flow, over 50 percent of Drying-with-Variability traces have a drier year than the lowest observed flow, with the lowest single-year flow in the ensemble falling below 5 maf. In the 2-to-10-year windows, 60 percent of traces or more are drier than the worst observed statistic; for the driest 10-year volume, approximately 85 percent of traces contain drier decades than the worst observed decade, which occurred from 2012 to 2021.



The purpose of describing the narrative, underlying data, and statistics of the Drying with Variability ensemble in the introduction to DMDU figures is to highlight that vulnerability bar plots provide a large amount of information that allows readers to use their judgment in determining the likelihood of negative resource impacts. The vulnerability bar plots combine information about the conditions in which each alternative is vulnerable, historical context, and the potential for a drier future.

3.2.7 Salton Sea

During scoping and public review of the Draft EIS, Reclamation received comments requesting analysis of impacts to the Salton Sea. The Salton Sea is a terminal lake in Riverside and Imperial Counties, California. Lake levels are influenced by runoff from the surrounding Imperial Valley and Coachella Valley watersheds, as well as agricultural drainage from the IID and CVWD. As explained below, analysis of impacts to the Salton Sea is not included in this EIS.

[7] For additional information about this ensemble, refer to **Appendix F**, Approach to Hydrologic Uncertainty.

Figure 3-6
Key Statistics for the Drying with Variability Ensemble

The Salton Sea acts as a terminal sump for agricultural drainage; therefore, reductions in agricultural runoff could impact Salton Sea elevations, which, in turn, could impact air quality and shoreline wildlife habitat. Agriculture in the IID and CVWD service areas, as well as smaller non-agricultural uses, are sustained by Colorado River water diverted at the Imperial Dam and delivered via the All American and Coachella Canals. In recent years, total diversions of Colorado River water were approximately 2.8 mafy at the Imperial Dam (California Natural Resources Agency 2024).

Over the past 20 years, inflows to the Salton Sea have declined from 1.3 mafy to approximately 1.1 mafy (California Natural Resources Agency 2024), primarily related to California's reduced usage of Colorado River water due to the prolonged drought in the Basin and changing agricultural practices, including implementation of water conservation programs.

The California Natural Resources Agency established the Salton Sea Management Program (SSMP) to oversee restoration efforts at the Salton Sea. Currently, the SSMP is working with local, state, tribal, and federal partners to implement the first phase of habitat restoration projects to establish at least 14,900 acres of aquatic habitat and up to 14,900 acres of vegetated habitat by the year 2028 (USACE 2024). Additionally, the SSMP released a long-range plan to address future recession of the Salton Sea beyond the year 2028 (California Natural Resources Agency 2024). The goal of the plan is to protect or improve air quality, water quality, and wildlife habitat to prevent or reduce health and environmental consequences anticipated from the long-term recession of the Salton Sea shoreline (California Natural Resources Agency 2024).

Given that inflows into the Salton Sea depend on a highly managed system, subject to growing water demands, and uncertain weather patterns and water polices, the SSMP used a range of projected annual net inflows to the Salton Sea as baselines for analysis: (1) high probability of inflow at 889,000 af, (2) low probability inflow at 684,000 af, and (3) very low probability at 444,000 af. These flows are used to project the future baseline of the Salton Sea and the restoration needs. The SSMP's long-range plan specifically acknowledges the uncertainty around policy decisions on this Colorado River Post-2026 process and is a reason for using a range of net inflows.

The SSMP's long-range plan is informing the scope of the Imperial Streams and Salton Sea Ecosystem Restoration Feasibility Study and NEPA compliance that the USACE is currently preparing. Once that process is complete, state and federal funding will be pursued to support the resultant design and construction of restoration projects, beginning around 2028.

For this Post-2026 process, Reclamation's action is to develop operational guidelines for the storage and release of water through Lake Powell at Glen Canyon Dam and Lake Mead at Hoover Dam. Reclamation's contracts with IID and CVWD do not provide Reclamation with the discretion to determine how individual water users within these districts use or allocate their water resources, including user decisions to participate or not participate in conservation programs.

Any reductions of Colorado River water available for diversion at the Imperial Dam for use by IID and CVWD could result in less available water for agriculture and, depending on the conservation activity or how the reduction would be implemented, subsequent drainage to the Salton Sea. While Reclamation cannot control Basin hydrology, there could be policy decisions that result in shortages.

In summary, analysis of impacts to the Salton Sea are not included in this EIS for the following reasons:

1. Any resultant impacts are within the scope and range of inflows being considered as part of the baseline in the SSMP's long-range plan and the USACE's ongoing NEPA process. While any resultant impacts to the Salton Sea may be accelerated by Post-2026 policies, the overall magnitude of impacts would not change.
2. Reclamation does not manage or control the end use of water after the point of delivery. As such, Reclamation has no management authority over the distribution of end use or allocation by these water districts and individual users, including user decisions to participate in conservation programs. The State of California oversees management of the Salton Sea, and Reclamation has no management or enforcement authority over inputs to the Sea. Reclamation would need new authorities and compliance to implement any policies that change how water shortages are distributed to IID and CVWD.[8]

[8] Reclamation's potential contribution of funds through contribution agreements does not affect the enforcement mechanisms of those state and local authorities.

3.3 Hydrologic Resources

3.3.1 Affected Environment

Overview and Study Area

This section summarizes the Basin's hydrology from the full pool elevation of Lake Powell to the SIB with Mexico. It also includes groundwater under direct influence of the Colorado River and the Lower Basin reservoirs. For a more detailed account of the affected environment for the hydrologic resources, please see **TA 3**, Hydrologic Resources.

Key Drivers and Trends

Worsening drought conditions have been a major driver for changes to hydrologic resources in the Basin. Since 2000, the Basin has experienced persistent drought conditions, exacerbated by higher temperatures, resulting in increased evapotranspiration, reduced soil moisture, and ultimately reduced runoff (Lukas and Payton 2020). The flow in the Colorado River is highly variable from year to year because of variations in precipitation in the Basin. However, the Basin is currently experiencing a prolonged period of drought; 2000 to 2024 was the driest 25-year period in more than a century. A paleo reconstruction of Colorado River streamflow at Lee Ferry, Arizona, back to 762 current era (CE), indicates that the recent 25-year period has lower streamflow than any other period in the last 1,200 years (Meko et al. 2007). These conditions have led to a cumulative streamflow deficit of about 70.0 maf relative to twentieth-century conditions (Reclamation 2025b).

Operational Impacts

The overall characteristics and connectivity of the Basin remain unchanged from when the 2007 Final EIS was issued. However, since 2007, key operational changes have affected hydrologic resources. Domestic agreements specifying such operations include the 2007 Interim Guidelines (supplemented in 2024), the 2016 Glen Canyon Dam LTEMP (supplemented in 2024), and the 2019 DCP. More details on operational changes since 2007 can be found in **Section 1.8.2.1**, The Law of the River.

Reservoirs and River Reaches Overview

Upper Basin – CRSP Upper Initial Units

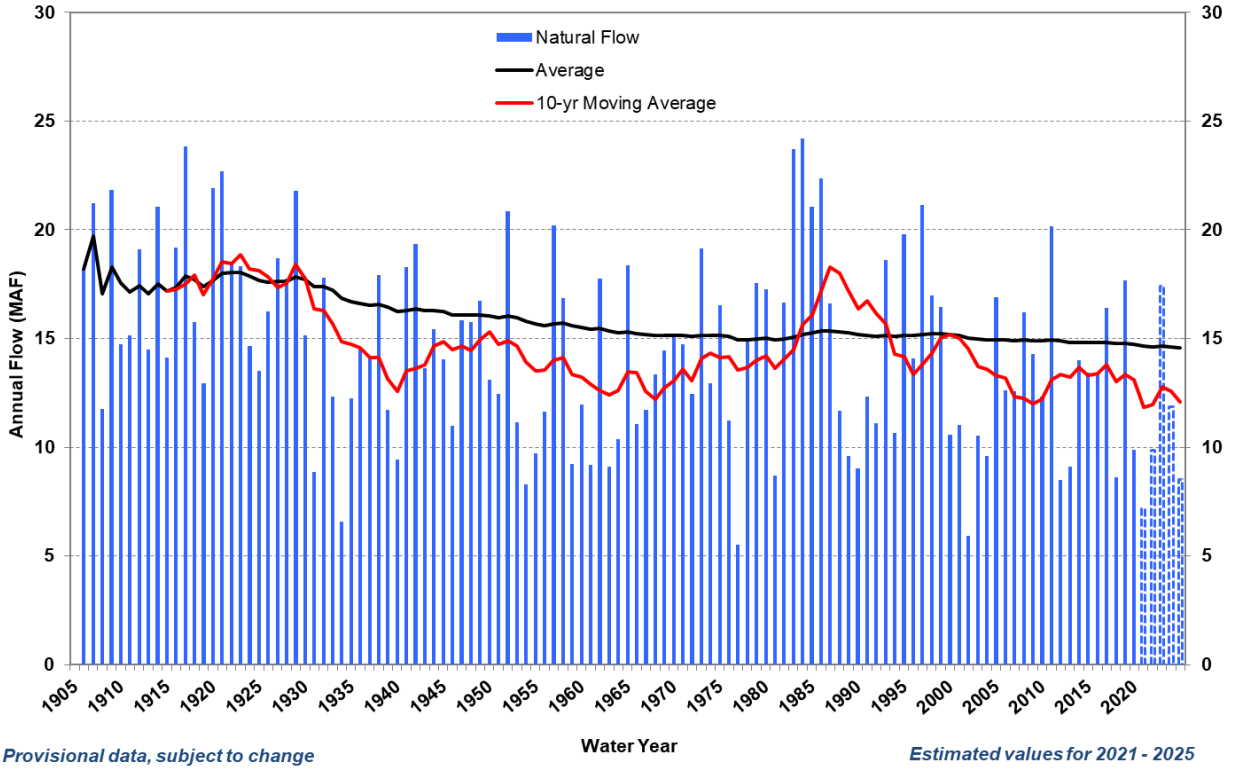
The 1956 CRSPA created four major Upper Basin reservoirs to support Colorado River Compact compliance: Flaming Gorge in Utah, Navajo in New Mexico, Blue Mesa in Colorado, and Lake Powell in Utah and Arizona. The CRSP Upper Initial Unit reservoirs include Flaming Gorge, Navajo, and Blue Mesa. Total live storage volume of the CRSP Upper Initial Units is 6.15 maf. Prolonged drought and low runoff conditions prompted the 2019 DROA (a component of the 2019 DCP) to allow strategic releases from the CRSP Upper Initial Units reservoirs to protect elevations at Lake Powell. As described in **Section 3.2.1**, operations at the CRSP Upper Initial Units specifically contemplated in the Final EIS alternatives are intended to remain within the scope of the existing RODs. Accordingly, the Final EIS does not expand the geographic scope of analysis upstream of Lake Powell.

Lake Powell and Glen Canyon Dam

Lake Powell is a reservoir located in southern Utah and northern Arizona. The water surface operating range of Lake Powell is between 3,490 feet (corresponding to the minimum power pool) and 3,700 feet (corresponding to the top of Glen Canyon Dam spillway). The total live storage capacity of Lake

Powell at the full pool elevation of 3,700 feet is 23.31 maf (excluding 1.9 maf of flood control space). Due to persistent drought, storage levels in Lake Powell have declined, particularly in the early 2000s and from 2020 to 2022, when elevations were at an all-time low since filling. Should elevations drop below 3,490 feet, routine operations of Glen Canyon Dam would be discontinued, and hydropower could no longer be produced. Releases can be made through the river outlet works down to elevation 3,370 feet (corresponding to dead pool) below which water cannot be delivered downstream. However, the outlet works are not designed nor intended for long-term use at low reservoir levels. The infrastructure at Glen Canyon Dam is described further in **Section TA 3.1.3**, Lake Powell and Glen Canyon Dam.

Unregulated inflows to Lake Powell from the Upper Basin vary year to year based on hydrologic conditions. A period of drought that began in 2000, exacerbated by increasing temperatures, has led to a 20 percent decrease in average annual Upper Basin (at Lees Ferry) natural flows (Reclamation 2025a). This continued dry period and decrease in inflows in recent years have resulted in Lake Powell approaching critically low elevations. Drought conditions from 2020 to 2022 triggered the need to supplement the 2007 Interim Guidelines with near-term provisions for addressing extremely low reservoir levels. The result was the 2024 ROD, providing for lower releases from Lake Powell. Since the implementation of the 2007 Interim Guidelines, the water surface operating range of Lake Powell has been between a low of 3,519.92 feet (occurring in 2023), and a high of 3,660.9 feet (occurring in 2011). Historical low and high elevations in Lake Powell are shown in **Figure TA 3-1** in **TA 3**, Hydrologic Resources. Annual Glen Canyon Dam releases from Lake Powell averaged 9.75 maf from 1996 through 2007, but have since averaged 8.62 maf (ranging from 7.00 maf to 12.52 maf from 2008 through 2025).



Lees Ferry Gaging Station and Lee Ferry Compact Point

The Lees Ferry Gaging Station is located in Arizona, approximately 15.9 river miles (RMs) downstream of Glen Canyon Dam. This differs from the Lee Ferry Compact Point, which is the division point between the Upper Basin and Lower Basin as established by the 1922 Colorado River Compact. The Lee Ferry Compact Point is located a few miles downstream of the Lees Ferry Gaging Station and the confluences with the Paria River. **Figure TA 3-2** in **TA 3**, Hydrologic Resources shows the difference between the two locations.

From 1906 to 2007, the average annual natural flow at the Lees Ferry Gaging Station was calculated to be 14.9 maf and ranged from 5.4 maf to 24.4 maf. Since the implementation of the 2007 ROD (2008 to 2025), the annual natural flow at the Lees Ferry Gaging Station averaged 12.7 maf and has ranged from a low of 6.7 maf (2021) to 20.3 maf (2011). **Figure 3-7** below shows the WY natural flows calculated at the Lees Ferry Gaging Station for 1906 through 2025.

Natural flows at Lees Ferry Gaging Station are calculated based on observed (gage) flow and corrected by Reclamation for upstream reservoir changes in storage and release, losses including evaporation, and depletions due to agriculture and domestic uses.

Figure 3-7
Colorado River Natural Flow at Lees Ferry Gaging Station, Arizona (1906-2025)

Source: Reclamation 2025f

Lake Mead, Lake Mohave, Lake Havasu, Cibola Gage, Imperial Dam, Northerly and Southerly International Boundaries

Approximately 292 miles downstream of Glen Canyon Dam is Lake Mead, formed by Hoover Dam. This reach of the Colorado River includes the Grand Canyon, which is approximately 277 miles long. Flows in this reach primarily consist of flow from Glen Canyon Dam releases but do include minor contributions from perennial tributaries. The two largest tributaries in this reach are the Paria River and the Little Colorado River, which make up approximately 3 percent of the total flows in the Colorado River in this reach (USGS 2025a).

Lake Mead is located in the Black Canyon, on both sides of the Arizona-Nevada state line near Las Vegas. The water surface elevation operating range for Lake Mead is between 895 feet (corresponding to dead pool) and 1,229 feet (corresponding to the top of the Hoover Dam spillway). The total live storage capacity of Lake Mead at the full pool elevation of 1,219.6 feet is 26.12 maf (excluding approximately 1.5 maf of flood control space). Lake Mead has a minimum power pool elevation of 950 feet, below which releases occur only through the river outlet works and hydropower cannot be generated. When elevations drop below 895 feet, water is no longer able to be delivered downstream from Hoover Dam.

Since 2007, water surface elevations at Lake Mead have generally declined. Since the implementation of the 2007 ROD, the water surface operating range of Lake Mead has been between a low of 1,040.6

feet (occurring in 2022) and a high of 1,134.5 feet (occurring in 2012). Historical low and high elevations in Lake Mead are shown in **Figure TA 3-5** in **TA 3**, Hydrologic Resources. Annual Hoover Dam releases from Lake Mead ranged from 8.275 maf to 12.781 maf (averaging 10.199 maf) from 1996 through 2007, but have since ranged from 8.515 maf to 9.615 maf (averaging 9.185 maf) from 2008 through 2024.

The 67-mile reach from Hoover Dam to Davis Dam forms Lake Mohave. Lake Mohave is located on both sides of the Arizona-Nevada state line near Bullhead City, Arizona. Flows in this reach are almost entirely comprised of releases from Hoover Dam. The average storage in Lake Mohave has remained constant, at approximately 1.6 maf over the past few decades. Lake Mohave is operated under an existing rule curve that determines specific target elevations at the end of each month. This rule curve was not affected by the 2007 Interim Guidelines, so the average annual water surface elevation at Lake Mohave was approximately 640.8 feet from 1996 to 2007 and 640.9 feet since 2008.

The 84-mile reach from Davis Dam to Parker Dam forms Lake Havasu, which is located on both sides of the California-Arizona state line near Lake Havasu City, Arizona. Flows in this reach primarily consist of releases from Davis Dam, although contributions from the Bill Williams River make up approximately 1 percent of the total flows (USGS 2025b). Lake Havasu provides a forebay and desilting basin that pumps water for delivery to the MWD and CAP service areas. Similar to Lake Mohave, Lake Havasu is operated under an existing rule curve that determines specific target elevations at the end of each month. This rule curve was not changed by the 2007 Interim Guidelines and maintains Lake Havasu's water surface elevation between 445 and 450 feet. While the 2007 Interim Guidelines did not explicitly target Parker Dam operations, decreased inflows to Lake Havasu (as a result of decreased releases from upstream Lake Powell and Lake Mead) have resulted in decreased annual release rates. Since the implementation of the 2007 Interim Guidelines, the average annual releases from Parker Dam have decreased by 1.0 maf.

One hundred five miles downstream of Parker Dam is Reclamation's Cibola Gage. Flows in this reach primarily consist of releases from Parker Dam. Decreased releases from Parker Dam in the last 20 years have resulted in decreased flows in this 105-mile reach. Two major diversion dams are located in this reach: Headgate Rock Dam and Palo Verde Diversion Dam. The impoundments of these dams facilitate the diversion of water for the Colorado River Indian Tribes and the Palo Verde Irrigation District. Current operations keep these reservoirs at constant elevations. Thirty-eight miles downstream from the Cibola Gage is Imperial Reservoir, formed by Imperial Dam. Flows in this reach primarily consist of releases from Parker Dam. Imperial Dam was constructed to raise the water surface elevation enough to provide gravity-controlled flow to meet water deliveries to California via the AAC and to Arizona via the Gila Main Canal. The AAC diverts water for the IID, the CVWD, the Yuma Project, and the City of Yuma. The Gila Gravity Main Canal diverts water for Gila Valley, Yuma Mesa, and the Wellton-Mohawk area. Imperial Dam also regulates deliveries to Mexico.

Five miles downstream of Imperial Dam is Laguna Dam. Originally, Laguna Dam diverted water to the Yuma Project area but then the Imperial Dam was built. The Laguna Dam is now used as a regulating structure for sluicing flows from Imperial Dam and also provides downstream toe protection for Imperial Dam. Flows in this reach primarily consist of releases from Imperial Dam and contributions from the Gila River. Twenty-six miles downstream of Imperial Dam is the NIB between the U.S. and Mexico.

The Morelos Diversion Dam is 1.1 miles downstream of the NIB and impounds the majority of the water supply that is diverted by Mexico into the Reforma Canal. The dam is owned, operated, and maintained by Mexico per the 1944 Water Treaty. To ensure the annual 1.5 maf water delivery under Normal Conditions per the 1944 Water Treaty, the Morelos Diversion Dam operations have not changed as a result of the 2007 ROD. Refer to **Appendix N**, International Border Region of the Colorado River, for more details related to previous binational coordination efforts. Since most of the water is diverted at Morelos Diversion Dam into the Reforma Canal, flows in the Colorado River limitrophe downstream of Morelos Diversion Dam are infrequent. Flows downstream of Morelos Diversion Dam in the limitrophe to the SIB only occur due to Flood Control operations at Hoover Dam, seepage from Morelos Diversion Dam, irrigation return flows, groundwater inflow, and any water released for environmental purposes in the Colorado River Delta. The upper portion of the limitrophe is a gaining reach due to high groundwater levels in adjacent irrigated fields; however, in the southern portions of the limitrophe, groundwater elevations decrease, and it becomes a losing reach.

3.3.2 Environmental Consequences

Methodology

CRSS was used to simulate Basin conditions and account for hydrologic uncertainty through the full analysis period (2060) on a monthly time-step. Reservoir elevations, reservoir releases, and river flows are outputs to the model and are used directly for the results presented in this resource section. To help visualize the different states of modeled futures, results from CRSS are framed using five potential flow condition categories that range from wet hydrologic conditions to critically dry hydrologic conditions. For background and guidance related to figures used in the analysis below (conditional boxplots, robustness heatmaps, and vulnerability bar plots), see **Section 3.2**, Analysis Methods.

Impact Analysis Area

The geographic scope of the hydrologic resources analysis is the Colorado River corridor from the upstream limits of full pool elevation of Lake Powell to the downstream limits of the SIB. Reservoirs upstream of Lake Powell are operated pursuant to their own RODs, which are not altered by the proposed alternatives.

Assumptions

The hydrologic resources results are direct outputs from CRSS. Refer to **Appendix A**, CRSS Model Documentation, for more details related to model assumptions and documentation. All action alternatives except for the Basic Coordination Alternative incorporate mechanisms related to the storage and delivery of conserved water in Lake Powell and/or Lake Mead (refer to **Appendix S**, Additional Description of Alternatives). Unless otherwise specified, impacts reflect modeling assumptions about voluntary conservation behavior.

Impact Indicators

Five impact indicators were used to assess impacts on hydrologic resources due to operational activities: reservoir elevations, system storage, reservoir releases, river flows, and qualitative (descriptive, non-modeled) impacts on groundwater adjacent to reservoirs and river reaches.

Issue 1: Reservoir Elevation

Water surface elevations at Lake Powell and Lake Mead are anticipated to be affected by the various alternatives as a result of changes to operational activities. Water surface elevations at Lake Mohave and Lake Havasu are not anticipated to be affected. The impacts on water surface elevations at each reservoir are summarized below. Refer to **Section TA 3.2.1**, Issue 1: Reservoir Elevations, in **TA 3**, Hydrologic Resources, for details regarding impacts on water surface elevations at Lake Powell, Lake Mead, Lake Mohave, and Lake Havasu.

Under the Average Flow Category, all action alternatives generally maintain reservoir elevations above critical thresholds, but performance diverges significantly as conditions become drier.

Lake Powell Reservoir Elevations

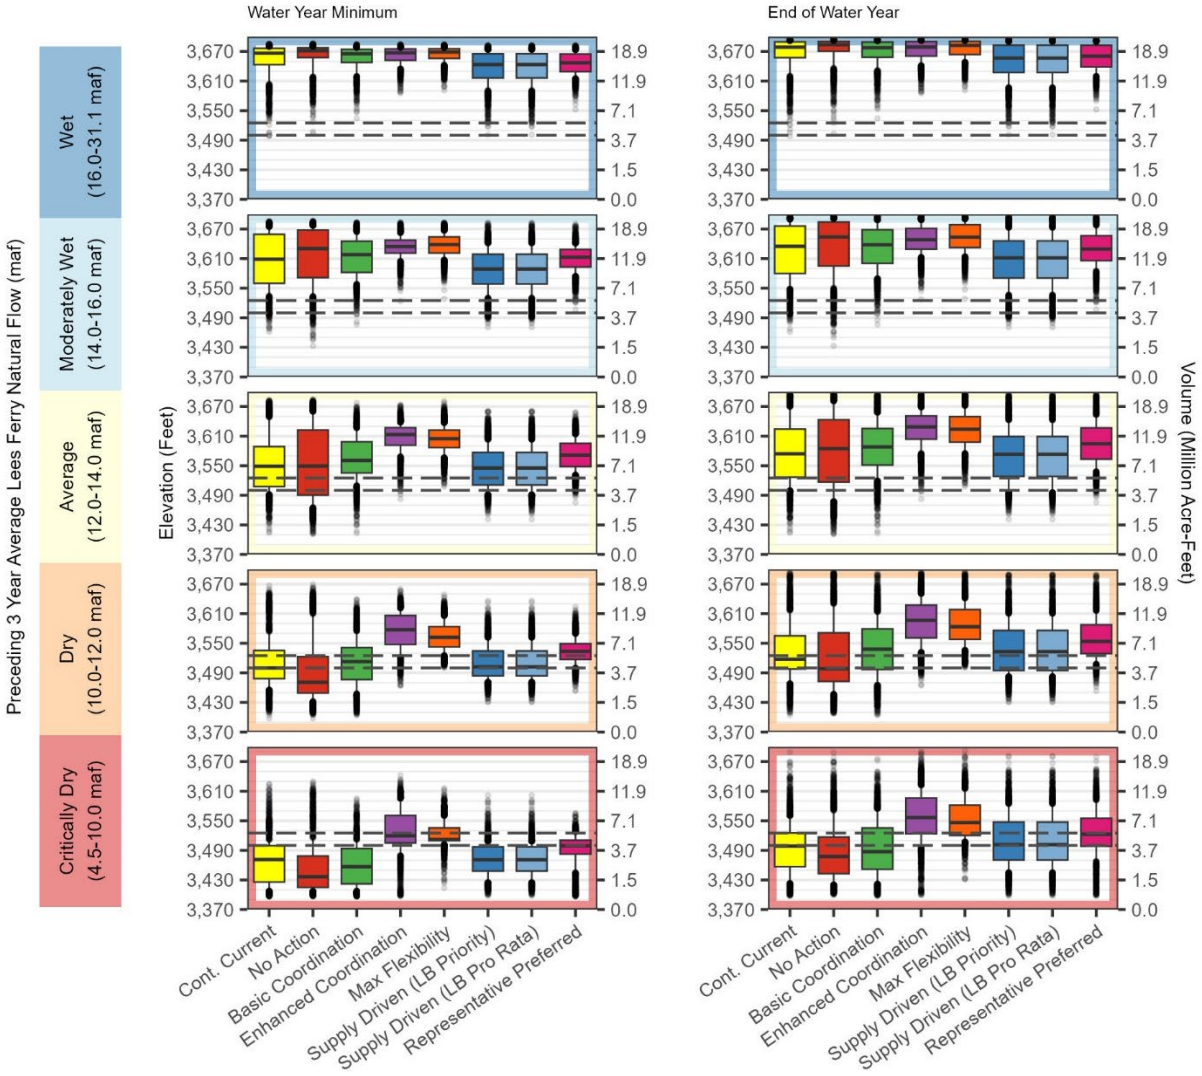
Refer to **Table TA 3-2** in **TA 3** for a list of critical elevations at Lake Powell. A statistical breakdown of CRSS modeling results for end of water year (EOWY) elevations and minimum WY elevations at Lake Powell can be found in **Table TA 3-3** and **Table TA 3-4** in **TA 3**, respectively.

Figure 3-8 below looks at the response of Lake Powell WY minimum elevations and storage volumes, and EOWY elevations and storage volumes, to different hydrologic conditions under different alternatives by looking at the preceding 3-year average of Lees Ferry natural flow. The figure visualizes the same data that is included in **Table TA 3-3** and **Table TA 3-4** in two side by side conditional box plot panels.

At Lake Powell, the critical elevations of 3,500 feet and 3,525 feet, shown as dashed lines, frame the analysis. These elevations are important because they provide a 10-foot and a 35-foot buffer above 3,490 feet—the elevation below which water can only be released through the river outlet works. Operating below 3,490 feet limits the volume of water that can be released, since water can only pass through the river outlet works. As described in **Section 1.8.4.1**, there are infrastructure concerns associated with the uncertainty of extended operations through the river outlet works as the sole means of sustained water releases from Glen Canyon Dam that could compromise the reliability and operational flexibility of Glen Canyon Dam and affect the ability to meet critical downstream water supply needs. There are additional impacts to hydropower associated with operating below 3,490 feet as this is minimum power pool.

Under the Average Flow Category, all alternatives keep median EOWY elevations well above these thresholds. As conditions dry, the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform best, maintaining median EOWY elevations of 3,557 and 3,546 feet respectively even under the Critically Dry Flow Category, while the No Action Alternative (3,478 feet) and Basic Coordination Alternative (3,487 feet) drop below the 3,500-foot threshold.

Figure 3-8
WY Minimum and EOWY Elevations and Storage Volumes of Lake Powell



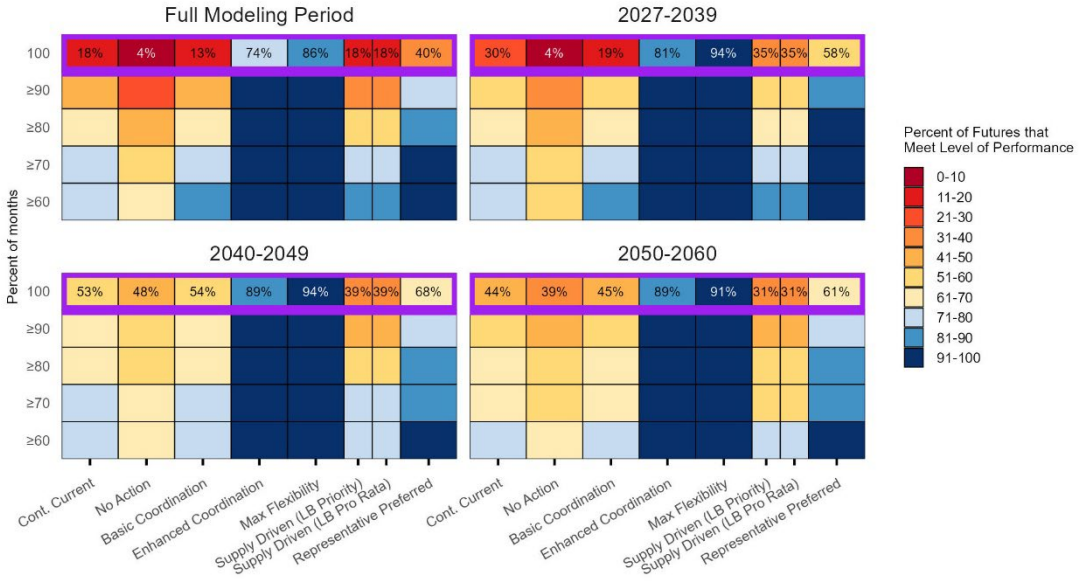


Figure 3-9 compares alternatives with respect to keeping Lake Powell above an elevation of 3,500 feet. As described above, this elevation is important because it provides a 10-foot buffer to protect critical infrastructure, water supply, and hydropower, which are critically impacted at an elevation of 3,490 feet. Over the full 34-year modeling period, the Maximum Operational Flexibility Alternative keeps Lake Powell above 3,500 feet in 100 percent of months in 86 percent of futures, and the Enhanced Coordination Alternative does so in 74 percent of futures. The Representative Preferred Alternative achieves this in 40 percent of futures overall and 58 percent in the critical first decade (2027–2039), ranking third among alternatives. The No Action Alternative is least robust at just 4 percent of futures.

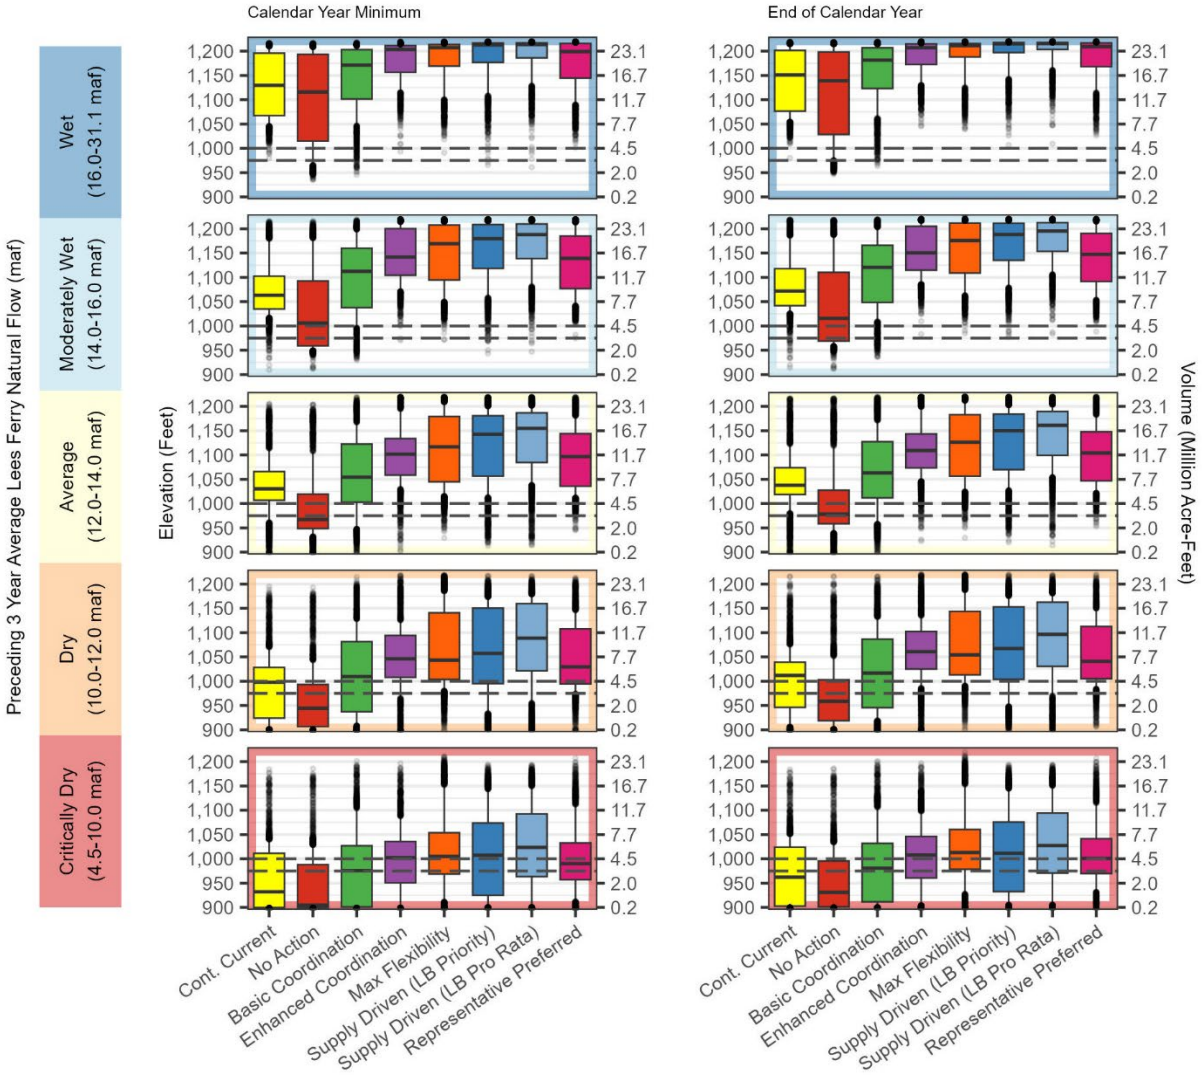
Figure 3-9
Lake Powell 3,500 Feet: Robustness.
Percent of futures in which Lake Powell elevation stays above 3,500 feet in the percent of months specified by each row

Lake Mead Reservoir Elevations



Refer to **Table TA 3-5** in **TA 3**, Hydrologic Resources, for a list of critical elevations at Lake Mead. A statistical breakdown of CRSS modeling results for end of calendar year (EOCY) elevations and minimum CY elevations at Lake Mead can be found in **Table TA 3-6** and **Table TA 3-7** in **TA 3**, Hydrologic Resources, respectively.

Figure 3-10 below looks at the response of Lake Mead CY minimum elevations, and EOCY elevations and storage volumes to different hydrologic conditions under different alternatives by looking at the preceding three-year average of Lees Ferry natural flow. The figure visualizes the same data that is included in **Table TA 3-6** and **Table TA 3-7** in two side by side conditional box plot panels. In each flow category shown in the box plots, the key elevations of 1,000 feet and 975 feet are identified with dashed lines. These elevations are important because they provide a 50-foot and a 25-foot buffer from 950 feet—the elevation below which water can only be released through the intake towers, constraining both the volume of water able to be released as well as the ability to generate power. Lake Mead requires larger buffers above the hydropower and critical infrastructure elevations than Lake Powell because Reclamation is required to deliver water orders that have already been approved. As a result, there is generally less flexibility to adjust releases from Hoover Dam than from Glen Canyon Dam.

Under the Average Flow Category, the No Action Alternative already performs poorly, with a median EOCY elevation of just 978 feet, which is between the two critical thresholds, while all action alternatives maintain medians above 1,000 feet. Under the Critically Dry Flow Category, the No Action Alternative and CCS Comparative Baseline fall to medians of 931 and 962 feet respectively, well below both thresholds, while the Enhanced Coordination, Maximum Operational Flexibility, and Supply

Driven (both LB Priority and LB Pro Rata approaches) Alternatives maintain medians above 1,000 feet. The Representative Preferred Alternative achieves a median EOCY elevation of 1,041 feet under the Dry Flow Category and 1,001 feet under the Critically Dry Flow Category, remaining above 975 feet in close to 75 percent of Critically Dry Flow Category years.

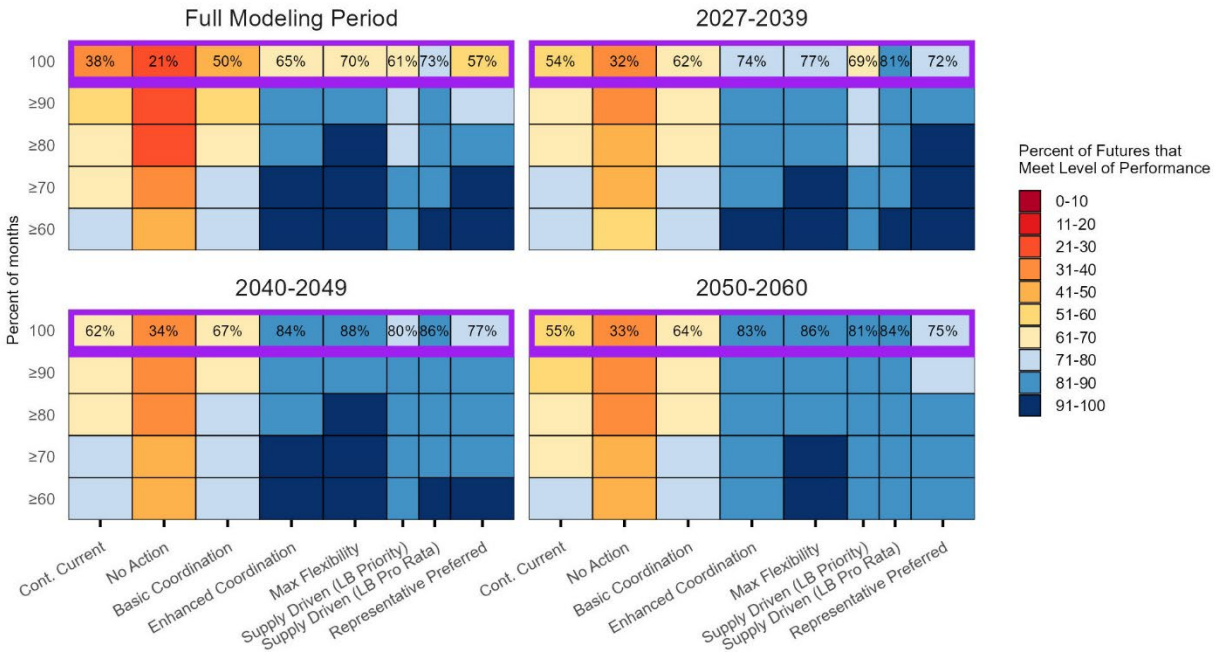


Figure 3-10
CY Minimum and EOCY Elevations and Storage Volumes of Lake Mead

The CY minimum elevations panel follows the same pattern as the EOCY elevations panel, but some median elevations are slightly lower.

Figure 3-11 compares alternatives with respect to keeping Lake Mead above elevation 975 feet in 100 percent of months. This critical threshold is important because it provides a 25-foot buffer to protect critical infrastructure and hydropower, which can no longer be produced at elevation 950 feet.

Figure 3-11
Lake Mead 975 Feet: Robustness.
Percent of futures in which Lake Mead elevation stays above 975 feet in the percent of months specified by each row

For the 975-foot robustness metric over the Full Modeling Period, the Maximum Operational Flexibility and Supply Driven (LB Pro Rata approach) Alternatives lead, meeting the preferred minimum performance in 70 percent and 73 percent of futures respectively, the Representative Preferred Alternative achieves the preferred minimum performance in 57 percent of futures over the Full Modeling Period (72 percent in the first decade), and the No Action Alternative performs worst meeting the preferred minimum performance in only 21 percent of futures.

Lake Mohave and Lake Havasu Elevations

Lake Mohave and Lake Havasu are operated under existing rule curves that determine specific target elevations at the end of each month. The existing rule curves were used in CRSS and applied to operations for all alternatives and the CCS Comparative Baseline. As such, water surface elevations at Lake Mohave and Lake Havasu are not affected.

Conservation Activity

Conservation activity modestly improves reservoir elevations for most action alternatives. For the Representative Preferred Alternative, enabling conservation raises median Lake Powell EOWY elevations by approximately 1.2 feet under the Dry Flow Category and 0.8 feet under the Critically Dry Flow Category. The effect is more pronounced at Lake Mead, where conservation raises the median EOCY elevation by 11.8 feet under the Dry Flow Category and 5.6 feet under the Critically Dry Flow Category.

Issue 2: System Storage

System storage is anticipated to be affected by the various alternatives as the result of changes to operational activities. The impacts on various combinations of system storage are summarized below. Refer to **Section TA 3.2.2**, Issue 2: System Storage, in **TA 3**, Hydrologic Resources, for details regarding impacts.

Combined system storage is evaluated across three reservoir groupings, each providing a different perspective on overall system conditions. Across all three groupings, storage declines with drying hydrology and the ranking of alternatives is generally consistent, with the Maximum Operational Flexibility and Enhanced Coordination Alternatives consistently producing the highest combined storage and the No Action Alternative producing the lowest.

Combined System Storage at Lake Powell and Lake Mead

Analysis of the combined storage across Lake Powell and Lake Mead helps to understand the overall condition of the Colorado River system. Based on this analysis, the primary drivers of Colorado River system conditions are related to assumptions for shortage operations and conservation activities. Refer to **Table TA 3-11** in **TA 3**, Hydrologic Resources, for a statistical breakdown of CRSS modeling results for EOWY combined system storage at Lake Powell and Lake Mead as a percentage of the total storage capacity. Refer to **Figure TA 3-18** in **TA 3** for the box plot representation of the combined system storage of Lake Powell and Lake Mead.

The combined live storage capacity of Lake Powell and Lake Mead is 49.43 maf. Under the Average Flow Category, the Maximum Operational Flexibility and Enhanced Coordination Alternatives maintain median combined storage above 50 percent of total capacity, while the No Action Alternative has the lowest median storage (27 percent) with nearly half of modeled years falling below the September 2022 historic low of 26.55 percent full.

Under the Critically Dry Flow Category, the Enhanced Coordination and Maximum Operational Flexibility Alternatives have median combined storages near the lowest observed EOWY storage reference of 26.55 percent, while under the CCS Comparative Baseline and No Action and Basic Coordination Alternatives, more than 75 percent of modeled years are below the 2022 historic low.

The Representative Preferred Alternative ranks fifth among alternatives, maintaining a median combined storage of 32 percent under the Dry Flow Category and 21 percent under the Critically Dry Flow Category, with roughly 75 percent of years in the Critically Dry Flow Category falling below the 2022 historic low.

Combined System Storage at CRSP Reservoirs

Analysis of the combined storage across CRSP reservoirs helps to understand the overall status of Lake Powell and the CRSP Upper Initial Units (Flaming Gorge, Navajo, and Blue Mesa reservoirs). Lake Powell makes up approximately 80 percent of the total CRSP storage capacity, so trends in combined storage capacity are primarily controlled by Lake Powell operations. The CRSP Upper Initial Unit reservoirs can be operated (within their RODs) so that releases help bolster elevations in Lake Powell and protect Glen Canyon Dam infrastructure. Refer to **Table TA 3-12** in **TA 3** for a statistical breakdown of CRSS modeling results for EOWY combined system storage at CRSP reservoirs as a percentage of the total storage capacity. Refer to **Figure TA 3-19** in **TA 3** for the box plot representation of the combined system storage at CRSP reservoirs.

Because the Upper Initial Unit reservoirs vary minimally across alternatives, CRSP median combined storage trends closely mirror Lake Powell elevation performance described in **Issue 1**. Under the Average Flow Category, the Enhanced Coordination and Maximum Operational Flexibility Alternatives lead with median combined storage of 63 and 62 percent of capacity respectively, while other alternatives cluster near 50 percent. Under the Critically Dry Flow Category, the Enhanced Coordination and Maximum Operational Flexibility Alternatives maintain the highest median combined storage at 41 and 38 percent respectively, while remaining alternatives fall to 21-26 percent.

The Representative Preferred Alternative ranks third overall with a median combined storage of 37 percent under the Dry Flow Category and 27 percent under the Critically Dry Flow Category.

Combined System Storage at Seven Reservoirs

Analysis of the seven-reservoir system storage (CRSP Upper Initial Units of Flaming Gorge, Navajo, and Blue Mesa Reservoirs, as well as Lake Powell, Lake Mead, Lake Mohave, and Lake Havasu) volumes over time can be used to better understand overall system conditions. Refer to **Table TA 3-13** in **TA 3** for a statistical breakdown of CRSS modeling results for EOWY combined system storage of the seven reservoirs as a percentage of the total storage capacity. Refer to **Figure TA 3-20** in **TA-3** for the box plot representation of the combined system storage of the seven reservoirs.

Under the Average Flow Category, the Maximum Operational Flexibility Alternative has the highest median combined storage (60 percent), followed by the Enhanced Coordination Alternative at 59 percent, while the No Action Alternative (35 percent) and the CCS Comparative Baseline (38 percent) have the lowest median combined storages.

The Representative Preferred Alternative achieves median combined storage of 37 percent under the Dry Flow Category and 27 percent under the Critically Dry Flow Category, ranking fifth among all alternatives which is consistent with its ranking in the Powell-Mead and CRSP groupings.

Issue 3: Reservoir Releases

Releases from reservoirs are anticipated to be affected by the various alternatives as the result of changes to operational activities. The impacts on reservoir releases are summarized below. Refer to **Section TA 3.2.3**, Issue 3: Reservoir Releases, **TA 3**, Hydrologic Resources, for details regarding impacts on reservoir releases.

Glen Canyon Dam (Lake Powell) Releases

Generally, alternatives that prioritize higher elevations in Lake Powell result in lower median annual releases from Glen Canyon Dam. This trend demonstrates the tradeoffs between maintaining reservoir elevations to protect critical infrastructure and annual releases from reservoirs. Refer to **Table TA 3-14** in **TA 3** for a statistical breakdown of CRSS modeling results for EOWY releases from Glen Canyon Dam. Refer to **Figure TA 3-21** in **TA 3** for the box plot representation of the EOWY releases from Glen Canyon Dam. In addition to annual releases, 10-year releases from Glen Canyon Dam are also considered. Refer to **Table TA 3-15** and **Figure TA 3-22** in **TA 3** for modeled results for the 10-year Glen Canyon Dam releases.

Under the Average Flow Category, median annual releases cluster near 8.23 maf for most alternatives. Under the Critically Dry Flow Category, releases diverge significantly: the No Action Alternative and

CCS Baseline release the most (6.36 and 6.41 maf respectively) partly due to infrastructure-constrained variability below 3,490 feet, while the Enhanced Coordination Alternative releases the least (5.11 maf).

The Representative Preferred Alternative has a median annual release of 7.20 maf under the Dry Flow Category and 6.0 maf under the Critically Dry Flow Category and has the least variability in Glen Canyon Dam releases under Critically Dry conditions.

At the Lee Ferry Compact Point median 10-year cumulative flows are highest under the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) (84.6 maf), followed by the No Action Alternative (83.6 maf) and the CCS Comparative Baseline (83.3 maf), with the Enhanced Coordination Alternative having the lowest cumulative flows (81.3 maf).

The Representative Preferred Alternative achieves a median 10-year flow of 76.4 maf under the Dry Flow Category, exceeding the 75.0 maf threshold in over 50 percent of Dry Flow Category years, but surpassing the 82.5 maf threshold in fewer than 25 percent of Dry Flow Category years.

Hoover Dam (Lake Mead) Releases

Generally, alternatives with higher Lake Mead elevations correspond to lower releases from Hoover Dam, especially in the Average Flow Category (12.0–14.0 maf). However, the range of interquartile variability for releases from Hoover Dam is wide, especially in the Wet Flow Category (16.0–31.11 maf) and the Critically Dry Flow Category (4.46–10.0 maf), indicating more variability in releases as flow conditions get more extreme (in both directions). Refer to **Table TA 3-17** in **TA 3** for a statistical breakdown of CRSS modeling results for EOCY releases from Hoover Dam. Refer to **Figure TA 3-24** in **TA 3** for the box plot representation of the EOCY releases from Hoover Dam.

Under the Average Flow Category, the No Action Alternative releases the most from Hoover Dam (median of 8.63 maf), while Enhanced Coordination releases the least (7.58 maf). In the Critically Dry Flow Category, the Enhanced Coordination and Maximum Operational Flexibility Alternatives have the lowest median releases (6.48 and 6.40 maf respectively). All alternatives except the Enhanced Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives have more variability under Critically Dry than Average conditions.

The Representative Preferred Alternative falls near the middle across all flow categories, with Hoover Dam median releases of 7.61 maf under the Dry Flow Category and 6.94 maf under the Critically Dry Flow Category and average variability compared to other alternatives.

Davis Dam (Lake Mohave), Parker Dam (Lake Havasu) Releases, and Morelos Diversion Dam

Releases from Davis Dam and Parker Dam are based on target elevations defined by the existing rule curves. Inflows into Lake Mohave vary across alternatives, so releases from Davis Dam and Parker Dam subsequently vary across alternatives to maintain target elevation ranges. These releases follow similar trends to Hoover Dam releases

Issue 4: River Flows

River flows throughout the seven analyzed reaches of the Colorado River, from Glen Canyon Dam to the SIB, largely reflect upstream reservoir releases, with tributary contributions and return flows accounting for only a small fraction of total flow. All alternatives show declining median flows with

drier hydrology across all reaches. Refer to **Section TA 3.2.4**, Issue 4: River Flows, in **TA 3**, Hydrologic Resources, for details regarding impacts on river flows within specific reaches of the Colorado River.

Downstream of Glen Canyon Dam

Reach 1 of the river extends 292 miles from Glen Canyon Dam, through GCNP, to Lake Mead. Flows in this reach are dominated by releases from Lake Powell plus smaller inflows from the Paria and Little Colorado rivers (3 percent of total flow).

Annual flow patterns in this reach generally follow the Glen Canyon Dam release patterns summarized in Issue 3. Tributary inflows are modeled identically across all alternatives. The Representative Preferred Alternative produces median Water Year releases of 8.23 maf under the Average Flow Category, consistent with the No Action and the Basic Coordination Alternatives, and the CCS Comparative Baseline, and 6.0 maf under the Critically Dry Flow Category; it is the least variable of any alternative under the driest conditions.

Downstream of Hoover Dam to Imperial Dam (Reaches 2–5)

Reaches 2 through 5 are primarily influenced by releases from Hoover, Davis, and Parker Dams, with additional localized effects from one major tributary (Bill Williams River), diversions, and return flows.

Flows through these reaches are driven almost entirely by upstream dam releases, declining progressively with drying hydrology across all alternatives. The Enhanced Coordination Alternative consistently produces the lowest median flows while the No Action and Basic Coordination Alternatives produce the highest flows under dry conditions. The Representative Preferred Alternative performs near the middle of all alternatives throughout these reaches, with median annual flows of 7.89 maf below Hoover Dam, 7.8 maf below Davis Dam, 6.2 maf below Parker Dam, and 5.3 maf at Imperial Dam under the Dry Flow Category, declining to 6.94, 6.9, 5.9, and 5.0 maf respectively under the Critically Dry Flow Category.

Downstream of Imperial Dam (Reaches 6–7)

Below Imperial Dam, flows are primarily driven by delivery requirements and remain relatively stable across alternatives, ranging from 0.8 to 1.1 maf median under most flow categories. Below the Morelos Diversion Dam in the limitrophe, flows are infrequent across all alternatives, occurring in fewer than 10 percent of years under the Average, Dry, and Critically Dry Flow Categories. The Representative Preferred Alternative produces median flows of approximately 0.9 maf below Imperial Dam across both the Dry and Critically Dry Flow Categories, which is on the low end compared to other alternatives, and sees flows in the limitrophe in greater than 25 percent of years only under the Wet Flow Category.

Issue 5: Groundwater

Groundwater elevations adjacent to reservoirs and within specific reaches along the Colorado River may be affected by the various alternatives, depending on the hydraulic connectivity and geotechnical characteristics of the area. In reaches of the Colorado River that have a direct connection to groundwater, changes in river flows and changes in reservoir elevations are anticipated to affect groundwater elevations. The reaches that are anticipated to have impacts on groundwater as the result of changes to operational activities are summarized below. Refer to **Section TA 3.2.5**, Issue 5:

Groundwater, in **TA 3**, Hydrologic Resources, for details regarding impacts on groundwater within specific reaches of the Colorado River.

Reaches Anticipated to Have Impacts

Adjacent to Lake Powell, groundwater elevations are expected to track reservoir pool elevations. The Representative Preferred is third most robust at maintaining Lake Powell elevations above critical thresholds yielding adjacent groundwater elevations lower than the Enhanced Coordination and Maximum Operational Flexibility Alternative and comparable to the CCS Comparative Baseline and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches). The No Action Alternative is least robust at maintaining Lake Powell elevations and is therefore expected to result in the lowest adjacent groundwater elevations.

Reaches 3 through 5 of the Colorado River are made up of alluvial fill groundwater basins and impacts on groundwater elevations mirror trends seen for river flows in Issue 4, where higher flows result in higher groundwater elevations. Under the Dry and Critically Dry Flow Categories, the Basic Coordination Alternative produces the highest flows in these reaches and is therefore expected to yield the highest groundwater elevations. The Representative Preferred Alternative falls near the middle of all alternatives and is likely to result in groundwater elevations that are higher than the Enhanced Coordination and Supply Driven Alternative (LB Pro Rata approach) but lower than the Basic Coordination, and Supply Driven (LB Priority approach) Alternatives, and the CCS Comparative Baseline in the Critically Dry Flow Category. The Enhanced Coordination Alternative is anticipated to result in the lowest groundwater elevations in these reaches due to its consistently lower river flows.

The downstream portion of Reach 7 is considered a losing reach where the river recharges groundwater. Groundwater elevations are likely to continue to decline under dry conditions.

Reaches Not Anticipated to Have Impacts

Reaches of the Colorado River that contain bedrock, that consist of lined canals, or which otherwise have limited hydraulic connectivity to groundwater are not anticipated to have impacts on groundwater associated with changes to operational activities. These portions of the analysis area include the Grand Canyon, Lake Mead, Reach 2 within the Black Canyon, and Reach 6 which diverts Colorado River water into lined canals. Likewise, reservoirs that maintain the same water surface elevation regardless of alternative are not anticipated to affect groundwater levels. These reservoirs include Lake Mohave and Lake Havasu, which will continue to be operated under their existing release rule curves, which keeps reservoir elevations within a tight range. The upstream portion of Reach 7 has high groundwater elevations from nearby irrigated fields, and the alternatives are not anticipated to impact groundwater elevations in this reach.

Summary Comparison of Alternatives

Beginning with reservoir elevations, performance differences among alternatives increase under drier conditions. The Representative Preferred Alternative meets the preferred minimum performance in 40 to 50 percent of futures over the Full Modeling Period and 52 to 58 percent in the first decade for Lake Powell, and 57 to 63 percent of futures over the Full Modeling Period and 62 to 72 percent in the first decade for Lake Mead. Absent additional action, the Representative Preferred Alternative is reasonably likely to be vulnerable to elevations below key thresholds within the next 10 years.

System storage declines under drier conditions across all alternatives and reservoir groupings, with the Enhanced Coordination and Maximum Operational Flexibility Alternatives generally maintaining the highest median storage. Under the Representative Preferred Alternative, median combined storage in the Dry Flow Category is 32 percent for Powell-Mead, 37 percent for CRSP, and 37 percent for the seven-reservoir system, declining to 21, 27, and 27 percent respectively in the Critically Dry Flow Category. More than 25 percent of Dry Flow Category years and nearly 75 percent of Critically Dry Flow Category years fall below the lowest observed historical Powell-Mead combined storage.

Alternatives that prioritize higher reservoir elevations generally release less water, demonstrating the operational tradeoff between maintaining reservoir elevations to protect critical infrastructure and annual releases from reservoirs. Releases generally decrease under drier conditions, with greater variability for most alternatives. Under the Representative Preferred Alternative, median Glen Canyon Dam releases decline from 7.20 maf in the Dry Flow Category to 6.0 maf in the Critically Dry Flow Category, remaining the least variable among alternatives under the Critically Dry Flow Category. At the Lee Ferry Compact Point, median 10-year volumes are 76.4 maf under the Dry Flow Category and 73.9 maf under the Critically Dry Flow Category. Releases under the Representative Preferred Alternative from Hoover, Davis, and Parker Dams are generally in the middle range of alternatives, decreasing as conditions dry.

For most reaches of the Colorado River, flows mostly comprise releases from upstream reservoirs and overall trends for river flows mirror those seen for reservoir releases. Inflows from perennial tributaries are minor and do not change between alternatives. River flows generally decrease with drying hydrology across all reaches and alternatives. Under the Representative Preferred Alternative, annual flow volumes are generally in the middle of the range of alternatives below Hoover and Davis Dams, and similar to most alternatives below Parker Dam. At Imperial Dam, median annual flow is 5.3 maf in the Dry Flow Category and 5.0 maf in the Critically Dry Flow Category. Below Imperial Dam, median annual flow is 0.9 maf in both categories, on the low end of all alternatives. Flows below Morelos Diversion Dam are infrequent across all alternatives in the Average, Dry, and Critically Dry Flow Categories.

Groundwater effects are qualitative, complex, and most likely near Lake Powell and in alluvial river reaches with hydraulic connectivity. Under the Representative Preferred Alternative, groundwater elevations near Lake Powell are anticipated to be lower than under the Maximum Operational Flexibility and Enhanced Coordination Alternatives but higher than under the CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata) Alternatives. Across river reaches, the Representative Preferred Alternative is generally not identified as producing either the highest or lowest anticipated groundwater elevations where flow-related effects are possible.

3.4 Water Deliveries

3.4.1 Affected Environment

Water from the Colorado River is delivered to entities in the Lower Division States and Mexico for domestic and agricultural use, in accordance with the Law of the River. Colorado River water is also used to serve many purposes in the Upper Basin. The geographic scope of this EIS does not extend

above Lake Powell and accordingly does not include an analysis of the impact on Upper Basin water users. With respect to Upper Basin conservation, the nexus to the proposed federal action is the storage and delivery of that conserved water in Lake Powell. The effects of this storage in and delivery from Lake Powell are within the scope of the EIS (see **Section 3.3**, Hydrologic Resources, and **TA 3**, Hydrologic Resources), while specific activities that may be undertaken in the Upper Basin to generate the conserved water are not within the scope of this EIS. Any such activities are unknown at this time and will not necessarily require federal decision making. Any federal decisions associated with these conservation activities will be assessed outside of this EIS.

Legal and Policy Framework

The Law of the River is an umbrella term for the collection of laws, compacts, decrees, court decisions, contracts, and regulatory guidelines that govern management and operation of the Colorado River. Notable documents that define the Law of the River are identified and further explained in **TA-4**, Water Deliveries.

Apportionments

The Colorado River Compact apportions 7.5 million acre-feet (maf) of water per year to the Upper Colorado River Basin (Upper Basin), and 7.5 maf to the Lower Basin with division of the two basins occurring at Lee Ferry, Arizona. Water is distributed among the Upper Division States by the 1948 Upper Colorado River Basin Compact as a percentage of the total amount available for consumptive use each year after the deduction of Arizona's 50 thousand acre-feet (kaf) apportionment of Upper Basin water. The water is distributed among Colorado (51.75 percent), Utah (23 percent), Wyoming (14 percent), and New Mexico (11.25 percent). The Upper Division State apportionments have not yet been fully developed. Water apportionments to the Lower Division States total 7.5 maf for consumptive use, subject to annual increases or reductions pursuant to Secretarial determinations of a Surplus or a Shortage condition. Lower Division State apportionments are set by the BCPA as follows: California (4.4 maf), Arizona (2.8 maf), and Nevada (0.3 maf). See **Section 1.8** for a description of historical water use across the Upper and Lower Basins.

Rights to use Colorado River water within the Lower Division States, known as entitlements, are established in accordance with the BCPA and the Consolidated Decree. All of the water apportioned to the Lower Division States is allocated in accordance with these documents. For users in the Lower Division States, entitlements arise through (i) a decreed right, (ii) a Section 5 water delivery contract, or (iii) a Secretarial reservation. According to Section 5 of the BCPA, the Secretary is authorized as the contracting authority for the Lower Colorado River, and any user of Colorado River water in the Lower Basin is required to have a contract with the Secretary acting through the Bureau of Reclamation. The Consolidated Decree lists and quantifies all PPRs in the Lower Division States. PPRs are the highest priority Lower Basin mainstream Colorado River water entitlements that were perfected before June 25, 1929. The Consolidated Decree also lists federal reserved water rights for five Indian reservations. PPRs are satisfied first in order of priority in years when less than 7.5 maf of water is available from the Colorado River for consumptive use in the Lower Division States before other entitlements are fulfilled.

Storage & Delivery of Conserved and Non-System Water and Treatment of Pre-2027 Intentionally Created Surplus

As outlined in the 2007 Interim Guidelines, Lower Basin entitlement holders can store conserved water in Lake Mead, provided they have an ICS exhibit and an approved ICS creation plan. ICS may only be created in a given year via approved conservation actions and a reduction in consumptive use. Beginning in 2027, guidelines regarding the delivery and creation of ICS will change in accordance with the 2007 ROD and Lower Basin DCP to incorporate additional thresholds and repayment timelines. Additional information is available in **TA-4**, Water Deliveries.

Lower Basin Water Supply Determination

Annually, the Secretary determines the water supply condition for the Lower Division as Normal, Surplus, or Shortage Condition based on Lake Mead's projected elevation on January 1, as modeled by the prior year's August 24-Month Study. The 2007 ROD provides objective criteria used to make annual water supply determinations. The guidance provides supply thresholds under which consumptive use from Lake Mead would be Normal, Surplus, or Shortage Condition, and outlines coordinated reservoir management strategies between Lake Powell and Lake Mead. From 2008 to 2021, Lake Mead operated under Normal/ICS Surplus Conditions, shifting to Shortage Conditions from 2022 through 2025. Further historical information is available in **TA-4**, Water Deliveries.

Mexico's Allotment

Mexico's allotment of Colorado River water is described under Article 10 of the 1944 Water Treaty. The 1944 Water Treaty guarantees that 1.5 maf will be delivered to Mexico annually. Additionally, it outlines Surplus Conditions such that no greater than 1.7 maf shall be delivered to Mexico in a given year, and Extraordinary Drought such that deliveries are reduced in proportion to reductions of U.S. consumptive uses. Minute 242 provides guidance for the geographic locations where deliveries from the U.S. will be made. Minute 323 adjusts how and under what conditions deliveries occur but does not change Mexico's allotment. For further information regarding Mexico's allotment and pertinent policy, refer to **Appendix N**, International Border Region of the Colorado River.

Distribution of Shortages and Reductions to and within the Lower Division States

The 2007 Interim Guidelines, the 2019 DCP and Minute 323 to the 1944 Water Treaty provide for a maximum of 1.375 maf of shortages and reductions (including DCP Contributions and BWSCP savings). Beyond these required activities, Reservoir Protection Conservation implemented through the 2024 ROD resulted in additional Lower Basin conservation from 2023 to 2026. The Reservoir Protection Conservation may vary year to year but is designed to achieve a collective total volume of 3.0 maf. A summary of the 2007 Interim Guidelines Shortages, 2019 DCP contributions, and 2024 ROD conservation is shown in **Table TA-4-6** in **TA-4**, Water Deliveries.

Apportionment is allocated for Arizona, California, and Nevada as outlined in **Tables TA-4-7** through **TA-4-9** in **TA-4**, Water Deliveries.

3.4.2 Environmental Consequences

Methodology

Reclamation uses CRSS for long-term planning studies. CRSS simulates Basin conditions decades into the future (the full analysis period is through 2060) and can be used to account for hydrologic uncertainty. Refer to **Appendix A**, CRSS Model Documentation for more details related to model documentation. For background and guidance related to figures used in the full analysis, see **Section 3.2**, Analysis Methods. Additionally, the SAMs and ADMs were used to analyze potential impacts of the alternatives on individual water users within each Lower Division State under varying levels of shortage. Modeling assumptions for the SAMs and ADMs are summarized in **Appendix C,** Shortage Allocation Model and Alternative Distribution Model Documentation.

Reclamation uses CRSS for long-term planning studies. CRSS simulates Basin conditions decades into the future (the full analysis period is through 2060) and can be used to account for hydrologic uncertainty. Refer to **Appendix A**, CRSS Model Documentation for more details related to model documentation. Additionally, the SAMs and ADMs were used to analyze potential impacts to individual water users within each Lower Division State under varying levels of shortage. Modeling assumptions are summarized in **Appendix C**, and additional details on the DMDU framework and figure interpretation are provided in **Appendix E** and **Section 3.2.6**.

Impact Analysis Area

The geographic scope of the water deliveries analysis is the Colorado River corridor from the upstream limit of full pool elevation of Lake Powell to the downstream limit of the Southerly International Boundary. The geographic scope of this EIS does not extend above Lake Powell and accordingly does not include an analysis of the impact on Upper Basin water users. Although assumptions about Upper Basin conservation are included in various alternatives, no assumptions are made with respect to where conserved water is generated nor about the specific activities that produce it (see **Appendix B** for more information).

Assumptions

CRSS was used to analyze shortage volumes and Lower Basin water deliveries, and the SAMs and ADMs were used to analyze shortage impacts to specific groups of water users. CRSS also includes assumptions regarding Upper Basin conservation activities but does not make assumptions with respect to conservation by different entities or via specific activities. Refer to their respective appendices for more details related to model assumptions and documentation. All action alternatives except for the Basic Coordination Alternative incorporate mechanisms related to the storage and delivery of conserved water in Lake Powell and/or Lake Mead (see **Appendix S**, Additional Description of Alternatives). Unless otherwise specified, impacts reflect modeling assumptions about voluntary conservation behavior.

Impact Indicators

The following indicators were used to assess impacts on water deliveries due to operational activities: magnitude of shortage volumes, distribution of shortages, and depletions among and within the Lower Division States.

Issue 1: Apportionments to the Upper Division States

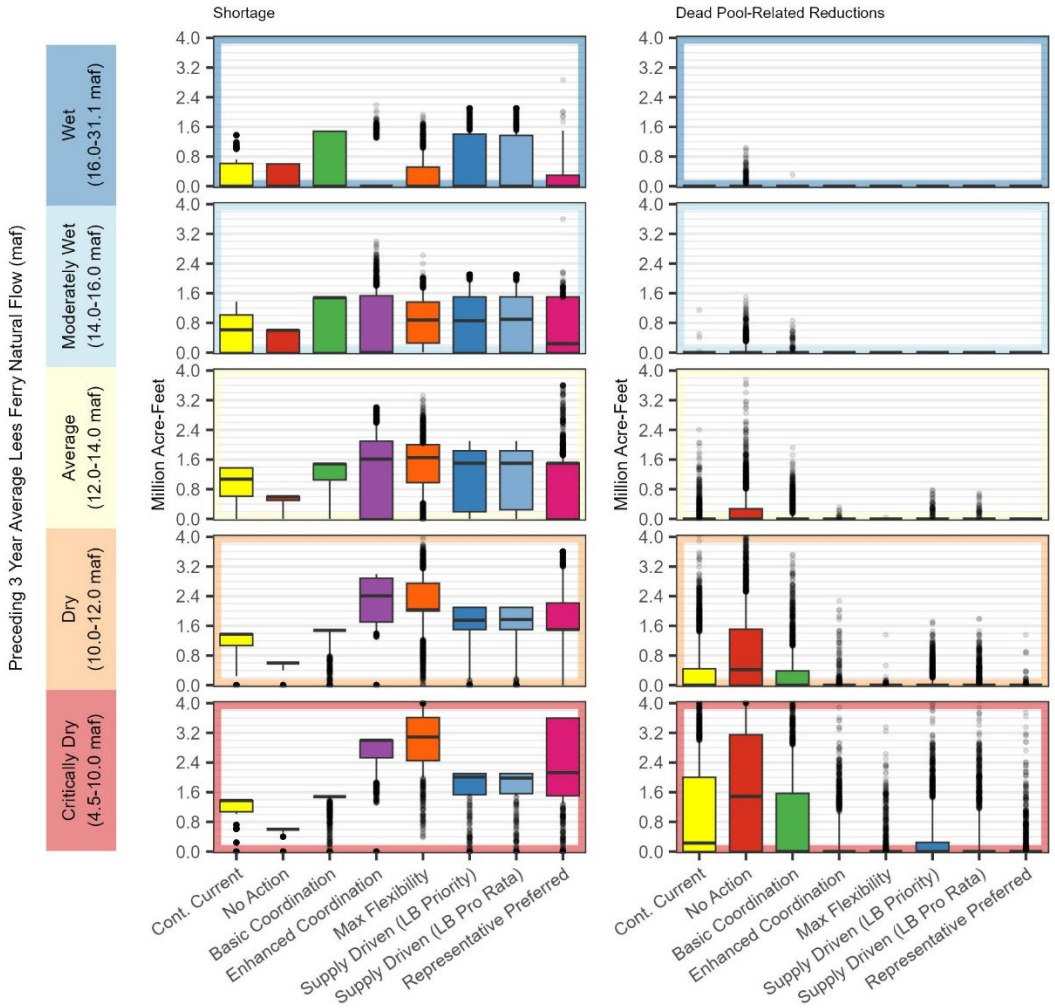
The alternatives would not affect apportionments to the Upper Division States. Therefore, no impact analysis is warranted.

Issue 2: Lower Division States Apportionments and Water Entitlements

The approaches to distributing shortages incorporated in all alternatives are designed to explore a wide range of potential concepts and impacts; they do not reflect an intention by Reclamation to alter apportionments or water entitlements. However, because the concepts would affect a range of users, impacts on deliveries to different entities are analyzed in Issues 3, 5, and 7, and addressed in **Appendix C,** Shortage Allocation Model and Alternative Distribution Model Documentation. Once an alternative is selected, the Department will supplement the analysis if necessary.

Issue 3: Lower Division States Water Supply Determinations and Total Water Deliveries

Issue 3 addresses how operational activities affect water deliveries for the Lower Division States and Mexico. This is analyzed through the following key metrics: shortage versus dead pool–related reductions, conservation modeling assumption effects, shortage, annual depletions, and surplus.



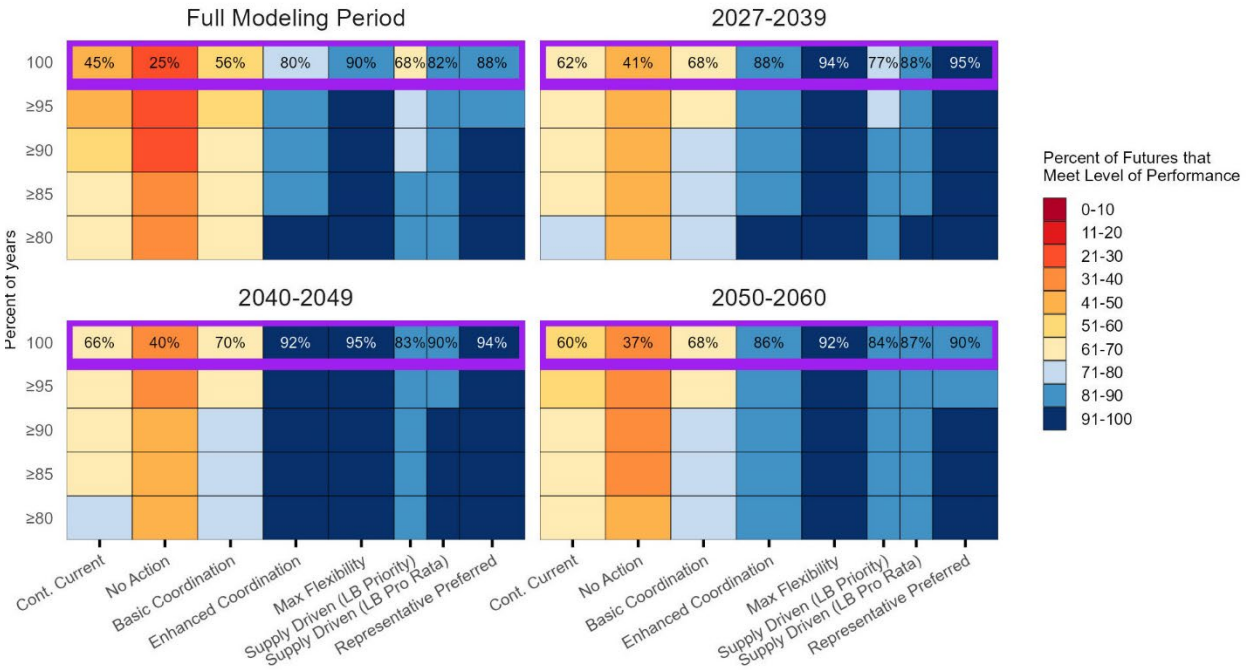
Shortage versus Dead Pool–Related Reductions: Comparison for Full Lower Basin

Shortage refers to delivery reductions at the Basin, state, or individual apportionment level that are defined and distributed as part of an alternative's shortage operations. Volumes and distributions of shortage are described in **Chapter 2**. Dead pool–related reductions occur when there is not enough water in Lake Mead to fully meet downstream demands and/or when Hoover Dam infrastructure constraints result in releases below the demand volume. In some cases, these unplanned reductions occur because Lake Mead is approaching dead pool (elevation 895 feet) and in some cases they occur higher (up to elevation 950 feet).

Annual Lower Basin Reductions

Figure 3-12 compares modeled annual Lower Basin shortages and dead pool-related reductions across alternatives and flow categories, including modeling assumptions for reductions in deliveries to Mexico. Overall, alternatives with lower maximum shortage volumes tend to have more frequent or larger dead pool-related reductions, most notably the No Action Alternative. Under the Average Flow Category, median shortages are 2.1 maf or less. The Maximum Operational Flexibility and Enhanced Coordination Alternatives have the highest median shortages at 1.7 and 1.6 maf, while the CCS Comparative Baseline and No Action Alternative are lower at 1.1 and 0.6 maf. Dead pool-related reductions are generally infrequent for action alternatives under the Average Flow Category, except under the Basic Coordination Alternative, while the No Action Alternative has the most frequent and highest-magnitude reductions. Differences are greatest under the Critically Dry Flow Category, where most action alternatives have higher median shortages but lower dead pool-related reductions than the CCS Comparative Baseline and No Action Alternative. For the Representative Preferred Alternative, the Dry Flow Category shows a median shortage of 1.5 maf, median dead pool-related reductions of 0.0 maf, and dead pool-related reductions only in outlier years. Under the Critically Dry Flow Category, its median shortage is 2.1 maf, median dead pool-related reductions remain 0.0 maf, and 10 percent of years have dead pool-related reductions.

Figure 3-12
Annual Lower Basin Reductions



Note: Shortage and dead pool-related reduction volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Lake Mead Dead Pool-Related Reductions

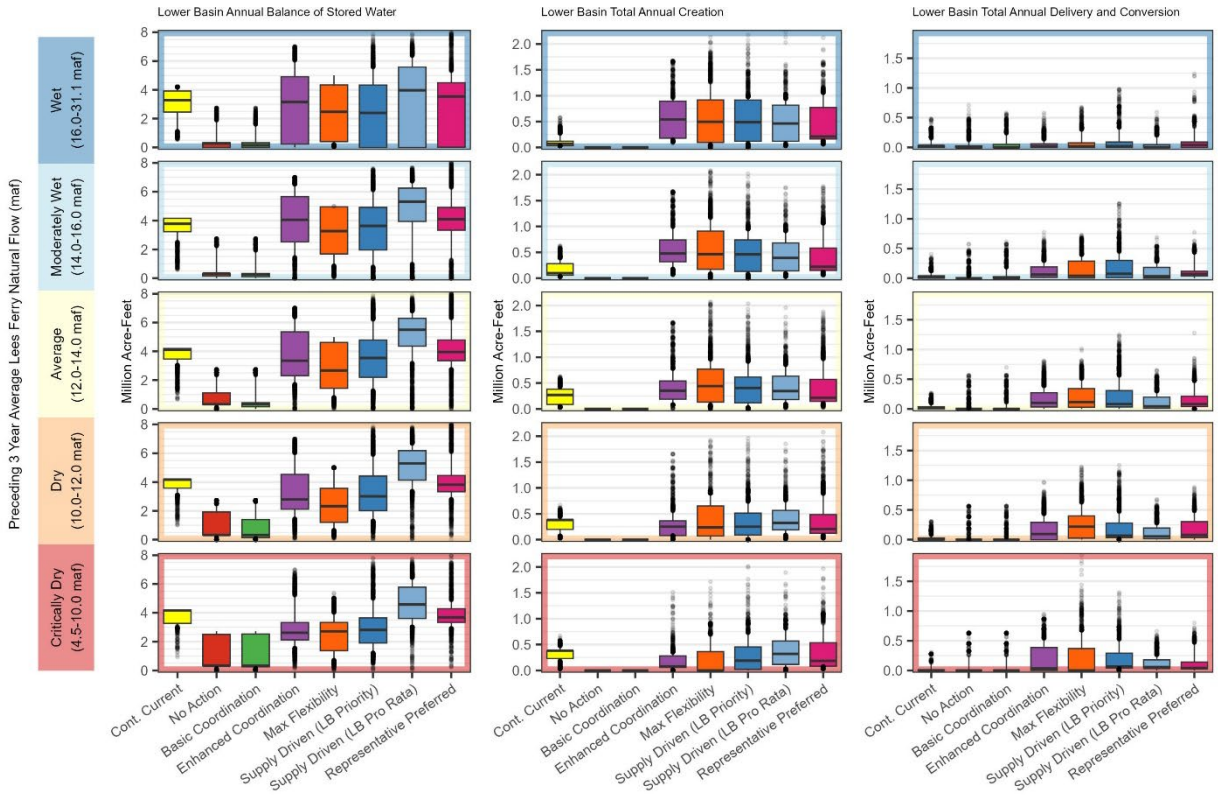
Figure 3-13 compares the robustness of each alternative in avoiding dead pool-related reductions at Lake Mead across the full modeling period and three subperiods. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures that an alternative avoids dead pool-related reductions in 100 percent of years. Over the full modeling period, the Maximum Operational Flexibility Alternative is the most robust, avoiding dead pool-related reductions in 90 percent of futures, followed by the Representative Preferred Alternative at 88 percent, Supply Driven Alternative (LB Pro Rata approach) at 82 percent, and Enhanced Coordination Alternative at 80 percent. These alternatives perform better than the Basic Coordination Alternative,

CCS Comparative Baseline, and No Action Alternative, which avoid dead pool-related reductions in 56, 45, and 25 percent of futures, respectively. For 2027-2039, the Representative Preferred and Maximum Operational Flexibility Alternatives are the most robust, meeting the preferred minimum performance in 95 and 94 percent of futures, respectively. The Representative Preferred Alternative performs among the best alternatives in both the full modeling period and the 2027-2039 period.

Figure 3-13
Lake Mead Dead Pool–Related Reductions: Robustness.
Percent of futures in which dead pool-related reductions are avoided in the percent of years specified by each row

Note: Dead pool-related reduction volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

The Lake Mead dead pool vulnerability analysis shows what flow conditions are likely to cause dead pool-related reductions from Lake Mead in any year. Undesirable performance is based on the highlighted row in **Figure 3-13**, above. The driest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The No Action Alternative is vulnerable at 11.6 maf, which is near the driest observed 10-year average flow of 11.8 maf, while the Basic Coordination Alternative and the CCS Comparative Baseline are vulnerable at 10.4 and 10.9 maf, respectively. Other action alternatives are not likely vulnerable unless flows are much drier than observed conditions. The Representative Preferred Alternative is likely vulnerable at a 10-year average flow of 8.0 maf, a condition not observed and present in fewer than 10 percent of Drying with Variability Ensemble traces. Further information and detailed figures can be found in **Figure TA 4-3** in **TA-4**, Water Deliveries.



Conservation Activity

All action alternatives except for the Basic Coordination Alternative incorporate mechanisms related to the storage and delivery of conserved water in Lake Powell and Lake Mead. **Table TA 4-12** in **TA-4**, Water Deliveries summarizes the various conservation mechanisms for each action alternative.

Lower Basin Conservation Activity

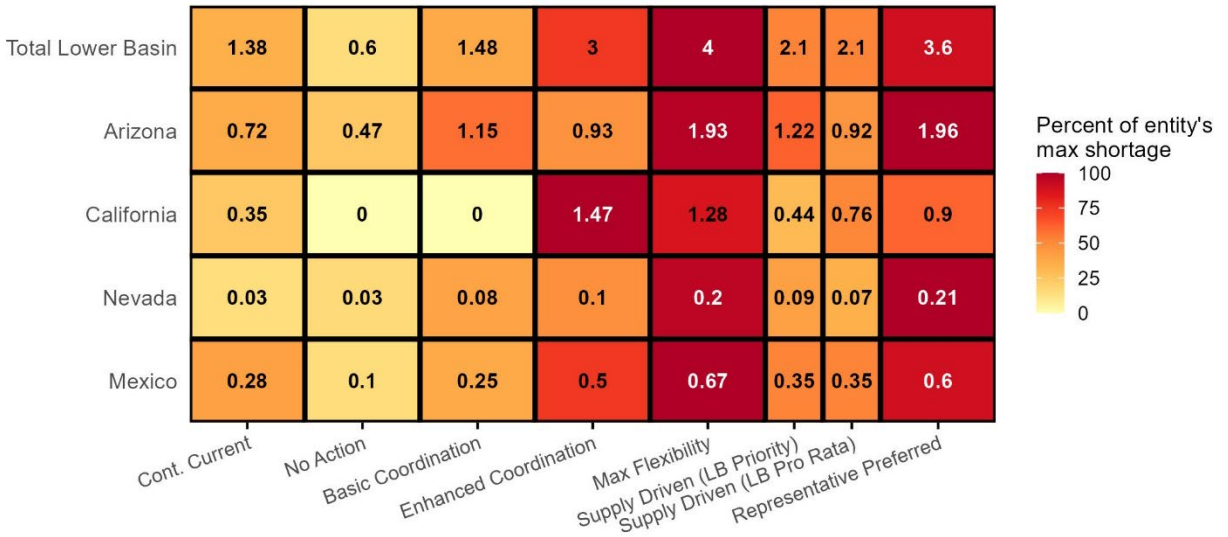
Figure 3-14 shows Lower Basin conservation activity by alternative using conditional boxplots for stored water balance, annual conservation creation, and annual delivery and conversion. Stored water balances generally decline in the Dry and Critically Dry Flow Categories as annual creation decreases. Delivery and conversion volumes increase from the Average Flow Category to the Dry Flow Category, then stay the same or decrease in the Critically Dry Flow Category due to lower available stored water and/or low Lake Mead elevations. The No Action and Basic Coordination Alternatives have small balances because they do not include new conservation mechanisms. For the Representative Preferred Alternative, median stored water balances are 3.8 maf in the Dry Flow Category and 3.7 maf in the Critically Dry Flow Category. Median annual creation is 0.2 maf in both categories, while median delivery and conversion is 0.1 maf in the Dry Flow Category and 0.0 maf in the Critically Dry Flow Category.

Figure 3-14
Annual Lower Basin Conservation Activity

Note: Lower Basin conservation activity includes assumptions related to the storage available to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Effects of Modeling Assumptions for Total Basin Conservation Activity on Lower Basin Shortages and Deliveries

Modeling assumptions for conservation activity do not substantially affect median Lower Basin shortages or depletions, but they can influence variability across flow categories. These assumptions can also affect the frequency or magnitude of Lake Mead dead pool-related reductions, particularly in drier flow categories. Further information and detailed figures can be found in **TA-4**, Water Deliveries.



Shortage

This section compares all the alternatives and the CCS Comparative Baseline with respect to shortages to each of the Lower Division States and Mexico.

Maximum Shortage

Figure 3-15 compares maximum modeled shortages for the total Lower Basin and for each state and Mexico. Because the alternatives have different maximum volumes and also different distributions of shortage, each row has an independent color scale to facilitate identifying the maximum shortage to each entity. For all entities except California, either the Maximum Operational Flexibility Alternative or Representative Preferred Alternative produces the largest maximum shortage. The Enhanced Coordination Alternative produces California's largest maximum shortage due to its pro rata distribution and large total shortage volumes. The No Action Alternative produces the lowest, or tied-lowest, maximum shortage for all entities. Under the Representative Preferred Alternative, actual shortage distributions under specific operating guidelines may differ from the representative approach shown here.

Figure 3-15
Maximum Shortage (maf)

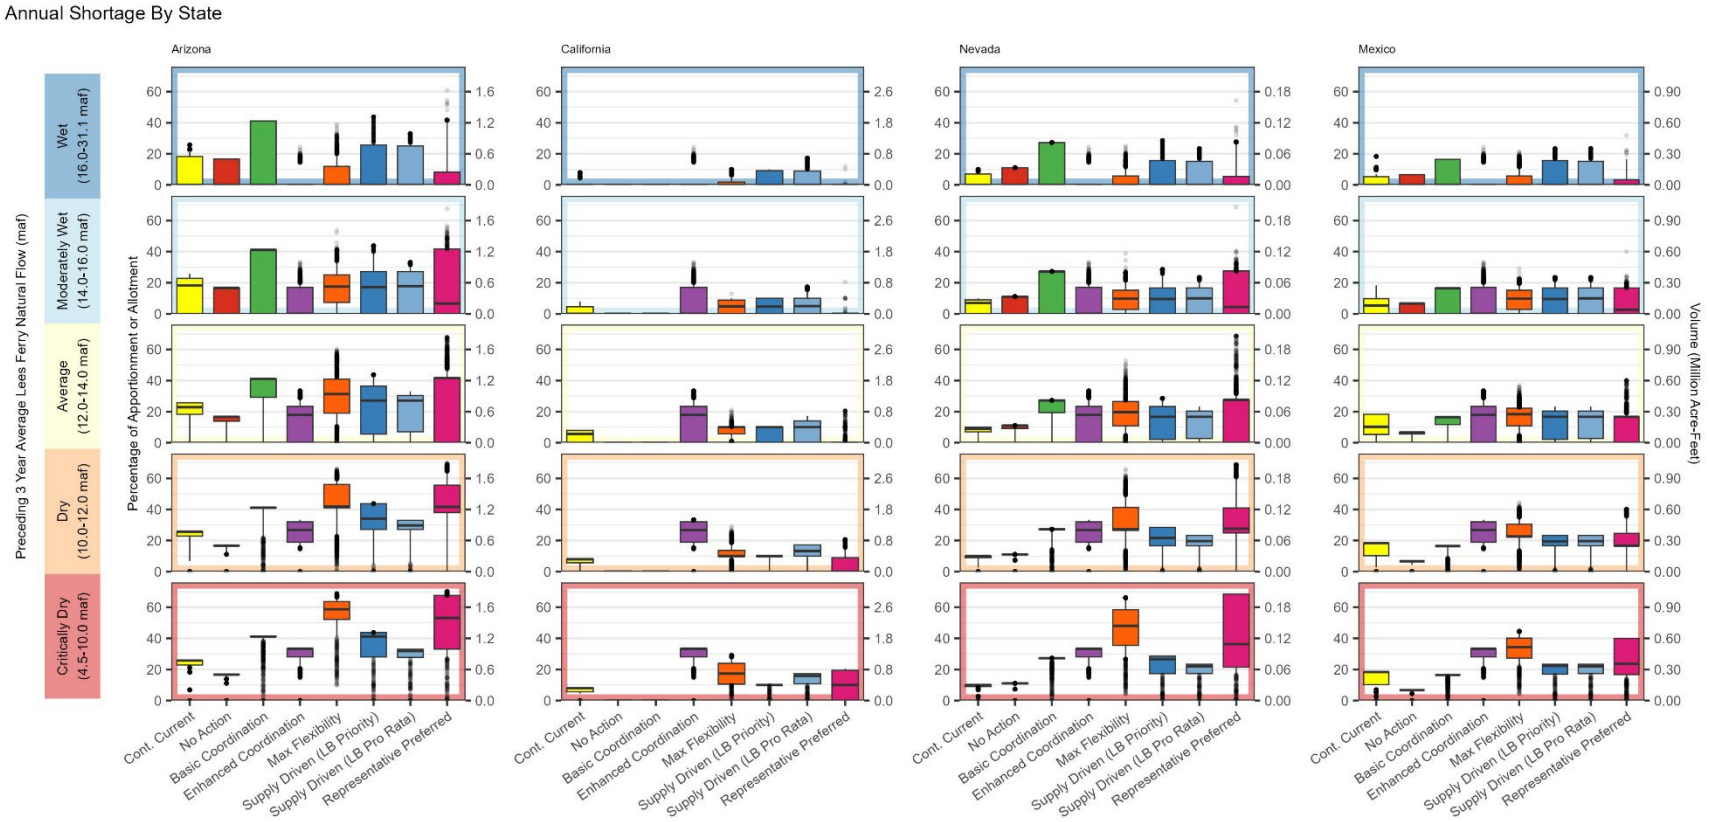
Note: Lower Basin shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Shortage by State

Shortage under different hydrologic conditions categorized by the preceding 3-year average of Lees Ferry natural flow is compared across alternatives in **Figure 3-16**. There is a column for each Lower Division State and Mexico. The vertical axis for each state's column is scaled based on its respective volume of apportionment; the percent apportionment is shown on the left side of each column, and the absolute volume of shortage is shown on the right. A summary by state for Arizona, California, and Nevada follows.

Arizona

In Arizona, all alternatives impose shortages on Priority 4 users. Shortages to more senior users occur only under alternatives that use pro rata-based shortage distribution or when total Lower Basin shortages are large enough to extend beyond Priority 4 users. The Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives affect Priorities 1, 2 and 3 through pro rata-based distribution. The Maximum Operational Flexibility and Representative Preferred Alternatives affect Priority 2 and 3 users when shortages are large enough. Under the Representative Preferred Alternative, Priority 4 median shortages are 1,167.1 kaf in the Dry Flow Category and 1,442.6 kaf in the Critically Dry Flow Category. Priority 1 users do not take shortage. The sum of the shortages across priority groups is shown in **Figure 3-16**, below. Shortage is also displayed by priority in **Figure TA 4-11** in **TA-4**, Water Deliveries.



California

In California, the No Action and Basic Coordination Alternatives do not apply shortages to water users because they combine low maximum Lower Basin shortages with priority-based shortage distribution. However, low maximum Lower Basin shortages correspond to higher dead pool-related reductions. The Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives apply shortages to senior priority groups through pro rata-based distribution. The Maximum Operational Flexibility Alternative also affects Priorities 1 and 2 and PPRs in a small number of years in the Dry and Critically Dry Flow Categories. Priority 4 users are the most junior and experience the largest shortage volumes relative to their total rights. Under the Representative Preferred Alternative, Priority 4 median shortages are 0.0 kaf in the Dry Flow Category and 255.7 kaf in the Critically Dry Flow Category. Priorities 3a and 3b median shortages are 0.0 kaf and 100.4 kaf, respectively. The sum of the shortages across priority groups is shown in **Figure 3-16**. Shortage is also displayed by priority in **Figure TA 4-12** in **TA-4**, Water Deliveries.

Nevada

In Nevada, modeled shortages are primarily associated with Priority 8 users, who represent the vast majority of Nevada water rights. Other priority groups receive shortages only under the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives because those alternatives use pro rata-based shortage distribution. Most action alternatives have higher median shortages as conditions become drier, while the Basic Coordination Alternative remains at 81.7 kaf because its maximum shortage is already applied in the Average Flow Category. Under the Representative Preferred Alternative, Priority 8 median shortages are 82.8 kaf in the Dry Flow Category and 108.9 kaf in the Critically Dry Flow Category. No other priority groups take shortage under this alternative. The sum of the shortages across priority groups is shown in **Figure 3-16**. Shortage is also displayed by priority in **Figure TA 4-13** in **TA-4**, Water Deliveries.

Figure 3-16
Calendar Year Shortage by State and Water Delivery Reductions to Mexico

Note: The modeled annual delivery reductions in Mexico include modeling assumptions for reductions in water deliveries to Mexico and storage available to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Annual Depletions

Depletion, also referred to as total consumptive use or the net amount of water used, is defined as the amount of water diverted from the river minus return flow. Return flow is the portion of water diverted for use that is not consumed and returns to the river for subsequent downstream use. Across entities, alternatives, and the CCS Comparative Baseline, median depletions do not uniformly decrease as conditions become drier, but the percentage of years affected by dead pool-related reductions increases.

Arizona

In Arizona, modeled depletions are below 100 percent of apportionment in most years because shortages are applied frequently and conservation activity does not fully offset them. Depletions change little from the Average Flow Category to the Dry Flow Category, but years affected by dead pool-related reductions increase. In the Critically Dry Flow Category, median and lower-percentile depletions decrease for most alternatives due to larger shortages and limited availability of, or access to, conserved water. Under the Representative Preferred Alternative, median Arizona depletions are 58.5 percent in the Dry Flow Category and 51.8 percent in the Critically Dry Flow Category, with dead pool-related effects in some outlier years and approximately 10 percent of years, respectively. The full range of annual depletions in Arizona across the different alternatives can be viewed in **Figure TA 4-14** in **TA-4**, Water Deliveries.

California

California's modeled depletions are below 100 percent of apportionment in most years under alternatives that apply shortages to the state. Under the No Action and Basic Coordination Alternatives, depletions below 100 percent are associated with dead pool-related reductions. Except under the Enhanced Coordination Alternative, median depletions change little from the Average Flow Category to the Critically Dry Flow Category, although years affected by dead pool-related reductions increase. Under the Representative Preferred Alternative, median California depletions are 95.8 percent in the Dry Flow Category and 86.0 percent in the Critically Dry Flow Category, with dead pool-related effects in some outlier years and fewer than 10 percent of years, respectively. The full range of annual depletions in California across the different alternatives can be viewed in **Figure TA 4-15** in **TA-4**, Water Deliveries.

Nevada

In Nevada, modeled depletions change little from the Average Flow Category to the Dry Flow Category, while years affected by dead pool-related reductions increase. In the Critically Dry Flow Category, median and lower-percentile depletions decrease for most alternatives due to larger shortages and limited availability of, or access to, conserved water. Under the Representative Preferred Alternative, median Nevada depletions are 89.7 percent in the Dry Flow Category and 73.3 percent in the Critically Dry Flow Category. Dead pool-related effects occur in some outlier years in the Dry Flow Category and approximately 10 percent of years in the Critically Dry Flow Category. The full range of annual depletions in Nevada across the different alternatives can be viewed in F**igure TA 4-16** in **TA-4**, Water Deliveries.

Surplus

Surplus deliveries become more frequent as flow conditions become wetter. In the Average Flow Category, the Representative Preferred Alternative has the highest frequency of surplus deliveries at

18.0 percent of years, followed by the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) at about 15 percent. All alternatives have surplus deliveries in fewer than 10 percent of years in the Dry Flow Category. In the Critically Dry Flow Category, only the CCS Comparative Baseline and the Supply Driven (both LB Priority and LB Pro Rata approaches) and Representative Preferred Alternatives have any surplus deliveries, at fewer than 3 percent of years. The full range of frequency of surplus across the different alternatives can be viewed in **Figure TA 4-17** in **TA-4**, Water Deliveries.

Issue 4: Deliveries to Mexico

Issue 4 addresses how operational activities affect deliveries to Mexico. Refer to **TA-4**, Water Deliveries for greater details regarding the analysis of impacts as well as **Appendix N**, International Border Region of the Colorado River for additional information regarding water deliveries to the International Border Region.

Annual Reductions

For Mexico, modeled water delivery reductions generally increase as conditions become drier, with higher median reductions in the Dry and Critically Dry Flow Categories than in the Average Flow Category. In the Average Flow Category, the CCS Comparative Baseline and No Action Alternative have among the lowest median reductions, while the Maximum Operational Flexibility and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are around 20 percent. Under the Representative Preferred Alternative, Mexico's median water delivery reduction is 16.7 percent in the Dry Flow Category and 23.6 percent in the Critically Dry Flow Category. Refer to **Figure 3-16,** above, and the tables and figures in **TA-4,** Water Deliveries for further information.

Annual Depletions

Mexico's modeled depletions are below 100 percent of allotment in most years because delivery reductions are applied frequently and conservation activity does not fully offset them. Median depletions change little from the Average Flow Category to the Dry Flow Category, while years affected by dead pool-related reductions increase. In the Critically Dry Flow Category, median and lower-percentile depletions decrease for most alternatives. Under the Representative Preferred Alternative, median Mexico depletions are 83.3 percent in the Dry Flow Category and 81.5 percent in the Critically Dry Flow Category, with dead pool-related effects in some outlier years and approximately 25 percent of years, respectively. Refer to **Figure TA 4-18** in **TA-4**, Water Deliveries for further information.

Issue 5: Lower Division States Combined Shortages

Issue 5 addresses how operational activities affect modeled distribution of combined shortages for the Lower Division States. As discussed in **Chapter 2**, the alternatives considered evaluate a distribution of shortages via priority and pro rata. Lower Division States' shortage distributions discussed under this issue were modeled with the SAM and ADM to estimate the volume of available water to entitlement holders or water users under Shortage Conditions over a specified range of shortage volumes. Refer to **TA-4**, Water Deliveries for greater details regarding the analysis of impacts as well as the **Appendix C,** Shortage Allocation Model and Alternative Distribution Model Documentation for additional information.

Tribal, Domestic, and Irrigation Shortage Impacts

For tribal users, priority-based alternatives result in greater shortage impacts than pro rata-based alternatives when comparing the same total shortage volume. Shortage impacts range from 209 to 582 kaf for priority-based alternatives and from 76 to 378 kaf for pro rata-based alternatives. Under the Representative Preferred Alternative, maximum 2027 and 2028 shortage impacts would be 346 kaf unless critical elevations at Lake Mead prompt consultation, while 2029-2060 modeling assumptions show a maximum potential impact of over 574 kaf.

For domestic users, priority-based alternatives result in greater shortage impacts than pro rata-based alternatives when comparing the same total shortage volume. Shortage impacts range from 277 to 1,501 kaf for priority-based alternatives and from 109 to 546 kaf for pro rata-based alternatives. Under the Representative Preferred Alternative, maximum 2027 and 2028 shortage impacts would be 858 kaf unless critical elevations at Lake Mead prompt consultation, while 2029-2060 modeling assumptions show a maximum potential impact of over 1,472 kaf.

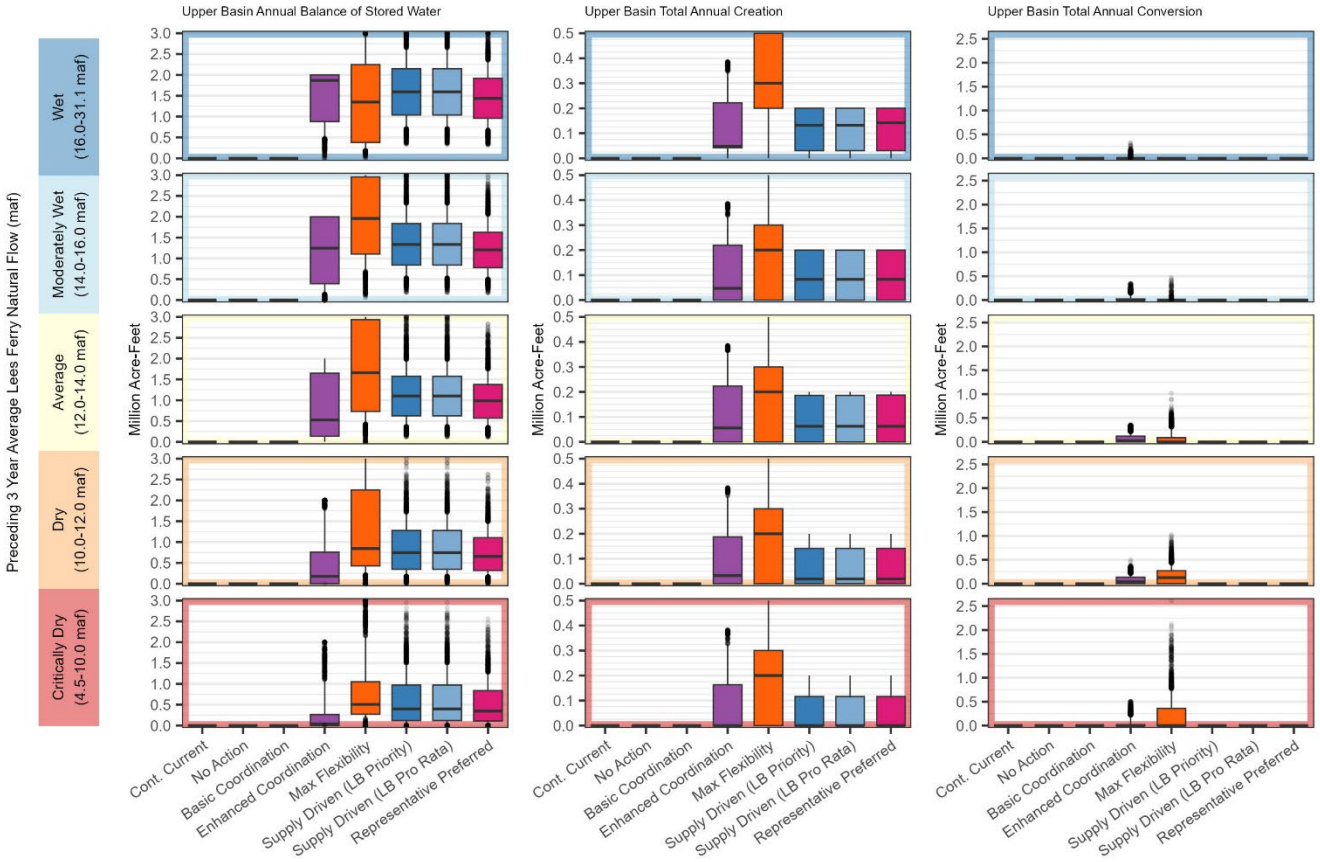
For non-tribal irrigation users, pro rata-based alternatives result in greater shortage impacts than priority-based alternatives when comparing the same total shortage volume. Shortage impacts range from 2 to 1,211 kaf for priority-based alternatives and from 206 to 1,578 kaf for pro rata-based alternatives. Under the Representative Preferred Alternative, maximum 2027 and 2028 shortage impacts would be 70 kaf unless critical elevations at Lake Mead prompt consultation, while 2029-2060 modeling assumptions show a maximum potential impact of over 829 kaf.

Volumes of Shortage by State (Arizona, California, Nevada)

State specific distribution of shortages can be viewed in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation.

Issue 6: Upper Basin Conservation

This section describes how alternatives perform in terms of annual Upper Basin conservation activity. **Figure 3-17** shows three components of Upper Basin conservation activity.[9] The first column shows the annual total volume of conserved water accumulated by Upper Basin conservation. The second column reports the annual volume of conserved water that is created. The third column reports the annual volume that is converted to system water.



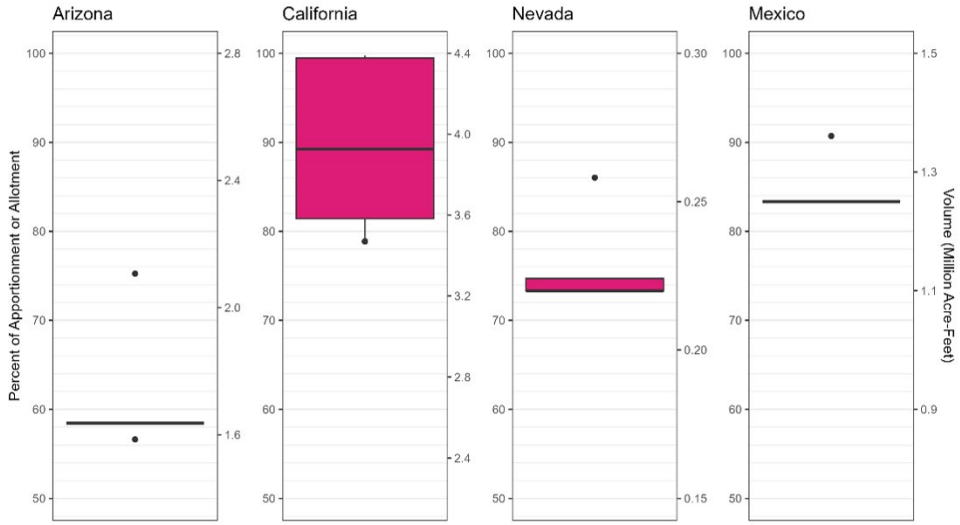
There is zero accumulation, creation, or conversion under the CCS Comparative Baseline or the No Action and Basic Coordination Alternatives, so the remainder of the discussion on **Figure 3-17** focuses on Enhanced Coordination, Maximum Operational Flexibility, Representative Preferred, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives.[10]

Among alternatives with Upper Basin conservation, the Maximum Operational Flexibility Alternative has the highest median accumulation in the Average and Critically Dry Flow Categories and also has the highest median creation in those categories. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) does not convert conserved water because conservation is created as system

[9] For all alternatives except the Maximum Operational Flexibility Alternative, Lower Basin conserved water is stored in Lake Mead. For the Maximum Operational Flexibility Alternative, this water can be stored in Lake Mead, Lake Powell, or both.
[10] UB conservation activity is the same for both the LB Priority and LB Pro Rata approaches under the Supply Driven Alternative.

water. For the Representative Preferred Alternative, median accumulation is 1.0 maf in the Average Flow Category and 0.3 maf in the Critically Dry Flow Category. Median creation is about 0.1 maf in the Average Flow Category and 0.0 maf in the Critically Dry Flow Category.

Figure 3-17
Annual Upper Basin Conservation Activity



Note: In addition to the conservation volumes, the Supply Driven Alternative also includes "gap water" (see EIS **A**ppendix S, Additional Description of Alternatives, and **Appendix A,** CRSS Model Documentation). The modeled gap water volume increases with higher natural flow release percentages and drier hydrologic conditions. The median is 0.0 maf for the 60 and 65 percent natural flow release scenarios in the Average and Critically Dry flow categories, and increases to slightly over 0.1 maf and 0.8 maf, respectively, for the 70 percent scenario; the maximum gap water volume across all flow categories is approximately 1.1 maf. **Appendix D**, Sensitivity Analysis – Effects of Natural Flow Percentage Used for the Supply Driven Alternative, includes additional information on the modeled volumes of gap water.

Issue 7: Lower Division States' 2027-2028 Water Supply Determinations in the Representative Preferred Alternative

Under the Preferred Alternative decision framework, specific operating guidelines, including shortage volumes and distributions, will be developed and adopted periodically. It is anticipated that the first set of operating guidelines will cover 2027 and 2028. The Lower Division States' proposal for distributing shortages up to 1.5 maf on May 1, 2026, was incorporated in the Representative Preferred Alternative for 2027 and 2028, as described in **Chapter 2**.

In the Representative Preferred Alternative modeling, all 400 traces show a 1.5-maf Lower Basin shortage in 2027. In 2028, 148 traces remain at 1.5 maf, while 252 traces show larger shortages, with up to 3.0 maf in 3 traces. It is anticipated that volumes and distribution of shortages above 1.5 maf, should they be deemed necessary, would be developed based on consultation and are not analyzed in this Issue. **Figure 3-18**, below, shows the distribution of annual depletions for each state in 2027 and 2028 in the Representative Preferred Alternative. Median 2027-2028 depletions are approximately 1.6 maf for Arizona, 3.9 maf for California, 0.2 maf for Nevada, and 1.3 maf for Mexico. As a percent of apportionment or allotment, they are 58.5 percent for Arizona, 89.2 percent for California, 73.3 percent for Nevada, and 83.3 percent for Mexico.

Figure 3-18
Distribution of 2027-2028 Annual Depletions by State in the Representative Preferred Alternative

Summary Comparison of Alternatives

A summary of each issue is provided below, with additional information and details provided in **TA-4**, Water Deliveries**.**

Issue 1 considered whether the alternatives could affect apportionments to the Upper Division States. Because no changes to those apportionments are expected, no further impact analysis was needed.

Issue 2 assessed whether the alternatives could affect the Lower Division States' apportionments or water entitlements. The shortage distribution approaches were evaluated to explore potential concepts and impacts and not to change existing apportionments or entitlements. Related delivery effects are addressed under Issues 3, 5 and 7, and further summarized below.

Issue 3 evaluates effects on water supplies for the Lower Division States and Mexico, including shortages, Lake Mead dead pool-related reductions, conservation activity, depletions, delivery reductions, and surplus deliveries. Across alternatives, lower planned shortages tend to leave Lake Mead more vulnerable to dead pool-related reductions, while larger or more responsive shortages tend to provide stronger protection against those reductions. Differences among alternatives become more

pronounced under drier hydrology, and outcomes vary based on shortage volume, shortage distribution, conservation assumptions, and dead pool-related constraints. Under the Representative Preferred Alternative, modeled shortages are higher in the Critically Dry Flow Category than in the Dry Flow Category, which helps limit the frequency of Lake Mead dead pool-related reductions. Dead pool-related reductions remain limited in the Dry Flow Category and occur more often under Critically Dry conditions. The vulnerability analysis indicates that this alternative would likely become vulnerable to at least one dead pool-related reduction only under hydrologic conditions much drier than the observed record.

Issue 4 evaluates effects on Colorado River deliveries to Mexico, including annual delivery reductions and depletions. Across alternatives, Mexico generally receives its full allotment infrequently, and Lake Mead dead pool-related reductions occur more often under No Action and Basic Coordination than under several other alternatives. Under the Representative Preferred Alternative, Mexico's median depletions are similar in Dry and Critically Dry conditions, at 83.3 percent and 81.5 percent of allotment, respectively. Dead pool-related reductions affect about 25 percent of Critically Dry years, which is less frequent than under No Action but more common than under Maximum Operational Flexibility and the Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives.

Issue 5 considered how action alternatives would affect the distribution of combined shortages among Lower Division States water users. Modeled outcomes vary by distribution approach, with priority-based methods generally increasing shortages for tribal and domestic users, while pro rata methods tend to increase impacts to non-tribal irrigation users. Assuming a maximum shortage volume of 1.5 maf distributed based on the Lower Division States' May 1, 2026, proposal, the Representative Preferred Alternative, maximum modeled shortages in 2027 and 2028 would be 346 kaf for tribal users, 858 kaf for domestic users, and 70 kaf for non-tribal irrigation users[11]. For 2029 through 2060, the Representative Preferred Alternative assumes shortages up to 3.6 maf distributed by priority and potential for larger impacts, but actual shortage distributions would depend on the operating guidelines adopted under the Preferred Alternative framework.

Issue 6 examined how alternatives perform in terms of annual Upper Basin conservation activity. Upper Basin conservation activity occurs only under Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and the Representative Preferred Alternatives. No accumulation, creation, or conversion occurs under the CCS Comparative Baseline, and the No Action or Basic Coordination Alternatives. The Maximum Operational Flexibility Alternative generally has the highest annual accumulation and creation, while conversion is more limited overall. Under the Representative Preferred Alternative, accumulation and creation occur, but no conversion is modeled because no conversion mechanism is assumed.

Issue 7 evaluates the Lower Division States' 2027-2028 water supply determinations in the Representative Preferred Alternative, which assumes that up to 1.5 maf of shortage is distributed based on the Lower Division States' May 1, 2026, proposal (i.e., LB Priority). The Preferred Alternative establishes a decision framework, so actual shortage volumes and distributions may differ from those modeled. In 2027 all traces show a 1.5-maf Lower Basin shortage. While shortages greater

[11] While the Representative Preferred Alternative models shortages above 1.5 maf in 2028, consistent with the sideboards, under the Preferred Alternative, Reclamation would consult with stakeholders if Lake Mead elevation is projected below 1,000 feet. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative).

than 1.5 maf are modeled in 2028, they are not analyzed. The median 2027-2028 depletions are approximately 1.6 maf for Arizona, 3.9 maf for California, 0.2 maf for Nevada, and 1.3 maf for Mexico. As a percent of apportionment or allotment, they are 58.5 percent for Arizona, 89.2 percent for California, 73.3 percent for Nevada, and 83.3 percent for Mexico.

3.5 Geomorphology and Sediment

3.5.1 Affected Environment

This section describes how sediment and geomorphic processes shape the Colorado River below Glen Canyon Dam. Sandbars within the Grand Canyon provide key ecological, cultural, and recreational functions, supporting habitat, vegetation, archaeological resource protection, and camping areas along the river (Rubin et al. 2002; Mueller et al. 2018; Hazel et al. 2022; Reclamation 2024c). In addition, beaches provide camping areas for whitewater river trips, a significant driver of economic activity in the region.

Sandbars and channel-margin deposits depend on the river's sediment mass balance—the difference between the sediment entering and leaving the system. Before Glen Canyon Dam was built, the river carried large amounts of suspended sediment year-round. After the dam's completion, about 95 percent of the historical sediment supply from the Upper Basin was cut off, leaving the river with a long-term sediment deficit (Topping et al. 2000). As a result, the river now erodes sandbars and channel deposits faster than tributaries can replace them. Since the 1960s, most years have shown net erosion in Marble and Grand Canyons (Topping et al. 2021).

Dam operations also influence sediment behavior. Today's managed flows are much lower and more stable than historical floods, and minimum flows remain above levels that once allowed seasonal sand accumulation. Combined with the reduced sediment supply, these regulated discharges limit sand deposition, shorten the time available for sand storage, and increase erosion of beaches and sandbars (USGS 2011).

Downstream of Glen Canyon Dam, the Paria and Little Colorado Rivers are the dominant sediment sources. Upstream of the Paria, modern Glen Canyon receives little sediment input, making its sediment effectively nonrenewable (Grams et al. 2007). Sand delivered from tributaries tends to remain in the system only for a few months unless flows remain below roughly 9,000 cubic feet per second (cfs) (Topping et al. 2000; Rubin et al. 2002; USGS 2011). Most sediment ultimately continues downstream toward Lake Mead.

Fine sediment—sand, silt, and clay—is the primary material transported by the river and the main contributor to sandbar formation. Sand stored on the riverbed supplies the material that forms sandbars during high flows. Sediment transport increases with flow volume, turbulence, and changes in sediment size delivered by tributary floods. Deposition occurs in low-velocity environments such as recirculation zones of eddies and along channel margins, and storage varies with riverbed topography and tributary activity.

Geomorphically, the river consists of long pools separated by steep rapids formed at debris-fan deposits left by tributary debris flows. These fans constrict the channel, generate rapids, and create

recirculating eddies where sandbars form (**Figure TA 5-1** in **TA 5**, Geomorphology and Sediment). Most Grand Canyon sandbars are tied to these fan-eddy complexes and remain dynamic features that continually exchange sand with the river.

To counteract long-term sandbar erosion, Reclamation conducts HFEs that release large, short-duration floods from Glen Canyon Dam. HFEs are the only mechanism capable of producing water stages high enough to rebuild sandbars. Bar size generally increases during HFEs and then diminishes between them, with erosion highest immediately after floods. More frequent HFEs can increase sandbar size if sufficient sand is available (Grams et al. 2025).

3.5.2 Environmental Consequences

Methodology

All modeling used for this resource section was based on modeling performed by the USGS, GCMRC (Grams et al. 2025; Salter et al. 2025), and developed using the CRSS hydrological modeling results. Tributary sediment inputs from the Paria and Little Colorado Rivers were generated using the Wright et al. (2010) model. Outputs were fed to the Mueller and Grams (2021) sandbar model, recalibrated to the 2002–2024 period, based on the long-term monitoring program, and initialized using the January 1, 2025, volume. The model ran each alternative for all 400 traces and 3 initial conditions. Some modifications were made to the Mueller and Grams (2021) sandbar model to include additional sandbars in the calibration dataset, incorporate discharge-dependence into the erosion model, and assume a constant sandbar area (Salter et al. 2025). Two versions of the sandbar model were used to predict sandbar deposition: one for flow rates exceeding 8,000 cfs, the average daily discharge flow; and one for flow rates exceeding 25,000 cfs, the discharge at which sandbars will not be inundated during normal dam operations and will result in usable sandbars for recreational purposes (Salter et al. 2025). Except for modeled HFEs, the sandbar model did not include any sustained releases above 25,000 cfs over the calibration period. See **Section TA 5.2.1**, Methodology, in **TA-5**, Geomorphology and Sediment Resources, for additional information. The modeled sand transport, sandbar volumes, and reservoir operations data used in the impacts analysis is sourced from the USGS, GCMRC (Salter and Grams 2026).

Impact Analysis Area

The impact analysis area used for GCMRC sediment modeling data extends from the Colorado River at Glen Canyon Dam to Lake Mead, including sediment inputs from the Paria and Little Colorado River tributaries. The analysis area for the sandbar model (quantitative model) is from Lees Ferry (RM 0) through Diamond Creek (RM 225). The extent of this model is limited by the availability of study sites in the calibration dataset. However, it is expected that the findings for the reach between Lees Ferry and Diamond Creek are also representative for similar sandbars downstream to Separation Canyon (RM 240), the full-pool extent of Lake Mead. With low Lake Mead elevations, the Colorado River will cut new paths through the mouth of the reservoir, resulting in sediment redistribution that forms new bars and alters the reservoir's delta. Finer particles may remain in suspension and travel further downstream in the reservoir before settling, increasing sediment concentration near the upper reaches of Lake Mead. Impacts on water surface elevations and consequently erosion and deposition patterns in the delta region of Lake Powell may also result. Sediment redistribution within the reservoirs is not evaluated in this EIS due to the absence of an applicable model.

The proposed alternatives may modify the magnitude, timing, or variability of releases from Hoover Dam relative to existing operations. Any such changes would affect sediment resources downstream by altering sediment transport capacity and the degree to which available fine sediment is mobilized or retained. However, because the downstream reach is sediment-starved and the alternatives would not introduce new sources of sediment, significantly modify sediment supply, or change channel morphology, any effects on geomorphology and sedimentation downstream of Hoover Dam are expected to be negligible.

Assumptions

- Reclamation's future operations will remain responsive to hydrology, system conditions, and applicable legal and operational requirements. Reclamation will continue to follow 2016 LTEMP EIS and 2024 LTEMP SEIS guidelines, which include the planning and implementation team process that helps assess monthly release volumes and Secretarial decision-making.
- HFEs require sufficient sand in Marble Canyon (positive sand mass balance) and adequate Lake Powell water levels, both dependent on the chosen HFE duration.
- HFE releases can only be implemented above a 3,500-foot Lake Powell elevation, the elevation required for a release magnitude of 37,000 cfs (Reclamation 2024c; Salter et al. 2025).
- Non-HFE flows can deposit sand, but only sand deposited during flows above 25,000 cfs is considered usable for recreation.
- Sandbar building is fastest during the first 4 days; a 60-hour HFE produces strong deposition while allowing more frequent events and reducing interim erosion.
- Maximum ramp rates (4,000 cfs up / 2,500 cfs down per hour) are in accordance with 2016 and 2024 LTEMP guidelines.
- Sandbar volume modeling uses the assumption that HFEs are implemented as often as possible.
- Most of the sand input from the Paria and Little Colorado Rivers occurs during the summer-fall thunderstorm season between July 1 and November 1.
- If no HFE releases were implemented during the 1-year sediment accounting period, any positive sediment balance would be carried forward to the next accounting period.

Impact Indicators

Issues related to geomorphology and sedimentation that are evaluated in this section are listed below. Each of the five issues is associated with one or two "indicators," which serve as preferred minimum performance against which the issues are compared for the purpose of this analysis.

1. Water Availability in Lake Powell
2. Sand Mass
3. HFE Frequency and Duration
4. Sandbar Volume
5. Sand Transport

Issue 1: Water Availability

An HFE likely to enlarge sandbars requires enough water for a release rate of 37,000 cfs, generally considered the flow rate needed for significant deposition on certain sandbar types (Hazel et al. 2022). A 37,000 cfs release requires Lake Powell to be at or above 3,500 feet in April or November, when HFEs are typically scheduled. Alternatives that more frequently result in water levels greater than this threshold are therefore deemed preferable.

It should be noted that there are challenges to conducting HFEs at a Lake Powell elevation of 3,500 feet. Historically, the lowest elevation at which an HFE has been implemented was approximately 3,523 feet in April 2023. Since the models used an elevation of 3,500 feet as the lowest possible elevation at which HFEs could occur, it is likely that modeling overestimates the number or frequency of HFEs. **Table TA 5-1** in **TA 5**, Geomorphology and Sediment, shows the percentage of modeled HFEs by alternative that were above (or below) this lowest historical elevation.

Figure TA 5-2 in **TA 5**, Geomorphology and Sediment, depicts the ability of each alternative to maintain a Lake Powell pool elevation greater than 3,500 feet in November or April. The preferred minimum performance (the minimum result used as the comparison standard across alternatives) is shown in the highlighted row, which represents the percentage of futures that that an alternative exceeds 3,500 feet in November or April in 100 percent of years. The 3,500-foot threshold was selected because it is undesirable to ever miss the opportunity to take advantage of other favorable conditions such as large sediment loads from the Paria River. Over the 2027–2039 modeling period, the Maximum Operational Flexibility Alternative is the most robust meeting the preferred minimum performance in 97 percent of modeled futures (simulated hydrologic scenarios), followed by the Enhanced Coordination Alternative at 88 percent. The Representative Preferred Alternative meets the preferred minimum performance in 60 percent of futures.

The lowest Lake Powell elevation in the historical record (3,523 feet) is shown in **Figure TA 5-3** in **TA 5**, Geomorphology and Sediment, and displays the same information as **Figure TA 5-2**. With a 3,523-foot threshold, the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 29 percent and 24 percent of modeled futures, which is lower than with the 3,500-foot threshold. **Figure TA 5-4** in **TA 5**, Geomorphology and Sediment, also demonstrates that these two alternatives would be the least vulnerable with respect to water availability. The Representative Preferred Alternative meets the preferred minimum performance in 14 percent of futures.

Issue 2: Sand Mass

The second condition required for an HFE release is the availability of sand. Sand that accumulates in Marble Canyon and is transported downstream outside HFE events does not result in sandbar formation. While management under the proposed alternatives would not attempt to control the sediment generation in the Paria River and Little Colorado River, the alternatives would affect how much of that sediment is available for HFEs by impacting the timing and magnitude of releases outside HFE releases.

Glen Canyon Dam releases for hydropower generation tend to be high in July and August (Reclamation 2016). This period also coincides with the summer-fall thunderstorm season in the Paria and Little Colorado watersheds that causes sand to be transported to Marble Canyon. Sand tends to

accumulate during September and October because the reduced releases are not enough to transport the sand downstream. Unless it is a particularly dry year, flows increase during the winter months, resulting in the transport of increasing quantities of sediment downstream.

While average flows must be lower than about 11,000 cfs to allow sediment accumulation under most initial conditions (bed conditions following a tributary sediment-supply event), flows greater than 15,000 cfs (900,000 af per month) are likely to be erosive regardless of those initial conditions (Salter et al. 2025). Therefore, futures with flows less than 900,000 af per month (i.e., non-erosive flows) for at least 90 percent of a simulation period are considered preferable. As detailed in **Figure TA 5-5** in **TA 5**, Geomorphology and Sediment, over the 2027–2039 modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives meets this condition in 68 percent and 50 percent of simulated futures, respectively, while none of the other alternatives meet this condition in more than 41 percent of simulated futures (the Representative Preferred Alternative meets this conditions in 41 percent of simulated futures).

Historical data indicate that sandbar deposition typically occurs at HFE durations of 60 hours or greater (Grams et al. 2025). A 60-hour duration is required for successful beach building. **Figure TA 5-8** in **TA 5**, Geomorphology and Sediment, shows how often Marble Canyon sand mass exceeds 294,000 metric tons, the average transport capacity for a 60-hour HFE, in November or April. The highlighted row indicates the percentage of futures that meet this condition at least once every 4 years (the preferred minimum performance). Aside from the CCS Comparative Baseline, the percentage of futures in which November or April sand mass exceeds 294,000 metric tons at least every 4 years is comparable across the alternatives, ranging from 77 percent to 79 percent for the 2027–2039 modeling period. All alternatives perform better during each of the three subperiods than over the full modeling period, as the chance of at least one year with a sand mass below 294,000 metric tons increases over longer periods.

Issue 3: HFE Frequency and Duration

To allow for sandbar deposition that is sufficient to at least partially compensate for natural erosion in between HFEs, futures are considered preferable if they predict a spring or fall HFE of 60 hours or greater at least once every 4 years. A 60-hour duration is the minimum duration associated with significant sandbar deposition.

As shown in **Figure TA 5-9** in **TA 5**, Geomorphology and Sediment, for the 2027–2039 modeling period, aside from the CCS Comparative Baseline and No Action Alternative, the percent of futures in which annual HFE duration is greater than 60 hours at least once every four years, is comparable across the alternatives. The percentages range from 54 percent to 64 percent, but the Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best at 60 percent and 64 percent of simulated futures, respectively. This metric is limited by the availability of sand, given the high percentage with which Maximum Operational Flexibility and Enhanced Coordination Alternatives result in enough water for an HFE release (**Figure TA 5-2**). **Figure TA 5-10** in **TA 5**, Geomorphology and Sediment, also shows that Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives perform the best for HFE releases lasting 12 to 96 hours, with 46 percent, 43 percent, and 42 percent of years having HFE releases greater than or equal to 60 hours, respectively. This performance is notable because, excluding the HFE implemented on March 26, 1996, all HFEs implemented have been between 60 and 96 hours (Grams et al. 2025).

Figure TA 5-11 in **TA 5**, Geomorphology and Sediment, shows the distribution of HFE durations for the full sediment year (July 1 to July 1), fall, and spring. The distributions are further categorized into five hydrologic conditions based on the average natural flow rates at Lees Ferry over the preceding 3-year period. The figure illustrates a shift from fall HFE releases to spring HFE releases as the preceding 3-year average Lees Ferry natural flow decreases (i.e., conditions become drier). For the Critically Dry Flow Category (4.46–10.0 maf), only Maximum Operational Flexibility and Enhanced Coordination Alternatives result in HFE durations of any substantial duration, typically occurring in the spring, when snowpack is known and inflow volumes can be more easily predicted. It is important to note the modeling does not imply an expected outcome, just that HFEs remain possible. HFE triggers and final HFE implementation would be a result of the LTEMP process.

Issue 4: Sandbar Volume

The water level during a 25,000 cfs flow condition is the threshold above which camping and recreational activities are considered safe from flooding. The sandbar volume above this level represents the volume of "usable" sand in the canyon. As shown in **Figure TA 5-12** in **TA 5**, Geomorphology and Sediment, sandbar growth generally increases as hydrologic conditions become drier, and Enhanced Coordination and Maximum Operational Flexibility Alternatives perform the best in the Critically Dry Flow Category (4.46–10.0 maf).

Futures are considered preferable if *net* sandbar volumes exceed the sandbar volumes at the start of the simulation for 60 percent or more of the simulation period. As detailed in **Figure TA 5-13** in **TA 5**, Geomorphology and Sediment, the action alternatives perform well for this issue; at least 85 percent of futures have larger sandbar volumes than at the start of the 2027–2039 period for at least 60 percent of the simulation period. Even the CCS Comparative Baseline results in the preferred minimum performance for 68 percent of futures. For reference, the sandbar volume at the start of the simulation period is approximately 1,170 cubic meters (41,300 cubic feet). It is important to note that **Figure TA 5-13** in **TA 5**, does not show the percentage of years with year-over-year sandbar growth; if large increases in sandbar volume occur at the start of a period, it is very possible for sandbar volume to be lower than it was the year before and still be higher than it was at the start of the period. In addition, each future is based on a single simulation and consequently subdivided into the three modeling subperiods. The significant increase in sandbar volume during the 2027–2039 modeling period, when compared with the other subperiods, could be partially attributed to the modeling assumption that HFEs are implemented as often as possible.

Figure TA 5-14 in **TA 5**, Geomorphology and Sediment, shows this issue from a different perspective, providing the percentage of simulated years for which the maximum sandbar volume is less than or equal to a given value. Curves with lower placement in the plot imply better performance for that alternative. While the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) results in the best performance, differences among the alternatives are minimal. The average sandbar volume for the 25 sandbar monitoring sites at the start of the full modeling period is 1,169.512 cubic meters (see **Section TA.5.2.1**, Methodology).

Issue 5: Sand Transport

While sand can be transported downstream with flows well below 37,000 cfs, lower flows are not conducive to sandbar formation and retention. The higher the fraction of sand transported above 37,000 cfs, the more sand will be available for sandbar formation (Hazel et al. 2022; Salter et al. 2025).

Figure TA 5-15 in **TA 5**, Geomorphology and Sediment, shows the percentage of futures for which the total sand mass transported by flow rates above 37,000 cfs (sandbar-forming flow rates) exceeds a given fraction over the 34-year simulation period. Futures are considered preferable if the fraction of sand mass transported by sandbar-forming flow rates is at least 0.4 (40 percent of the sand transport). The highlighted row provides the percentage of futures that meet this criterion. Under the Maximum Operational Flexibility Alternative, 85 percent of simulated futures are considered preferable—that is, at least 40 percent of sand mass is transported by sandbar-forming flow rates in 85 percent of simulated futures. The Enhanced Coordination Alternative is similarly robust, at 83 percent of simulated futures. Performance for the Supply Driven (both LB Priority and LB Pro Rata approaches), Representative Preferred, and Basic Coordination Alternatives are similar, with 78 percent, 76 percent, and 75 percent of futures considered preferable, respectively.

Summary Comparison of Alternatives

Taken as a whole, the results of the analysis suggest that the Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with respect to geomorphology and sediment. This appears to be largely due to their superior ability to preserve Lake Powell water levels above 3,500 feet in November and April, one of two conditions required for an HFE release (**Figure TA 5-2** in **TA 5**, Geomorphology and Sediment). In contrast, the Representative Preferred Alternative performs noticeably weaker in this category, though slightly better than the other alternatives. Impacts to sand mass in Marble Canyon, the other condition required for an HFE release, are comparable across alternatives, including the CCS Comparative Baseline (**Figure TA 5-7** in **TA 5**, Geomorphology and Sediment). During the driest climatic conditions (for which the preceding 3-year average Lees Ferry natural flow is less than 10.0 maf), Maximum Operational Flexibility and Enhanced Coordination Alternatives are the only two alternatives that would result in HFEs of any substantial duration, typically occurring in the spring.

3.6 Water Quality

3.6.1 Affected Environment

Salinity

The Colorado River Basin Salinity Control Forum reviews and makes salinity criteria recommendations for the Colorado River every 3 years. Flow-weighted average annual salinity criteria for the Colorado River are currently 723 milligrams per liter (mg/L) below Hoover Dam, 747 mg/L below Parker Dam, and 879 mg/L at Imperial Dam (Colorado River Basin Salinity Control Forum 2023). The water quality standards for salinity in the Colorado River were approved by the Environmental Protection Agency (EPA) and are reviewed every three years pursuant to Section 303(c)(1) of the Clean Water Act (Colorado River Basin Salinity Control Forum 2023).

Salinity control is accomplished through multiple programs. Federal agencies, including Reclamation, the BLM, and the U.S. Department of Agriculture, pursue improvements on federal lands to reduce salinity loading to the Colorado River (Reclamation 2022). Since the construction of Glen Canyon Dam, annual salinity concentrations downstream of Glen Canyon Dam have varied between 400 and 600 mg/L (Richards 2025). In a review of sampling efforts from 2007–2023, Reclamation has not exceeded the salinity criteria for the Colorado River. See **Section TA 6.1.1**, Salinity, in **TA 6**, Water Quality, for more information on salinity in the planning area and historical salinity concentrations in the Lower Basin.

Temperature

Lake Powell is a monomictic[12] reservoir with strong thermal stratification through much of the spring, summer, and early fall; this means the water is layered, with distinct temperatures and chemical characteristics. Generally, Lake Powell's epilimnion, or uppermost layer, ranges from 25 to 30 degrees Celsius (°C; 77 to 86 degrees Fahrenheit [°F]) in the summer, dropping to 6 to 10 °C (42.8 to 50 °F) in the winter (Deemer et al. 2023). Lake Powell's hypolimnion, or deeper layer, ranges from 6 to 9 °C (42.8 to 48.2 °F) year-round. Since the early 2000s, lower water levels in Lake Powell have led to warmer summer water temperatures in the Colorado River below Glen Canyon Dam (Reclamation and NPS 2016). Temperatures in the Colorado River in the Grand Canyon vary widely over space and time and are primarily controlled by the discharge and temperature released from Glen Canyon Dam and solar radiation dynamics along the river corridor (Mihalevich et al. 2020).

Lake Mead is also monomictic. Lake Mead inflow temperatures are a function of Glen Canyon Dam discharges and downstream weather conditions (Reclamation 2016). Lake Mead's hypolimnion is around 12 °C (53.6 °F) year-round. Its epilimnion ranges from about 14 to 29 °C (57.2 to 84.2 °F) in the spring, summer, and early fall, and drops to about 13 to 15 °C (55.4 to 59 °F) in the winter (SNWA 2023). Further declines in reservoir elevation, coupled with rising air temperatures, may continue to lead to warmer releases from Lake Mead, though this depends on whether the lower Hoover Dam outlet is used (Hannoun et al. 2022).

Harmful Algal Blooms and Nutrients

Nutrients, such as nitrogen and phosphorus, are essential for life, but excess nutrients in water can harm human health and ecosystems and impact recreational opportunities (USGS 2019a; NPS 2025a). In the project area, the most severe algal blooms are caused by cyanobacteria, which can produce toxins that can threaten drinking water quality and harm human health (USGS 2019a). In Lake Mead, water within Las Vegas Bay has the highest concentration of nutrients due to discharges of highly treated wastewater from the Las Vegas metropolitan area. Wastewater is a persistent contributor of phosphorus, whereas stormwater with higher phosphorus contributions is an acute contributor but a minor source overall. This is because storm events are infrequent. Since phosphorus is a limiting nutrient in the Colorado River system, these contributions support algal growth (USGS 2012). Lowering reservoir levels could increase the concentration of nutrients and temperatures, especially in shallow areas, which could be more favorable for algal growth (Hannoun et al. 2022).

[12] Monomictic waterbodies are those that mix completely during one mixing period each year.

Dissolved Oxygen

Dissolved oxygen is a critical factor for fish health. Research on dissolved oxygen thresholds for both warmwater and cold-water fish species shows that salmonids are particularly vulnerable to low dissolved oxygen concentrations compared with warmwater species (Saari 2018). Sustained dissolved oxygen levels below 3 mg/L can significantly reduce survival rates and feeding efficiency, whereas concentrations in the range of 6 to 9 mg/L are considered optimal for growth and survival across all life stages (EPA 1986).

Generally, Lake Powell's dissolved oxygen concentrations are at their highest in the spring to early summer, when inflows are well oxygenated and wind-induced mixing is high. Low dissolved oxygen concentrations move through the reservoir and closer to the dam during the summer into the fall because of organic matter decomposition and chemical reactions that consume oxygen. Dissolved oxygen gradually increases in the winter as a result of the higher oxygen-carrying capacity of cold water and the natural mixing during turnover. When water is discharged through the river outlet works, it becomes well aerated and increases the dissolved oxygen levels in the tailwaters, but only while the river outlet works are open.

Recently, dissolved oxygen levels in Lake Powell and the Glen Canyon Dam tailwaters[13] have been low compared with historical dissolved oxygen levels. This is due to low reservoir elevations and the increasing reservoir age (Deemer et al. 2025). Dissolved oxygen levels below Glen Canyon Dam vary throughout the year, falling as low as 2.2 mg/L in the summer and rising as high as 9 to 10 mg/L in the spring (GCMRC 2025). Dissolved oxygen increases approximately 1 mg/L between Glen Canyon Dam and Lees Ferry. Low dissolved oxygen conditions improve downstream of the Paria Riffle and Badger Rapids as the water is reaerated through whitewater action.

In Lake Mead, dissolved oxygen levels decrease in the bottom of Las Vegas Bay as a result of high decomposition of organic matter from the Las Vegas Wash. When there are greater nutrients in surface water, generally more decomposition and low oxygen occur in bottom waters. Monitoring is ongoing to determine the cause of decreased dissolved oxygen concentrations in isolated areas, but the driver is likely higher temperatures from inflows (Reclamation and NPS 2016).

Metals, Perchlorate, and Per- and Polyfluoroalkyl Substances

The planning area contains sources of metals and regulated chemicals, including perchlorate and per- and polyfluoroalkyl substances (PFAS), although metals are not a typical concern in the planning area and mitigation programs have successfully reduced perchlorate concentrations below applicable regulatory limits throughout the lower basin (Hannoun and Tiejen 2022). Generally, as reservoir elevations decrease, the dilution capacity of reservoirs like Lake Powell and Lake Mead would also decrease. Decreased dilution capacity from lower reservoir elevations could result in greater concentrations of pollutants of concern. For more information, see **Sections TA 6.1.5**, Metals; **TA 6.1.6**, Perchlorate; and **TA 6.1.7**, PFAS, in **TA 6**, Water Quality.

[13] Tailwater refers to waters located immediately below the dam. It is the reach of river immediately downstream of a reservoir that is heavily influenced by reservoir characteristics. Tailwaters are generally expected to have water quality that is more similar to the water quality in reservoirs compared with reaches farther downstream.

3.6.2 Environmental Consequences

Methodology

The analysis methodology for water quality is based on a combination of DMDU; CRSS; GCMRC Dissolved Oxygen and Temperature Models for Glen Canyon, Lees Ferry, and Grand Canyon; and qualitative analysis. For detailed information on the dissolved oxygen and water temperature models, see **Section TA 6.2.1**, Methodology, in **TA 6**, Water Quality, for more information.

CRSS simulates Colorado River Basin conditions decades into the future and can account for hydrologic uncertainty. CRSS is a monthly time-step model that produces reservoir elevations, dam releases, and salinity concentrations. Refer to **Appendix A**, CRSS Model Documentation for more details on model documentation.

In this section, salinity is analyzed as it relates to the salinity criteria set by the Colorado River Salinity Control Forum. For information on salinity concentration and salinity related to the potential effects on resources in the International Border Region, see **Appendix N**, International Border Region of the Colorado River.

Conditional box plots and robustness heat maps that describe impacts on water quality can be found in **TA 6**. Refer to **Section 3.2**, Analysis Methods, for additional information on interpreting the DMDU conditional box plots, robustness heat maps and vulnerability bar plots.

While reduced water deliveries could have impacts to downstream municipal users, the analysis does not include an analysis of these impacts since the operations of municipal water providers fall outside of Reclamation's regulatory authority and are carried out independently by these third parties.

Impact Analysis Area

The analysis area for water quality is the geographic and temporal scope introduced in **Section 3.2**, Analysis Methods. Due to the data available, the analysis was limited to surface water quality.

Assumptions

- There will be modifications in quantity, timing, temperature, and quality of water released from Glen Canyon Dam and Hoover Dam.

Impact Indicators

- Salinity
- Temperature
- Dissolved oxygen
- Reservoir elevation
- Dilution capacity

Issue 1: How would reservoir storage, reservoir releases, and corresponding changes in river flows downstream of the reservoirs affect salinity?

Increased salinity concentrations from human activities pose a threat to drinking water, irrigation, agricultural production, municipal water supplies, and infrastructure. Reservoirs like Lake Powell and

Lake Mead influence salinity by reducing the effect of salinity transport downstream and possibly acting as a source or a sink (Deemer 2020). Dam releases are typically from deeper in the water column and generally have elevated salinity concentrations relative to surface waters. As reservoir water levels drop, reservoir salinity can often increase (Zohary and Ostrovsky 2011).

Using CRSS outputs, annual flow-weighted average salinity concentrations below Hoover Dam, below Parker Dam, and at Imperial Dam were simulated under various hydrologic conditions. Under all alternatives, a majority (90 percent or greater) of simulated futures did not exceed the salinity criteria in even the most challenging hydrologic conditions. For the Average Flow Category, maximum simulated annual flow-weighted salinity concentrations exceeded the salinity threshold below Hoover Dam under the CCS Comparative Baseline and the No Action and Basic Coordination Alternatives. See **Figure TA 6-4** in **TA 6**, Water Quality, for box plots depicting these annual flow-weighted average salinity concentrations.

Under the Dry Flow Category, all alternatives exceeded the threshold, with an increasing number in the Critically Dry Flow Category due to the low reservoir elevations associated with these hydrologic conditions. The highest median salinity concentrations occur in the Enhanced Coordination Alternative, with the difference between the alternatives largest in the Critically Dry Flow Category. Simulated flow-weighted average salinity concentration median values did not exceed salinity thresholds at all sites under all alternatives, even under the driest flow scenarios. Therefore, no significant negative impacts on salinity were associated with any of the alternatives.

All alternatives are truly robust, meeting the preferred level of performance in 90 percent of futures or greater in the first decadal period (that is, 2027 to 2039) below Hoover Dam, below Parker Dam, and at Imperial Dam. See **Figures TA 6-5**, **TA 6-6**, and **TA 6-7** in **TA 6**, Water Quality, for robustness plots of the percentage of futures in which the salinity concentration is less than salinity criteria below Hoover Dam, below Parker Dam, and at Imperial Dam in 100 percent of years.

In a vulnerability analysis of conditions that could cause salinity concentrations below Hoover Dam to exceed 723 mg/L in one or more years, if the future includes a 10-year average flow of 11.8 maf or lower, modeling results do not indicate undesirable performance for all alternatives; over 75 percent of the reference hydrology include averages this low or lower. Further, the hydrologic conditions associated with undesirable performance for the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) (6.8 maf) are less than that of any previously observed conditions in the reference hydrology (7.8 maf). See **Figure TA 6-8** in **TA 6**, Water Quality, for additional information on the vulnerability plot displaying conditions that could cause salinity below Hoover Dam to exceed 723 mg/L in one or more years under each alternative.

Issue 2: How would reservoir storage, reservoir releases, and the corresponding changes in river flows downstream of the reservoirs affect water temperature?

Water temperature strongly influences biological and chemical processes. For example, the temperature of dam releases affects fish population dynamics in downstream river segments, and elevated reservoir temperatures can lead to harmful algal blooms. **Sections TA 8.2.3**, Issue 2 and **TA 8.2.5**, Issue 4 in **TA 8**, Biological Resources – Fish and Other Aquatic Species, describe the impacts of temperature on fish and other aquatic species at temperature thresholds of 12 °C, 16 °C, and 20 °C (53.6 °F, 60.8 °F, and 68 °F).

Using outputs from GCMRC Dissolved Oxygen and Temperature Models for Glen Canyon, Lees Ferry, and Grand Canyon, the annual average of daily temperatures and annual maximum Colorado River temperatures at Lees Ferry were simulated under various hydrologic conditions. As shown in **Figure TA 6-9** in **TA 6**, Water Quality, at Lees Ferry under the Average Flow Category, the Enhanced Coordination and Maximum Operational Flexibility Alternatives had lower median simulated annual average and maximum daily temperatures, with a narrower interquartile range, compared with the other alternatives at both Lees Ferry and Pearce Ferry.

Under the Dry and Critically Dry Flow Categories, simulated median values for temperatures increased across alternatives, compared with the Wet and Moderately Wet Flow Categories, and the Enhanced Coordination Alternative had the lowest median values for simulated average and maximum temperatures. Additionally, the interquartile ranges increased across all alternatives, indicating more variability in the annual average of daily temperatures and maximum temperatures as flow conditions become drier. For additional information on the simulated average and maximum Colorado River temperatures at Lees Ferry under various hydrologic conditions, see **TA 6**, Water Quality.

Considering the impacts on fish and other aquatic species, the Enhanced Coordination Alternative had the greatest number of simulated futures that maintained cooler water temperatures at Lees Ferry. These cooler temperatures are beneficial for rainbow trout, and they limit smallmouth bass reproduction, but these temperatures also inhibit native fish growth and reproduction. See **TA 8**, Biological Resources – Fish and Other Aquatic Species, for additional information on changes in water temperature from Glen Canyon Dam downstream through the Grand Canyon to Pearce Ferry and impacts to sportfish, native Grand Canyon fish, and nonnative predatory fish. See **TA 14**, Recreation, for more detailed information on temperature impacts associated with sportfish populations.

Issue 3: How would reservoir storage, reservoir releases, and the corresponding changes in river flows downstream of the reservoirs affect dissolved oxygen?

Dissolved oxygen dynamics can be affected by reservoir drawdowns through several pathways, including remobilization of deposited sediment as water levels change. As older reservoirs like Lake Powell experience lower elevations, there is greater metalimnion dissolved oxygen consumption, with larger spring snowmelt inflows furthering dissolved oxygen declines (Deemer et al. 2025). Dissolved oxygen is also affected by certain operations. For example, as reservoir levels decrease below 3,490 feet at Lake Powell, use of the river outlet works is triggered; this leads to high dissolved oxygen concentrations downstream of Glen Canyon Dam due to aeration as water passes through the river outlet works (Vernieu 2010).

Using outputs from GCMRC Dissolved Oxygen and Temperature Models for Glen Canyon, Lees Ferry, and Grand Canyon, minimum annual dissolved oxygen concentrations released from Glen Canyon Dam under each alternative were simulated under various hydrologic conditions. Under dry conditions, the Enhanced Coordination and Maximum Operational Flexibility Alternatives generally had higher simulated minimum annual dissolved oxygen concentrations than the other alternatives, but generally lower simulated minimum annual dissolved oxygen concentrations under critically dry conditions. See **Figure TA 6-11** in **TA 6**, Water Quality, for additional information on minimum annual dissolved oxygen concentration released from Glen Canyon Dam under various hydrologic conditions.

Below 3,490 feet at Lake Powell, releases from the river outlet works would effectively aerate the water, but its use would be limited over the long term to protect Glen Canyon Dam infrastructure. Therefore, elevation at Lake Powell below 3,490 feet and minimum annual dissolved oxygen concentration greater than 2 mg/L were considered. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust, meeting the preferred level of performance in a majority of futures for the first decadal period (that is, 2027-2039). The simulated minimum dissolved oxygen concentrations are greater than 2 mg/L in the fewest number of futures under the CCS Comparative Baseline and the No Action and Basic Coordination Alternatives in the first decadal period (that is, 2027-2039). See **Figure TA 6-12** in **TA 6**, Water Quality, for additional information on the robustness of minimum annual dissolved oxygen concentration where the Lake Powell elevation stays above 3,490 feet.

Due to the limitation of long-term use of the river outlet works, vulnerability was only analyzed for conditions that could cause dissolved oxygen concentration less than 2 mg/L or Lake Powell elevation below 3,490 feet in more than 10 percent of years. Only the Enhanced Coordination and Maximum Operational Flexibility Alternatives resulted in undesirable performance (dissolved oxygen concentrations from Glen Canyon Dam releases falling below 2 mg/L or Lake Powell elevations below 3,490 feet) below the lowest 25 percent of previously observed hydrologic conditions. The hydrologic conditions associated with undesirable performance for the CCS Comparative Baseline and the No Action, Basic Coordination, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives fall within a majority of hydrologic conditions that have already been observed. See **Figure TA 6-14** in **TA 6**, Water Quality, for additional information on the vulnerability analysis of conditions that could cause a dissolved oxygen concentration less than 2 mg/L or Lake Powell elevation below 3,490 feet in more than 10 percent of years.

Dissolved oxygen impacts on fish were also analyzed by considering dissolved oxygen concentrations less than 3 mg/L, which is a concentration that leads to reduced survival and feeding efficiencies. Under the Critically Dry Flow Category (4.46–10.0 maf), Lake Powell elevations stay above 3,490 feet, and the simulated minimum annual dissolved oxygen concentration is greater than 3 mg/L, which is critical for fish survival and feeding efficiencies, in at least 90 percent of the years in the greatest percent of futures under the Enhanced Coordination Alternative. See **TA 8**, Biological Resources – Fish and Other Aquatic Species, for more information on the impact of dissolved oxygen on fish.

Issue 4: How would reservoir storage, reservoir releases, and the corresponding changes in river flows downstream of the reservoirs affect harmful algal blooms and nutrients?

Cyanobacteria blooms can alter physical and chemical water quality properties, threaten aquatic species, and release toxins into waterbodies, leading to health effects on recreationists and affecting water supplies. In a mixed-methods literature review assessing risk for cyanobacteria and phytoplankton in response to water level changes, with potential application to Lake Powell and Lake Mead, cyanobacteria were substantially more likely to increase in response to decreases in water levels. The review also suggested that the prevalence of cyanobacteria increases when reservoir water levels decline, subsequently increasing the risk of cyanobacterial blooms in reservoirs with more severe fluctuations in water levels (Hoffman 2025). However, examples also exist of no marked water quality response to long-term water level drawdown, including at Lake Mead. For example, Lake Mead

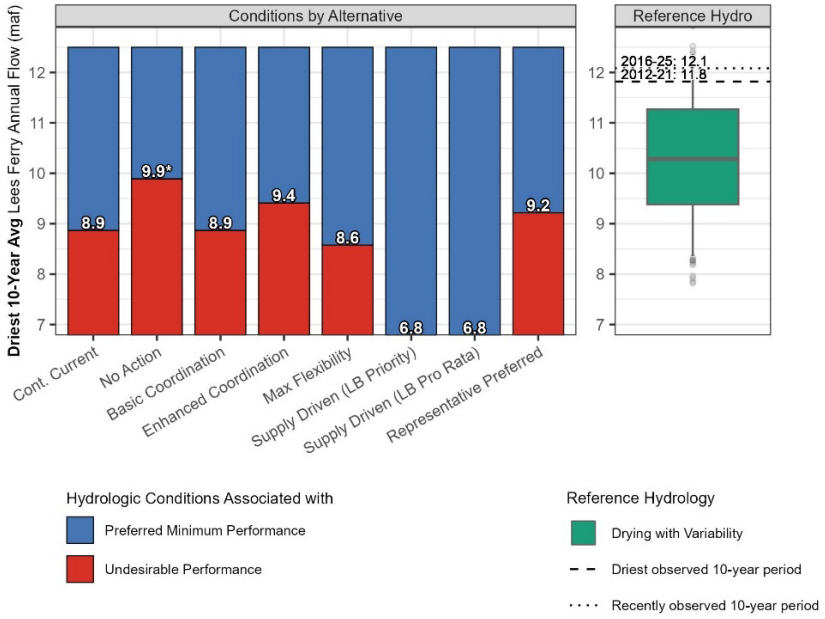
experienced dramatic multiyear reductions in the water level with no apparent effects on nutrient or chlorophyll concentrations (Hannoun and Tietjen 2022).

In a qualitative analysis of simulated reservoir elevations at Lake Powell, the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would pose an increased risk of cyanobacterial blooms due to the lower simulated Lake Powell elevations. These increased risks would be greatest under the Critically Dry Flow Category (4.46–10.0 maf) associated with lower reservoir elevations. The Enhanced Coordination and Maximum Flexibility Alternatives had the greatest number of simulated futures in which the maximum annual change in water surface elevation was less than 30.71 feet in 5 years or more out of 10 years during the first decadal period (that is, 2027-2039). This could decrease the risk of cyanobacterial blooms associated with severe fluctuations in water levels under the Enhanced Coordination and Maximum Flexibility Alternatives, compared with the other alternatives. For additional information about water quality impacts related to cyanobacteria, see **Section TA 6.2.5**, Issue 4, in **TA 6**, Water Quality. For additional information on how operational activities for the various alternatives would affect reservoir elevations, see **Section TA 3.2.1**, Issue 1: Reservoir Elevations, in **TA 3**, Hydrologic Resources.

Issue 5: How would reservoir storage and reservoir releases affect reservoir dilution capacity?

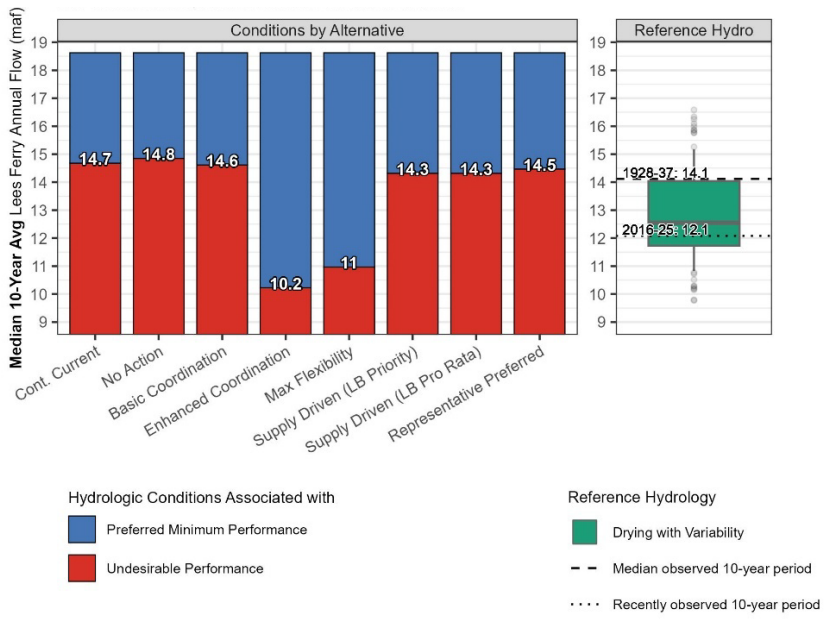
Generally, as reservoir elevations decrease, the dilution capacity of reservoirs like Lake Powell and Lake Mead also decreases. Decreased dilution capacity from lower reservoir elevations could result in greater concentrations of pollutants of concern, such as PFAS and perchlorate.

Given the current data and modeling capabilities, the impacts of the alternatives on pollutants of concern could not be quantitatively assessed. A qualitative review of reservoir elevations under **Section TA 3.2.1**, Issue 1: Reservoir Elevations, indicates that the impact of decreased dilution capacity associated with lower reservoir elevations on pollutants of concern, such as PFAS and perchlorate, would be greatest under the alternatives with the lowest median WY minimum reservoir elevations, including the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives. However, this impact would likely be negligible since it is unlikely that any of the reservoir elevations under the alternatives would significantly reduce dilution capacity or increase the concentration of pollutants of concern.



Summary Comparison of Alternatives

In a comparison of the vulnerability analyses for conditions that could cause undesirable performance for simulated salinity and dissolved oxygen, **Figure 3-19** shows that, generally, the CCS Comparative Baseline, and the No Action, Basic Coordination, and Representative Preferred Alternatives are vulnerable to undesirable performance under a relatively wide range of conditions for both simulated salinity and dissolved oxygen compared to the least vulnerable alternatives. **Figure 3-19** also shows that there are vulnerability trade-offs between the two indicators associated with the other alternatives.



Considering simulated salinity, under the Supply Driven Alternative (both the LB Priority and LB Pro Rata approaches), the hydrologic conditions associated with undesirable performance (a 10-year drought averaging 6.8 maf or lower) are drier than any conditions in the observed record or the reference hydrology ensemble, in which the lowest 10-year drought averaged 7.8 maf, so they have

Figure 3-19
Conditions that Could Cause Undesirable Performance for Salinity and Dissolved Oxygen

Salinity*

Dissolved Oxygen**

*Undesirable performance for salinity means conditions that could cause salinity below Hoover Dam above 723 mg/L in one or more years.
**Undesirable performance for dissolved oxygen means conditions that could cause dissolved oxygen concentration less than 2 mg/L or Lake Powell elevation below 3,490 feet in more than 10 percent of years.

low vulnerability. However, vulnerability with respect to dissolved oxygen is high: the median 10-year-average flows associated with undesirable performance under the Supply Driven Alternative (both the LB Priority and LB Pro Rata approaches) was 14.3 maf; this is wetter than the median observed 10-year period flow from 1928 to 1937 (14.1 maf). Additionally, almost 75 percent of the traces in the reference hydrology ensemble have median 10-year average flows drier than this.

Similarly, there are vulnerability trade-offs associated with the Enhanced Coordination and Maximum Operational Flexibility Alternatives. Considering simulated dissolved oxygen, the Enhanced Coordination Alternative would be vulnerable if the median 10-year-average flow was 10.2 maf or drier, and the Maximum Operational Flexibility Alternative would be vulnerable in the median 10-year-average flow was 11 maf or drier; these conditions are drier than 90 to 100 percent of the traces in the refence hydrology ensemble and far below any observed 10-year-average flow. However, considering simulated salinity, the Enhanced Coordination and Maximum Operational Flexibility Alternatives result in undesirable performance under hydrologic conditions that are greater than the Supply Driven Alternative (both the LB Priority and LB Pro Rata approaches). Still, more than 75 percent of the traces in the reference hydrology ensemble are wetter than these values, so the vulnerability is not high.

In comparison of relative values for Lake Powell's reservoir elevation and the Colorado River temperature at Lees Ferry, the alternatives that had higher reservoir elevations would decrease the risk for cyanobacterial blooms and increase the dilution capacity for pollutants. These alternatives also had lower temperatures. This is because the Colorado River temperature at Lees Ferry is influenced in part by Lake Powell's reservoir elevation. The Enhanced Coordination Alternative had the highest median values for WY minimum Lake Powell elevations and the lowest average and maximum temperatures, compared with the other alternatives. The Maximum Operational Flexibility Alternative also had some of the highest median values for WY minimum Lake Powell elevations and some of the lowest average and maximum temperatures, compared with the other alternatives. The Representative Preferred Alternative had the third highest median WY minimum.

Lake Powell elevation so this alternative poses a decreased risk for cyanobacterial blooms and decreased risk of greater concentration of pollutants of concern but it is unlikely that any of the reservoir elevations of the alternatives would substantially reduce the dilution capacity and increase the concentration of pollutants of concern.

Overall, the Enhanced Coordination and Maximum Operational Flexibility Alternatives had the lowest vulnerability for dissolved oxygen and relatively lower maximum and average Colorado River temperatures at Lees Ferry, compared with the other alternatives. These two alternatives were slightly more vulnerable with respect to simulated salinity compared with the Supply Driven Alternative (both the LB Priority and LB Pro Rata approaches); however, the hydrologic condition associated with undesirable salinity performance for the Enhanced Coordination and Maximum Operational Flexibility Alternatives were still drier than more than 75 percent of the traces in the reference hydrology ensemble.

3.7 Air Quality

3.7.1 Affected Environment

This section presents the existing conditions, regulatory framework, applicable laws, and available studies and resources related to air quality. Congress enacted the Clean Air Act (CAA) to ensure acceptable and nonhazardous air quality for the people of the U.S. The EPA subsequently established the National Ambient Air Quality Standards (NAAQS) for pollutants considered harmful to public health and the environment, referred to as criteria pollutants (EPA 2025a). **Table TA 7-1**, in **TA 7**, shows the current NAAQS for each pollutant, which have been fully adopted by Utah, Arizona, and Nevada. The air pollutant sources in Arizona, Nevada, and Utah fall under different jurisdictions and each state implements regulations that further govern fugitive dust, which are discussed in more detail in **Section TA 7.1.4.**

For each criteria pollutant, the EPA classifies areas as in "attainment" if the area complies with the NAAQS or as "nonattainment" if one or more of the NAAQS are exceeded. Areas for which available data are not sufficient to make an attainment status designation are listed as unclassifiable. Air quality is considered in "attainment" or "unclassifiable" for all criteria pollutants within the Arizona counties of La Paz, Mohave, Coconino, Yavapai, and Navajo and the Utah counties of Washington, Kane, and San Juan. Clark County, Nevada, has been designated as serious nonattainment for the 2015 8-hour ozone (O_3) standard and a maintenance area for carbon monoxide (CO) and particulate matter less than 10 microns in diameter (PM_{10}); the county is considered in "attainment" or "unclassifiable" for all other pollutants (EPA 2025b). Air quality within Yuma County, Arizona, has been designated as marginal nonattainment for the 2015 8-hour O_3 standard and moderate nonattainment for PM_{10}; it is considered in "attainment" or "unclassifiable" for all other pollutants. Therefore, the General Conformity Rule would apply for O_3, CO, and PM_{10}. The general conformity de minimis thresholds for all pollutants are presented in **Table TA 7-2**.

CAA regulations also control the release of hazardous air pollutants (HAPs), which are chemicals that are known or suspected to cause cancer or other serious health effects. The NAAQS have not been set for HAPs; rather, HAP emissions are controlled by source type– or industrial sector–specific regulations using maximum achievable control technology standards. There are no project-specific applicable maximum achievable control technology requirements regarding HAPs, as these standards only apply to stationary sources within specific industrial groups.

Several tables present the existing conditions for the analysis area. Criteria pollutants are monitored throughout various parts of the country. The EPA uses the criteria pollutant monitoring data to determine a "design value" for each pollutant and averaging time, which can be compared with the NAAQS. The most recent available 2024 design values for the analysis area counties are provided in **Table TA 7-3**, **Table TA 7-4,** and **Table TA 7-5**. The design value for O_3 for Clark County exceeds the NAAQS for O_3 (0.70 parts per million), and the number of exceedances of the PM_{10} NAAQS exceeds the standard for Clark County. No other design value listed in **Table TA 7-3**, **Table TA 7-4,** and **Table TA 7-5** exceed or approach proximity to the NAAQS (EPA 2025c). In addition, triennially, the EPA publishes a comprehensive summary of air emissions data, known as the National Emissions Inventory (NEI). **Table TA 7-7** through **Table TA 7-10** present the most recent 2020 emissions for the six criteria air pollutants and HAPs for the U.S.; the states of Arizona, Nevada, and Utah; and all

counties in the analysis area. The EPA uses the NEI to develop and review regulations, conduct air quality modeling, and conduct risk assessments to understand how air pollution may affect the health in communities across the country.

As set forth in the CAA, the EPA developed and implemented the Prevention of Significant Deterioration (PSD) regulations to protect public health and welfare and to preserve, protect, and enhance the air quality in areas of special value. As part of the PSD, the EPA classifies airsheds as Class I, which are areas for which the PSD regulations provide special protection, or Class II, which allows for moderate pollution increases and reasonable growth, while still applying stringent air quality constraints (NPS 2023a). **Table TA 7-11** presents the Class I areas located within the analysis area and those located in counties adjacent to the analysis area. For those Class I areas that are national parks, the table also provides visibility data. **Table TA 7-11** shows that the visibility ranges from fair to good. In addition, the NPS monitors and evaluates deposition to identify parks that are most at risk and where conditions are declining or improving (NPS 2024a). **Table TA 7-12** shows that nitrogen deposition conditions are fair to poor and sulfur deposition conditions are good, with trend data unavailable for most locations.

Regional modeling, studies, and data discussed that pertain to the analysis area are as follows:

- Historical to present Lake Powell and Lake Mead pool elevations: Figures showing the Lake Powell pool elevations for 1963 through 2025 and the Lake Mead pool elevations for 1935 through 2025.
- Lake Powell and Lake Mead Modeling: This is a 2024 study to model the exposed shoreline area and potential dust emissions at the two reservoirs (Sankey et al. 2024).
- Lake Mead Annual High and Low Elevations: Annual high and low elevations of Lake Mead for years 1935–2024 are available from Reclamation.
- Lake Powell Annual High and Low Elevations: Annual high and low elevations of Lake Powell for years 1964–2024 are available from Reclamation.
- Lake Mead Mapping: The USGS completed a detailed geophysical mapping of the floor of Lake Mead during 1999, 2000, and 2001. These data indicate that a large volume of sediment carried by the Colorado River has accumulated in Lake Mead.
- Lake Powell Mapping: This is a survey of Lake Powell for the purpose of calculating the elevation-area-capacity relationships in Lake Powell.
- Impact of Lost Generation at the Glen Canyon Powerplant: This report presents data showing the changes in generation sources for each of the years 2024–2027.
- Owens Lake California Environmental Quality Act (CEQA) Initial Study: Discussed the Owens Lake Dust Mitigation Program and the objective to implement dust control measures on Owens Lake to reduce emissions. The potential future change for Lake Powell and Lake Mead may also highlight the need for a similar dust mitigation program, should water levels decrease below 500 km^2, for each lake.

Past and present climate trends and impacts are provided for Nevada, Arizona, and Utah. An analysis of regional climate impacts concluded that the rate of average annual temperature increases in the southwest U.S. was among the most rapid nationally (IPCC 2021). Analysis of past records indicates an overall increase in regional temperatures, including in the analysis area. The National Oceanic and

Atmospheric Administration's National Centers for Environmental Information released its climate summaries by state in 2022. The climate summaries for the analysis area states are summarized. More detailed climate discussions for each state can be found through the State Climate Summaries web page (NOAA 2022).

3.7.2 Environmental Consequences

Methodology

This section examines potential effects on air quality resources under the action alternatives and the No Action Alternative, compared with the CCS Comparative Baseline. Potential impacts are considered for the following air quality resources: shoreline exposure area, fugitive dust emissions, and how changes in hydropower impact CO_2e.

CRSS is used in the hydrologic analysis, and the output is organized into five flow condition categories. The five flow condition categories are framed as the Wet Flow Category (16.0–31.11 maf), Moderately Wet Flow Category (14.0–16.0 maf), Average Flow Category (12.0–14.0 maf), Dry Flow Category (10.0–12.0 maf), and Critically Dry Flow Category (4.46–10.0 maf). There are 400 different hydrologic traces for each year over a 34-year period, as shown in **Figure TA 7-2** in **TA 7**, Air Quality.

To support evaluating how potential changes in reservoir water storage might affect potential dust emissions from subaerially exposed reservoir sediment, the subaerial shoreline area and potential dust emissions within Lake Powell and Lake Mead were modeled for this analysis. The shoreline exposure analysis used previously published topographic and bathymetric surveys and geologic mapping (Hirschberg and Pitts 2000; Jones and Root 2021, 2022; Ferrari 2001; Root et al. 2019; Root and Jones 2022; Twichell et al. 2003; Twichell and Cross 2009; Wilson et al. 1969) with new predictions of potential dust emissions using the FENGSHA model (Mallia et al. 2017). The results are presented as Glen Canyon and Lake Mead exposed shoreline area and associated emission rates (Fischella et al. 2026). Resource modeling predicts: 1) the area of subaerial shoreline exposed as a function of monthly water surface elevations at Lake Powell and Lake Mead (respectively); 2) potential dust emissions ($kg/m^2/hr$) as a function of monthly water surface elevations at Lake Powell and Lake Mead modeled using FENGSHA with sustained winds for 15 m/s (approximately 35 miles per hour) for 6 hours. The results are presented as Glen Canyon and Lake Mead exposed shoreline area and associated emission rates (Fischella et al. 2026). Impacts on shoreline exposure and fugitive dust emissions are then described using conditional box plots, as well as DMDU robustness heat maps and vulnerability bar plots. In a conditional box plot, the bold center line of each box represents the median value, the top and bottom of each box capture the 25th to 75th percentile of the modeled results, the lines extend to the 10th and 90th percentiles, and the outliers are represented as dots beyond these lines. Refer to **Appendix E**, DMDU Overview and Approach, for an overview of how to interpret the DMDU robustness heat maps and vulnerability bar plots.

Subaerially exposed shoreline area and potential dust emissions increase as water storage decreases. However, the relationships differ at the two reservoirs due to surficial geology, deposition of reservoir sediment, and topographic and bathymetric terrain; Glen Canyon Dam impounded a deep canyon-bound segment of the Colorado River at Lake Powell, whereas Hoover Dam impounded a comparably broader valley of the river at Lake Mead. When Lake Powell and Lake Mead are filled to minimum power pool, approximately 500 km^2 (123,552 acres) of shoreline is exposed at each

reservoir, although this estimate is highly approximate. The minimum power pool, or the lowest reservoir water level at which turbines can continue generating electricity efficiently, is 3,450 feet for Lake Powell and 950 feet for Lake Mead.

Lake Mead $PM_{2.5}$ emissions below 500 million kg (1,102 million pounds) ensures that fugitive dust would be minimized protecting air quality in the area and represents the reasonable approximation of the emission value that would occur when the lake is full enough with water to operate the dam to generate power. Lake Powell $PM_{2.5}$ emissions below 450 million kg (992 million pounds) ensures that fugitive dust would be minimized protecting air quality in the area and represents the reasonable approximation of the emission value that would occur when the lake is full enough with water to operate the dam to generate power.

The increase or decrease in metric tons of CO_2e emissions due to changes in hydropower generation at Glen Canyon Dam, Hoover Dam, Parker Dam, and Davis Dam are presented in conditional box plots. The conditional box plot for each dam compares the median CCS Comparative Baseline generation to the median generation for each alternative and multiple natural flow groups. In each year of every modeled future, the difference in annual hydropower generation between the CCS Comparative Baseline and each alternative was computed to determine the change in generation, whether that be an increase or a decrease. The annual change in generation was multiplied by the 2025 and 2050 Emissions and Generation Resource Integrated Database/National Laboratory of the Rockies emission factor. **Table TA 7-19** and **Table TA 7-20** in **TA 7**, Air Quality, show how the 2025 and 2050 weighted average emission factors were calculated. These emission factors represent the potential CO_2e from each resource type per megawatt-hour (MWh) and the current and future resource mix percentages for the Western Regional Climate Center energy production. The weighted emission factors are multiplied by the changes in MWh for each alternative and flow category.

Impact Analysis Area

The geographic scope of the air quality resources analysis includes Lake Powell to the SIB, which includes Mohave, Coconino, Yavapai, and Navajo Counties in Arizona; Washington, San Juan, and Kane Counties in Utah; and Clark County, Nevada. Specifically, the shoreline exposure analysis area includes Lake Powell and Lake Powell. The analysis areas for changes in CO_2e due to hydropower generation include Glen Canyon Dam, Hoover Dam, Parker Dam, and Davis Dam. The climate trends analysis area is discussed for the western U.S.

Assumptions

- The hydrologic resources results are direct results from CRSS. Refer to **Appendix A**, CRSS Model Documentation, for more details related to model assumptions and documentation.
- The National Laboratory of the Rockies publishes life cycle assessments and which CO_2e emission factors are associated with each type of electricity generation (NLR 2021).
- The EPA 2023 Emissions and Generation Resource Integrated Database was used to determine the North American Electric Reliability Corporation resource mix (coal, natural gas, oil, nuclear, hydropower, biomass, wind, solar, and geothermal sources) for the Western Electricity Coordinating Council region (EPA 2025d).
- The U.S. Energy Information Administration's Annual Energy Outlook 2023 (EIA 2023) provides the potential generation mix for 2050.

The equivalency calculator is used to convert emissions into concrete, understandable terms, such as the annual CO_2 emissions of cars, households, and powerplants (EPA 2025e).

Impact Indicators

Specific impact indicators were selected to help frame the air quality resources analysis for each alternative. The following indicators were used to assess impacts:

- Shoreline Exposure: These are effects on the shoreline exposure area due to operational activities.
- Shoreline Dust Emissions: These are effects on shoreline dust emissions due to operational activities.
- Potential Change of CO_2e Emissions due to a Fluctuation of Hydropower Generation: These are effects on CO_2e emissions due to operational activities.

Issue 1: How would changing flow characteristics affect the potential exposed shoreline, fallowed agricultural lands, and fugitive dust?

Changes in water storage in lakes can affect the area of shoreline sediment exposed subaerially and potentially available for aeolian transport. This resource modeling evaluates how potential changes in reservoir water storage might affect potential dust emissions from subaerially exposed reservoir sediment. Relationships between potential dust emissions and water storage could be useful for evaluating air quality and related resource impacts associated with Colorado River water management decisions.

Figure TA 7-4 in **TA 7**, Air Quality, shows the WY maximum exposed shoreline area for Lake Powell and Lake Mead. In the Average Flow Category (12.0–14.0 maf), Lake Powell alternatives have varying distributions, with the 25th to 75th percentiles across all alternatives spanning from 225 to 500 km^2 (55,598 to 123,552 acres) of maximum exposed shoreline. The CCS Comparative Baseline, as well as the No Action, Basic Coordination, Representative Preferred and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, all show similar medians of roughly 400 km^2 (98,842 acres) of maximum exposed shoreline. The Enhanced Coordination and Maximum Operational Flexibility Alternatives have lower and comparable medians of about 300 km^2 (74,132 acres) of maximum exposed shoreline.

The Lake Mead alternatives have varying Average Flow Category distributions, with the 25th to 75th percentiles across all alternatives spanning from 125 to 500 km^2 (30,888 to 123,552 acres) of maximum exposed shoreline. The Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative has the lowest median maximum exposed shoreline, at about 230 km^2 (56,834 acres). The No Action Alternative has the highest median value at roughly 470 km^2 (66,718 acres). The Representative Preferred Alternative has a median maximum exposed shoreline of about 300 km^2 (74,132 acres), with the 25th to 75th percentiles across all alternatives spanning from 220 to 390 km^2 (54,393 to 96,371 acres) of maximum exposed shoreline.

In the Dry Flow Category (10.0–12.0 maf), the 25th to 75th percentiles across all Lake Powell alternatives span from approximately 300 to 545 km^2 (74,132 to 134,672 acres) of maximum exposed shoreline. The Enhanced Coordination and No Action Alternatives have the lowest and highest median maximum exposed shoreline at about 365 and 520 km^2 (90,194 and 128,495 acres),

respectively. For Lake Mead, the 25th to 75th percentiles across all alternatives span from approximately 200 to 530 km^2 (49,421 to 130,966 acres) of maximum exposed shoreline. The Supply Driven (both LB Priority and LB Pro Rata approaches) and No Action Alternatives have the lowest and highest median maximum exposed shoreline at about 360 and 490 km^2 (88,598 and 121,082 acres), respectively.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Lake Powell maximum exposed shoreline, the median maximum exposed shoreline is about 450 km^2 (111,197 acres), with the 25th to 75th percentiles across all alternatives spanning from 415 to 475 km^2 (102,549 to 117,375 acres) of maximum exposed shoreline. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Lake Powell maximum exposed shoreline, the median maximum exposed shoreline is about 495 km^2 (122,317 acres), with the 25th to 75th percentiles across all alternatives spanning from 484 to 520 km^2 (119,599 to 128,495 acres) of maximum exposed shoreline. For the Lake Mead maximum exposed shoreline, the median maximum exposed shoreline is about 400 km^2 (98,842 acres), with the 25th to 75th percentiles across all alternatives spanning from 280 to 445 km^2 (69,190 to 109,962 acres) of maximum exposed shoreline. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Lake Mead maximum exposed shoreline, the median maximum exposed shoreline is about 450 km^2 (111,197 acres), with the 25th to 75th percentiles across all alternatives spanning from 395 to 489 km^2 (97,606 to 120,835 acres) of maximum exposed shoreline.

Lake Mead Robustness

Figure TA 7-5 in **TA 7**, Air Quality, depicts the ability of each alternative to maintain Lake Mead shoreline exposure below the specified area in every month. The preferred minimum performance is shown in the purple highlighted row, which represents the percentage of futures in which the exposed shoreline area for each alternative remains below 500 km^2 (123,552 acres) in every month. For Lake Mead, 500 km^2 (123,552 acres) is a very rough approximation of the area of shoreline exposed when the reservoir is filled to minimum power pool (950 feet). Keeping the Lake Mead shoreline exposure below 500 km^2 (123,552 acres) ensures that fugitive dust will be minimized. Four modeling periods are shown to capture the full modeling period, 2027-2039, 2040-2049, and 2050-2060. The color of a heat map square corresponds with the percent of futures that meet the specified level of performance, which increases from less than 10 percent of futures keeping the Lake Mead shoreline exposure area below the specified value in every month (least robust), to greater than 91 percent of futures keeping the Lake Mead shoreline exposure area below the specified value in every month (most robust). The higher the percentage, the more probable Lake Mead shoreline exposure will remain below the specified km^2 under most future hydrologic scenarios.

Figure TA 7-5 in **TA 7**, Air Quality, shows that the Enhanced Coordination, Representative Preferred, and Maximum Operational Flexibility Alternatives are the most robust at staying below 500 km^2 (123,552 acres) of shoreline exposure over the full modeling period (shown in the top row), doing so in 80 percent, 82 percent, and 88 percent of modeled futures, respectively. The No Action Alternative has the worst performance at a 35 percent success rate over the full analysis period.

In the first decadal breakout (2027–2039), the Representative Preferred, Maximum Operational Flexibility, and Enhanced Coordination Alternatives meet the preferred minimum performance in 92

percent, 93 percent and 88 percent of modeled futures, respectively, which is more robust than the other alternatives. The No Action Alternative has the worst performance at a 54 percent success rate over the full analysis period.

For the full modeling period, 2027–2039 modeling period, 2040–2049 modeling period, and 2050–2060 modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives consistently achieve 71–100 percent robustness, while the No Action Alternative only reaches a maximum of 51 percent robustness at even the lowest levels of performance for the 500 km^2 (123,552 acres) of shoreline exposure category.

Figure TA 7-6 in **TA 7**, Air Quality, shows flow conditions that could cause the Lake Mead shoreline exposure area to be above 500 km^2 (123,552 acres) in one or more months. This definition of undesirable performance is based on the highlighted row in **Figure TA 7-5**, which defined a future as successful when exposed shoreline area for an alternative remains below 500 km^2 (123,552 acres) in every month. For this vulnerability analysis, the driest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

The Basic Coordination Alternative would likely be vulnerable to a Lake Mead exposed shoreline area greater than 500 km^2 (123,552 acres) under a 10-year average Lees Ferry natural flow of 10.2 maf or drier, which is slightly less vulnerable than the CCS Comparative Baseline, which is likely to be vulnerable if the 10-year average is 10.5 maf or drier. The No Action Alternative is vulnerable to a 10-year average of 11.4 maf, which is similar to the driest observed 10-year average of 11.8 maf. The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 8.7 maf or less. Compared to the historical periods shown in the reference hydrology panel, this flow has not occurred before. Compared to the Drying with Variability Ensemble that represents potential future hydrologic conditions, 100 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

Lake Powell Robustness

Figure TA 7-7 in **TA 7**, Air Quality, depicts the performance of each alternative with regard to keeping the Lake Powell shoreline exposure area below 500 km^2 (123,552 acres) in every month. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust at staying below 500 km^2 (123,552 acres) of shoreline exposure over the full modeling period (shown in the bottom row), doing so in 81 percent and 95 percent of the futures, respectively. The No Action Alternative has the worst performance at a 16 percent success rate over the full analysis period.

In the first decadal breakout (2027–2039), the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 87 percent and 98 percent of modeled futures, respectively. The No Action Alternative meets the preferred minimum performance in 25 percent of modeled futures. The CCS Comparative Baseline, as well as the Basic Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives meet the preferred minimum performance in 54 percent, 45 percent, and 46 percent of futures, respectively. Based on the

planned length of this decision, it is important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 66 percent of futures in the 2027-2039 modeling period.

For the full modeling period, 2027–2039 modeling period, 2040–2049 modeling period, and 2050–2060 modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives consistently achieve 81–100 percent robustness, while the No Action Alternative only reaches a maximum of 48 percent robustness at even the lowest levels of performance for the 500 km^2 (123,552 acres) of shoreline exposure category.

Figure TA 7-8 in **TA 7**, Air Quality, looks at flow conditions that could cause the Lake Powell shoreline exposure area to be above 500 km^2 (123,552 acres) in one or more months. This definition of undesirable performance is based on the highlighted row in **Figure TA 7-7**, Air Quality, which defined a future as successful when exposed shoreline area for an alternative remains below 500 km^2 (123,552 acres) in every month. For this vulnerability analysis, the driest 10-year average Lees Ferry annual flow was determined to be skillful at predicting undesirable performance. The vulnerability threshold for each alternative is described and compared to the Drying with Variability ensemble using this streamflow summary statistic. The driest observed 10-year average flow from 2012-2021 (11.8 maf) and the average flow from 2016-2025 (12.1 maf) are also provided as dashed and dotted lines, respectively, for comparison.

The Enhanced Coordination Alternative modeling results indicate undesirable performance at a 10-year average flow of 9 maf or drier, which occurs in less than 25 percent of the Drying with Variability traces. The Maximum Operational Flexibility Alternative is least vulnerable, with no Drying with Variability traces occurring below the undesirable performance level of 6.8 maf.

The Representative Preferred Alternative is likely to be vulnerable if the driest 10-year average Lees Ferry annual flow is 10.9 maf or less. Compared to the historical periods shown in the reference hydrology panel, this flow has not occurred before. Compared to the Drying with Variability Ensemble that represents potential future hydrologic conditions, 30 percent of the traces have a 10-year period drier than the vulnerability threshold for the Representative Preferred Alternative.

Shoreline Exposure

Figure TA 7-9 in **TA 7**, Air Quality, shows the WY maximum shoreline dust emissions for Lake Powell and Lake Mead. In the Average Flow Category (12.0–14.0 maf), Lake Powell alternatives have varying distributions, with the 25th to 75th percentiles across all alternatives spanning from approximately 105 to 460 million kg (231 to 1,014 million pounds) of particulate matter less than 2.5 microns in diameter ($PM_{2.5}$) as a result of shoreline exposure. The CCS Comparative Baseline and the Supply Driven (both LB Priority and LB Pro Rata approaches), Basic Coordination, and No Action Alternatives all have similar median maximum monthly emission rates of around 300 million kg of $PM_{2.5}$ as a result of shoreline exposure. The Enhanced Coordination and Maximum Operational Flexibility Alternatives have lower medians. Therefore, these two alternatives would result in less $PM_{2.5}$ than the other alternatives.

The Lake Mead alternatives have varying distributions, with the 25th to 75th percentiles across all alternatives spanning from 80 to 540 million kg (176 to 1,190 million pounds) of $PM_{2.5}$ emissions as a result of shoreline exposure. with the No Action and Supply Driven (both LB Priority and LB Pro

Rata approaches) Alternatives displaying the highest and lowest values at about 500 and 160 million kg (1,102 and 353 million pounds) of $PM_{2.5}$, respectively. As flow categories get drier for WY minimums, the medians for all Lake Powell and Lake Mead alternatives increase the millions of kg of $PM_{2.5}$. As flow categories get wetter for WY minimums, the potential $PM_{2.5}$ decreases.

Lake Mead Robustness

Figure TA 7-10 in **TA 7**, Air Quality, depicts the performance of each alternative with regard to keeping Lake Mead $PM_{2.5}$ below 500 million kg from a shoreline exposure area. The color of a heat map's square corresponds with the percentage of futures that meet this level of performance; the percentage increases from less than 10 percent of futures keeping the Lake Mead emissions below 100 million kg (220 million pounds) (least robust) to greater than 91 percent of futures keeping the Lake Mead emissions above 500 million kg (1,102 million pounds) (most robust). The higher the percentage, the more likely Lake Mead will remain above the minimum power pool (950 feet) under most future hydrologic scenarios. Keeping the Lake Mead emissions below 500 million kg (1,102 million pounds) ensures that fugitive dust would be minimized, which would protect air quality in the area.

The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust at staying below 500 million kg (1,102 million pounds) over the full modeling period, doing so in 69 percent and 76 percent of the futures, respectively. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) can meet the preferred minimum performance in 64 percent of modeled futures. The No Action Alternative has the worst performance at a 22 percent success rate over the full analysis period. The Representative Preferred Alternative meets staying below 500 million kg (1,102 million pounds) of shoreline dust emissions robustness criteria in 58 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it's important to note that it meets the preferred minimum performance level in 74 percent of futures in the first modeling period.

In the first decadal breakout (2027–2039), the Enhanced Coordination and Maximum Operational Flexibility Alternatives can meet the preferred minimum performance in 79 percent and 84 percent of modeled futures, respectively, which is more robust than the other alternatives. Based on the planned length of this decision, it is important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 74 percent of futures in the 2027-2039 modeling period.

For the full modeling period, 2027–2039 modeling period, 2040–2049 modeling period, and 2050–2060 modeling period, the Maximum Operational Flexibility Alternative consistently achieves 71–100 percent robustness.

Figure TA 7-11 in **TA 7**, Air Quality, looks at flow conditions that could cause Lake Mead emissions above 500 million kg (1,102 million pounds) during at least one or more months. The Enhanced Coordination, Maximum Flexibility, Representative Preferred, and Supply Driven (both LB Priority and LB Pro Rata) Alternatives are vulnerable to similar conditions: 10-year droughts of 9.9 maf, 9.6 maf, 10.2 and 10.2 maf, respectively. The CCS Continued Baseline is more vulnerable, with a 10-year drought of 11.0 maf likely to cause undesirable performance. The No Action Alternative is the most vulnerable; Lake Mead would likely go below 1,000 feet elevation in a 10-year drought averaging 12.1

maf. From 2012 to 2021, the 10-year average was 11.8 maf; therefore, the No Action Alternative is just below the vulnerability of conditions that have already occurred.

Lake Powell Robustness

Figure TA 7-12 in **TA 7**, Air Quality, depicts the performance of each alternative with regard to keeping Lake Powell $PM_{2.5}$ from a shoreline exposure area below 450 million kg (992 million pounds). The color of a heat map's square corresponds with the percentage of futures that meet this level of performance; the percentage increases from a less than 10 percent of futures keeping the Lake Powell emissions below 150 million kg (331 million pounds) (least robust), to a greater than 91 percent of futures keeping the Lake Powell emissions above 450 million kg (992 million pounds) (most robust). Keeping the Lake Powell emissions below 450 million kg (992 million pounds) ensures that fugitive dust would be minimized, which would protect air quality in the area.

The Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust at staying below 450 million kg, doing so in 78 percent and 91 percent of the futures, respectively. The Basic Coordination, Supply Driven (LB Priority approach), and Supply Driven (LB Pro Rata approach) Alternatives perform similarly to the CCS Comparative Baseline, if not slightly worse, succeeding in 21 percent, 22 percent, and 22 percent of futures, respectively, over the full analysis period. The No Action Alternative has the worst performance at a 10 percent success rate over the full analysis period. The Representative Preferred Alternative meets staying below 450 million kg (992 million pounds) of shoreline dust emissions robustness criteria in 38 percent of modeled futures in the full modeling period. Based on the planned length of this decision, it's important to note that it meets the preferred minimum performance level in 59 percent of futures in the first modeling period.

In the first decadal breakout (2027–2039), the Enhanced Coordination and Maximum Operational Flexibility Alternatives meet the preferred minimum performance in 84 percent and 96 percent of modeled futures, respectively, which is considerably more robust than the other alternatives. Based on the planned length of this decision, it is important to note that the Representative Preferred Alternative meets the preferred minimum performance level in 59 percent of futures in the 2027-2039 modeling period.

For the full modeling period, 2027–2039 modeling period, 2040–2049 modeling period, and 2050–2060 modeling period, the Maximum Operational Flexibility Alternatives consistently achieves 91–100 percent robustness (dark blue in color).

Figure TA 7-13 in **TA 7**, Air Quality, looks at flow conditions that could cause Lake Powell emissions above 450 million kg during at least one or more months. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are vulnerable to similar conditions: 10-year droughts of 9.2 and 6.8 maf, respectively. The No Action Alternative has a 10-year drought of 12.2, which is above the reference hydrology box plot averages for 2012–2021 (11.8 maf) and 2015–2024 (12.6 maf). Therefore, the No Action Alternative is more vulnerable and likely to cause undesirable performance.

Other effects are the potential dust-on-snow effects, which may occur when reservoir elevations are low, and there are more dust mobilization and potential acceleration of runoff. Also, changing flow characteristics can affect the fallowing of agricultural lands, especially in regions that rely on consistent irrigation from reservoirs.

Changes in flow characteristics may affect agricultural operations in regions dependent on reservoir-based irrigation, particularly if reduced dam releases decrease water availability for downstream users. In such cases, farmers may be forced to fallow some or all of their fields to conserve limited water supplies for higher-value crops and avoid unsupported planting and irrigation costs. As discussed in **TA 16.2.2** of **TA 16**, Socioeconomics, including **Figure TA 16-1**, estimates of potential fallowed acreage are based on simplifying assumptions regarding water availability, crop profitability, and agricultural decision-making and are intended for regional-scale economic analysis rather than site-specific predictions. Fallowed agricultural lands can be a source of fugitive dust emissions, especially under dry, unvegetated conditions. Screening-level estimates of windblown dust emissions can be developed using generalized U.S. EPA AP-42 emission factors, with PM_{10} emissions typically ranging from approximately 0.1 to 0.5 tons per acre per year depending on soil stability, vegetation cover, and wind exposure; $PM_{2.5}$ emissions are generally a smaller fraction of PM_{10} emissions. Because emissions depend on site-specific conditions such as soil characteristics, vegetation, wind, dust control measures, and the extent and timing of fallowing, these estimates are intended only to indicate the potential magnitude of fugitive dust emissions and are not site-specific predictions.

Clark County, Nevada, is the only county in the analysis area that has been designated as serious nonattainment for the 2015 8-hour O_3 standard and a maintenance area for CO and PM_{10} (EPA 2025b). The potential shoreline exposure discussed above has the potential to increase particulate matter that could further exacerbate the current PM_{10} issue in Clark County.

Issue 2: How would lake reservoir elevations and releases impact power generation and CO_2e emissions?

Issue 2 addresses how operational activities for the various alternatives affect reservoir elevations and, therefore, impact hydropower generation. When there is a change of hydropower, there would be a potential change in CO_2e emissions because emissive alternative energy generation with varying emissions would compensate for this reduction. The box plots compare present-day and potential future electricity mixes, reporting metric tons of CO_2e based on the 2025 resource mix emission factor on the left axis and the 2050 resource mix emission factor on the right axis, using the MWh increase or decrease for each alternative and flow category. Only the 2025 resource mix is discussed in detail. This is because the 2050 resource mix results would have lower metric tons of CO_2e because the emission factor includes more alternative energy resources.

Figure TA 7-14 in **TA 7**, Air Quality, shows the changes in CO_2e emissions due to a fluctuations in hydropower at Glen Canyon Dam for each flow category and the alternatives. In the Average Flow Category (12.0–14.0 maf), the Glen Canyon Dam alternatives have varying distributions of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 288-metric-ton decrease to a 115-metric-ton increase of CO_2e emissions. The No Action Alternative has a median close to zero, representing the smallest decrease relative to the CCS Comparative Baseline. The Enhanced Coordination (134 metric tons decrease of CO_2e) and Maximum Operational Flexibility (143 metric tons decrease of CO_2e) Alternatives have similar medians, resulting in the largest decrease in CO_2e emissions relative to the CCS Comparative Baseline.

In the Critically Dry Flow Category (less than 10.0 maf), all the alternatives, except the Enhanced Coordination and Maximum Operational Flexibility Alternatives, are projected to result in similar behavior, in terms of medians and variability, since they all show a potential increase of CO_2e

compared with the CCS Comparative Baseline. The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Glen Canyon Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 84-metric-ton decrease of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 275-metric-ton decrease to a 96-metric-ton increase of CO_2e emissions. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow category: For the Glen Canyon Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions results in a zero-metric-ton increase or decrease of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 153-metric-ton decrease to a 160-metric-ton increase of CO_2e emissions.

The Average Flow Category (12.0–14.0 maf) 75th percentile variance results in no more than a 115-metric-ton increase in CO_2e for the Supply Driven (LB Pro Rata approach) and Supply Driven (LB Priority approach) Alternatives, which is equivalent to 23.3 gasoline-powered passenger vehicles driven for 1 year or 20.8 homes' electricity for 1 year.

Figure TA 7-15 in **TA 7**, Air Quality, shows the changes in CO_2e emissions due to a fluctuation of hydropower at Hoover Dam for each flow category and the alternatives. The Hoover Dam powerplant has 17 commercial generators with a maximum combined capacity of 2,074 MW. The powerplant requires a minimum Lake Mead elevation of 950 feet to produce power. At minimum power pool, the powerplant has an estimated capacity of 117 MW. At Lake Mead elevation of 1,035 feet, Hoover Dam's generating capacity is drastically reduced from 1,274 to 382 MW. In the Average Flow Category (12.0–14.0 maf), the No Action Alternative has the highest median with a 244-metric-ton increase in CO_2e emissions, and the largest interquartile range, with the 25th percentile at 52 metric tons and the 75th percentile at 456 metric tons of CO_2e. The Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives have medians showing a decrease in metric tons of CO_2e emissions. The Basic Coordination Alternative shows a median near zero metric tons of CO_2e emissions.

In the Critically Dry Flow Category (less than 10.0 maf), the medians for the No Action and Basic Coordination Alternatives display no change in CO_2e emissions relative to the CCS Comparative Baseline. The Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives all have medians showing a decrease in metric tons of CO_2e emissions, with the Supply Driven Alternative (LB Pro Rata approach) showing the largest decrease at 158 metric tons of CO_2e. The 25th to 75th percentiles across all alternatives span from a decrease of 577 metric tons to an increase of 105 metric tons of CO_2e emissions. The No Action Alternative has the smallest interquartile range, while the Supply Driven Alternative (LB Pro Rata approach) has the largest. The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Hoover Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 146-metric-ton decrease of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 416-metric-ton decrease to a 75-metric-ton increase of CO_2e emissions. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Hoover Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 115-metric-ton decrease of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 374-metric-ton decrease to a zero-

metric-ton increase or decrease of CO_2e emissions. The Average Flow Category (12.0–14.0 maf) 75th percentile variance results in no more than a 456-metric-ton increase in CO_2e (under the No Action Alternative), which is equivalent to 90.3 gasoline-powered passenger vehicles driven for 1 year or 80.6 homes' electricity for 1 year.

Figure TA 7-16 in **TA 7**, Air Quality, shows the changes in CO_2e emissions due to a fluctuation of hydropower at Davis Dam for each flow category and the alternatives. In the Average Flow Category (12.0–14.0 maf), the Davis Dam alternatives exhibit varying distributions of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 19-metric-ton decrease to a 40-metric-ton increase in CO_2e emissions. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives display similar medians ranging from 19 to 26 metric tons of CO_2e increase. The Representative Preferred Alternative and Basic Coordination Alternative medians are similar at around 10 metric tons of CO_2e increase, while the No Action Alternative has an 8 metric ton decrease in CO_2e emissions. The No Action Alternative is the only alternative with both a median and 25th percentile below zero. In the Critically Dry Flow Category (less than 10.0 maf), the median for the Basic Coordination Alternative displays very little change in CO_2e emissions, while the No Action Alternative shows a 4 metric ton decrease of CO_2e emissions relative to the CCS Comparative Baseline.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Davis Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 15-metric-ton increase of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 2-metric-ton increase to a 31-metric-ton increase of CO_2e emissions. The Representative Preferred Alternative exhibits the following outcomes with respect to the critically Dry Flow Category: For the Davis Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 14-metric-ton increase of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 5-metric-ton decrease to a 32-metric-ton increase of CO_2e emissions.

The Maximum Flexibility and Enhanced Coordination Alternatives stay equal to or above the CCS Comparative Baseline under each flow category, except the Wet Flow Category (16.0–31.0 maf). Therefore, they perform consistently the worst. The Average Flow Category (12.0–14.0 maf) 75th percentile variance results in no more than a 40-metric-ton increase in CO_2e (under the Enhanced Coordination Alternative), which is equivalent to 10 gasoline-powered passenger vehicles driven for 1 year or 9 homes' electricity for 1 year.

Figure TA 7-17 in **TA 7**, Air Quality, shows the changes in CO_2e emissions due to a fluctuation of hydropower at Parker Dam for each flow category and the alternatives. In the Average Flow Category (12.0–14.0 maf), Parker Dam alternatives exhibit varying distributions of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 3-metric-ton decrease to a 25-metric-ton increase in CO_2e. Only the No Action and Basic Coordination Alternatives have medians that result in a decrease in CO_2e emissions; though, both are near a zero metric-ton change in CO_2e. The Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives have similar medians, ranging from near zero to a 5-metric-ton CO_2e increase. The Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives have the highest medians, exceeding an increase of 14 metric tons of CO_2e emissions.

In the Critically Dry Flow Category (less than 10.0 maf), the medians for the No Action, Basic Coordination, Supply Driven (LB Priority approach), and Representative Preferred Alternatives are similar, displaying a decrease in CO_2e emissions ranging from 2 to nearly zero metric tons. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (LB Pro Rata approach) Alternatives all have medians showing an increase in metric tons of CO_2e emissions, with Enhanced Coordination showing the largest increase at 23 metric tons of CO_2e.

The Representative Preferred Alternative exhibits the following outcomes with respect to the Dry Flow Category: For the Parker Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 2-metric-ton increase of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a zero-metric-ton increase to a 5-metric-ton increase of CO_2e emissions. The Representative Preferred Alternative exhibits the following outcomes with respect to the Critically Dry Flow Category: For the Parker Dam CO_2e emissions resulting from a loss of hydropower generation, the median CO_2e emissions is about a 1-metric-ton increase of CO_2e emissions, with the 25th to 75th percentiles across all alternatives spanning from a 3-metric-ton decrease to a 6-metric-ton increase of CO_2e emissions.

The Enhanced Coordination Alternative is the most reliable because it stays equal to or above the CCS Comparative Baseline under each flow category; therefore, it performs consistently the worst. The Average Flow Category (12.0–14.0 maf) 75th percentile variance results in no more than a 25-metric-ton increase in CO_2e (under the Enhanced Coordination Alternative), which is equivalent to 5.4 gasoline-powered passenger vehicles driven for 1 year or 4.8 homes' electricity for 1 year.

Issue 3: How would climate trends affect lake reservoir elevations?

Climate trends affect lake reservoir elevations in several interrelated ways, driven largely by changes in temperature, precipitation patterns, and hydrologic cycles. Climate trends typically cause more variability and extremes in lake reservoir elevations, including lower lows during droughts, higher highs during storm events, and greater management complexity overall. The following are potential events that could be affected by climate trends and that would potentially affect reservoir elevations:

- Reduced snowpack and earlier snowmelt
- Increased evaporation rates from both lake surfaces and the surrounding land
- Changes in precipitation patterns
- Increased water demand

As discussed in Issue 2, climate events may affect hydropower. Any reduction in hydropower would require other power-generation sources to increase to compensate. The regional power mix can be analyzed to determine the region's potential capacity in order to replace hydropower with other alternative energy sources. Using available information from the Emissions and Generation Resource Integrated Database (eGRID) for the analysis area, **Table TA 7-22** in **TA 7**, Air Quality, shows that renewables, such as hydropower, biomass, wind, solar, and geothermal sources, are 42.8 percent of the Western Electricity Coordinating Council's resource mix, compared with nonrenewable resources, such as coal, oil, nuclear, and gas, totaling 57.3 percent. If the 19.8 percent hydropower is reduced, both renewable and nonrenewable resources would compensate. Other generation sources would likely replace lost hydropower and the mix of replacement sources can vary. However, a recent Argonne study shows that when there is a reduction in hydropower at Glen Canyon Powerplant, the

replacement generation is from mostly natural gas–fired generation (gas-combined cycle) and generation from gas combustion turbines, with a small portion also coming from coal-fired generation for 2024 through 2027 (Veselka et al. 2024). In addition, as climate trends are further observed and monitored, Reclamation has an opportunity to discuss any strategies to increase management flexibility, enhance climate adaptation planning, and improve infrastructure resilience.

Summary Comparison of Alternatives

For the Lake Powell WY maximum exposed shoreline area Average Flow Category (12.0–14.0 maf), the alternatives all have similar medians and small variabilities, except the Enhanced Coordination and Maximum Operational Flexibility Alternatives, which have the lowest median km^2 of exposed shoreline and the smallest variability. For the Lake Mead WY maximum exposed shoreline area Average Flow Category (12.0–14.0 maf), the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives performed the best, with the lowest median shoreline exposure area. The CCS Comparative Baseline and No Action Alternative perform the worst and have the smallest variability. The Basic Coordination Alternative performs in the middle. These results are within the range analyzed across the other alternatives from this Final EIS.

For the full modeling period, the Lake Mead shoreline area robustness figure shows that the No Action Alternative performs the worst, with only 35 percent of the futures below 500 km^2 (123,553 acres) of shoreline area. The Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with 80 percent or more of the futures below 500 km^2 (123,553 acres) of shoreline area. These same trends were seen for the 2027–2039, 2040–2049, and 2050–2060 modeling periods with higher percentages. For the 2027–2039 modeling period and 2040–2049 modeling period, the Maximum Operational Flexibility and Enhanced Coordination Alternatives have 88 percent or more of the futures below 500 km^2 (123,553 acres) of shoreline area.

The Lake Mead vulnerability plot shows that the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are vulnerable to similar conditions and less than 50 percent of the Drying with Variability traces include a driest 10-year average Lees Ferry annual flow this dry or drier. The CCS Comparative Baseline and No Action Alternative are the most vulnerable at 10-year average flows of 10.5 maf and 11.4 maf, respectively.

For the full modeling period, the Lake Powell shoreline area robustness figure shows that the No Action Alternative performs the worst, with only 16 percent of the futures below 500 km^2 (123,553 acres) of shoreline area. The Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with over 80 percent of the futures below 500 square km^2 (123,553 acres) of shoreline area. Similar trends were seen for the 2027–2039, though with higher percentages. The 2040–2049 and 2050–2060 modeling periods show that the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs the worst, then the No Action Alternative. For the 2027–2039, 2040–2049, and 2050–2060 modeling periods, the Maximum Operational Flexibility and Enhanced Coordination Alternatives have 87 percent or more of the futures below 500 km^2 (123,553 acres) of shoreline area.

The Lake Powell vulnerability plot shows that the Enhanced Coordination and Maximum Operational Flexibility Alternatives are least vulnerable, as fewer than 25 percent of the Drying with Variability traces include a driest 10-year average Lees Ferry annual flow this dry or drier. The CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are vulnerable under flow conditions associated with more than 75 percent of the Drying with Variability traces and are therefore the most vulnerable.

For the Lake Powell WY maximum shoreline dust emissions Average Flow Category (12.0–14.0 maf), several alternatives have similar medians, though Enhanced Coordination and Maximum Operational Flexibility Alternatives have the lowest median shoreline dust emissions and the smallest variability.

For the Lake Mead WY maximum shoreline dust emissions Average Flow Category (12.0–14.0 maf), the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives performed the best, with the least shoreline dust emissions. The CCS Comparative Baseline and No Action Alternative perform the worst, with the highest shoreline dust emissions. The Basic Coordination Alternative performs in the middle.

For the full modeling period, the Lake Mead shoreline dust emissions robustness figure shows that the No Action Alternative performs the worst, with only 22 percent of the futures below 500 million kg (1,102 million pounds) of $PM_{2.5}$. The Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with 76 percent and 69 percent, respectively, of the futures below 500 million kg (1,102 million pounds) of $PM_{2.5}$. These same trends were seen for the 2027–2039, 2040–2049, and 2050–2060 modeling periods with higher percentages, and the Maximum Operational Flexibility and Enhanced Coordination Alternatives have 79 percent or more of the futures below 500 million kg of $PM_{2.5}$.

The Lake Mead vulnerability plot shows that the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are least vulnerable, with vulnerability thresholds corresponding to conditions associated with roughly 25 to 50 percent of the Drying with Variability traces. The CCS Comparative Baseline and Basic Coordination Alternative are vulnerable to conditions associated with roughly 50 to 75 percent of the Drying with Variability traces. The No Action Alternative has a vulnerability threshold of 11.7 maf, which is similar to the driest observed 10-year period of 11.8 maf.

For the full modeling period, the Lake Powell shoreline dust emissions robustness figure shows that the No Action Alternative performs the worst, with only 10 percent of the futures below 450 million kg (992 million pounds) of $PM_{2.5}$. The Maximum Operational Flexibility and Enhanced Coordination Alternatives perform the best with 78 percent or more of the futures below 450 million kg of $PM_{2.5}$. These same trends were seen for the 2027–2039 with higher percentages. The 2040–2049 and 2050–2060 modeling periods show that the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) perform the worst, then the No Action Alternative. For the 2027–2039, 2040–2049, and 2050–2060 modeling periods, the Maximum Operational Flexibility and Enhanced Coordination Alternatives have 84 percent or more of the futures below 450 million kg (992 million pounds) of $PM_{2.5}$.

The Lake Powell vulnerability plot shows that the Enhanced Coordination and Maximum Operational Flexibility Alternatives are vulnerable to conditions associated with less than 25 percent of the Drying

with Variability traces. The CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives have vulnerability thresholds corresponding to conditions associated with 75 to 100 percent of the Drying with Variability traces and are therefore the most vulnerable alternatives. The No Action Alternative has a vulnerability threshold of 12.2 maf, which is similar to the recently observed 10-year flow of 12.1 maf.

A general discussion of the effects of climate trends on lake reservoirs is discussed in **TA 7**, Air Quality; however, due to uncertainty, these effects cannot be determined for each specific alternative. In addition, **TA 3**, Hydrologic Resources, details the lake reservoir elevations for the flow categories and alternatives.

3.8 Biological Resources – Fish and Other Aquatic Species

3.8.1 Affected Environment

The affected environment consists of the Colorado River and its tributaries from Lake Powell downstream to the SIB. This area supports a diverse assemblage of aquatic organisms that form a complex food web that sustains both native and nonnative fish populations. Native fish include federally threatened and endangered species, range-wide conservation species (species under a multi-state conservation agreement), BLM sensitive species, and those covered under the LCR MSCP (Reclamation 2024c). Nonnative fish species, including cold-water and warmwater sportfish, are also present (see **Attachment 1** in **TA 8**, Biological Resources – Fish and Other Aquatic Species, for detailed life histories and distributions). River flow variations and dam operations, especially those related to Glen Canyon Dam, significantly influence aquatic habitats within the channel, shorelines, backwaters, and tributary mouths. Several invasive species have been inadvertently introduced, including quagga mussels (*Dreissena bugensis*), New Zealand mud snails (*Potamopyrgus antipodarum*), and various fish and aquatic plants (Reclamation 2024c).

Native Fish Species

Historically, the Colorado River supported 35 native fish species; of these, 26 were unique to the Basin (Miller 1955, 1958; Valdez and Muth 2005). Today, only eight native species remain within the analysis area: humpback chub, razorback sucker, Colorado pikeminnow, bonytail, bluehead sucker, flannelmouth sucker, desert pupfish, and speckled dace (FWS 2002; Valdez and Carothers 1998; Brockdorff 2022); see **Tables 8-1** and **8-2** in **Section TA 8.1**, Affected Environment. Of these species, the humpback chub, razorback sucker, Colorado pikeminnow, bonytail, and desert pupfish are ESA listed as endangered or threatened (Bestgen et al. 2020; Minckley et al. 2003).

Nonnative Fish Species

The presence of nonnative species has both beneficial and detrimental effects on the aquatic community. Although certain nonnative fish species support sport and recreational fisheries, they also pose substantial risks to native communities by increasing predation, competing for resources, and altering habitat conditions (NPS 2021a). High-risk species include smallmouth bass (*Micropterus dolomieu*), walleye (*Sander vitreus*), flathead catfish (*Pylodictis olivaris*), and brown trout (*Salmo trutta*). Other nonnatives, such as rainbow trout (*Oncorhynchus mykiss*), largemouth bass (*Micropterus salmoides*), green sunfish (*Lepomis cyanellus*), and striped bass (*Morone saxatilis*), are common and managed as sportfish

(see **Table TA 8-2** in **Section TA 8.1**, Affected Environment and **Attachment 1** in **TA 8**) (UDWR 2023).

Native and nonnative aquatic species are summarized across the following three Colorado River reaches: Lake Powell, Glen Canyon Dam to Pearce Ferry, and the LCR MSCP reaches (Lake Mead to Imperial Dam).

Lake Powell

Lake Powell supports 6 native fish species and at least 17 nonnative species (see **Table TA 8-2** in **Section TA 8.1**, Affected Environment) (Smith 2022). Native fish species include razorback sucker, bluehead sucker, flannelmouth sucker, and bonytail. Razorback suckers are present in the reservoir, and bonytail are stocked, with recent signs of reproduction. Colorado pikeminnow are rare, mainly occurring in inflows from the Colorado and San Juan Rivers. Flannelmouth and bluehead suckers are widespread, while speckled dace inhabit shorelines and tributaries.

Recent low water levels have created new riverine habitats, influencing fish movement and connectivity (Cathcart et al. 2018; Ahrens 2022). Water temperature and stratification dynamics affect habitat suitability and downstream releases from Glen Canyon Dam (Hueftle and Stevens 2001). Limnological data indicate changes in phytoplankton biomass and community composition, with potential implications for harmful algal blooms and water quality (Deemer et al. 2023). Invasive bivalves, including Asian clam (*Corbicula fluminea*) and quagga mussel, also alter plankton communities and threaten ecosystem health (USGS 2024).

Glen Canyon Dam to Pearce Ferry

This reach spans nearly 300 miles and is shaped by altered flow regimes and habitat diversity (Valdez and Ryel 1995). Native species include razorback sucker, humpback chub, bluehead sucker, flannelmouth sucker, and speckled dace (see **Table TA 8-2** in **Section TA 8.1**, Affected Environment) (NPS 2023b). Humpback chub also persists in tributaries such as the Little Colorado River and Havasu Creek. Currently, the Grand Canyon supports a native-dominated fish community, with the highest abundance of humpback chub anywhere in its current range and flourishing populations of bluehead and flannelmouth sucker. Nonnative species include rainbow trout, brown trout, bass, sunfish, catfish, and minnows (Shollenberger et al. 2025). Smallmouth bass and green sunfish recruitment are influenced by temperature and flow management (Reclamation 2025b). Invasive species, such as quagga mussels and New Zealand mud snails, are present but face environmental constraints (NPS 2015).

LCR MSCP Reaches (Lake Mead to Imperial Dam)

Lake Mead supports a unique, naturally recruiting population of razorback sucker and a diverse fish community, including humpback chub near the Colorado River confluence (see **Table TA 8-2** in **Section TA 8.1**) (Rogers et al. 2023). Downstream reaches (Lake Mohave, Lake Havasu, and Parker Strip) are managed for sportfish and native fish conservation, with stocking and augmentation programs for razorback sucker and bonytail (LCR MSCP 2024). Habitat creation, genetic monitoring, and pond rearing improve survival and recruitment (Kesner et al. 2012; Reap et al. 2023; Bestgen et al. 2020). Invasive species, including quagga mussel, crayfish, Asian clam, and snails, continue to threaten water quality and native biota (USGS 2025c).

3.8.2 Environmental Consequences

Methodology

DMDU modeling was used to evaluate potential Colorado River management strategies across a wide range of plausible hydrologic futures. The analysis compared five alternatives, a Preferred Alternative, and a Continued Current Strategies baseline representing different river flow and reservoir management approaches. For the Final EIS, modeling used 400 hydrologic traces under a Dry initial condition (with Mid and Wet conditions removed), and analysis of the Preferred Alternative focuses on the first 10 years of impacts due to its 10-year implementation period. DMDU evaluates how alternatives may affect aquatic habitats, water quality, and fish populations, and measures performance using robustness scores that indicate how often resource objectives are met across modeled futures. Results are summarized using visual tools, including conditional box plots that show resource responses under different hydrologic conditions, robustness heat maps that compare long-term performance across scenarios, and vulnerability bar plots that identify the hydrologic conditions under which alternatives fail to meet thresholds. Together, these tools provide a comparative framework for understanding potential system outcomes and the relative resilience of alternatives under uncertain future conditions. Additional issue-specific methodology is described in **Section TA 8.2.1**, Methodology, in **TA 8**, Biological Resources – Fish and Other Aquatic Species.

Impact Analysis Area

The impact analysis area includes the Colorado River corridor from the full-pool elevation of Lake Powell downstream to the SIB, including various habitats and reaches described in the analysis area (see **Section 3.2**).

Assumptions

Modifications in the quantity, timing, temperature, and quality of water released from Glen Canyon Dam and Hoover Dam through the lower Colorado River are expected to influence fish habitats, distributions, and population abundances; this is because changes in flow can alter available habitat and affect species' numbers. Reduced flows are likely to affect backwaters and riverine habitats that support native fish; reduced flows may also affect known spawning sites for razorback sucker. Reservoir conditions are also considered, particularly the potential for low Lake Powell elevations (below 3,570 ft) to increase entrainment of smallmouth bass and other nonnative fishes, which could negatively affect humpback chub and other native species in the action area. The analyses use models such as CRSS and the smallmouth bass population model developed in collaboration with various agencies. For efficiency of analysis, some LCR MSCP reaches are combined for analysis where special status species, habitat conditions, operations, and management are similar. Ongoing fisheries management practices by agencies within the Colorado River Basin are expected to remain consistent into the future.

Impact Indicators

Key impact indicators included the abundance and location of razorback sucker larvae, elevation thresholds where spawning habitats may become limited, and annual monitoring data for sportfish catches. Additional indicators were habitat availability and abundance of native fish species by life stage, changes in backwater area at different flow stages, and shifts in the distribution and abundance

of Colorado pikeminnow, razorback sucker, and humpback chub with expanded inflows. The analyses also considered electrofishing and angler catch rates for rainbow trout and brown trout in the Lees Ferry sub-reach, changes in fish habitat and population numbers based on dam releases and flow conditions, and the suitability and area of razorback sucker spawning sites at different flow stages.

Other indicators included changes to Colorado pikeminnow and razorback sucker critical habitat in the Lake Powell inflows, changes to razorback sucker critical habitat in Lake Mead, increased smallmouth bass escapement through Glen Canyon Dam, downstream distribution, salinity concentration changes, and the effects of lower reservoir elevations on shoreline spawning and nursery habitat for razorback sucker. Maintaining reservoir elevation to protect the power pool at Lake Powell (above 3,490 feet) and Lake Mead (above 1,000 feet) and to preserve the Piute Farms Rapid (above 3,666.5 feet) and the Pearce Ferry Rapid (above 1,090 feet) was also important. The analyses further considered reduced abundance and distribution of fish species, water quality impacts, and reduced wetland area and river inflow habitat.

Issue 1: Lower reservoir elevations have reduced lake habitat and extended the inflows of the Colorado River and San Juan River by approximately 35 miles each. How will changes in flow affect the quantity and quality of lake, wetland, and riverine inflow habitats?

Recent declines in Lake Powell's elevation have altered aquatic habitat conditions, affecting ESA-listed native fish and other aquatic species in the Colorado River Basin. Lower reservoir elevations have reduced traditional lake environments while expanding riverine inflow reaches in the Colorado and San Juan Rivers. This change increases the length of exposed riverine habitat, which benefits endangered species such as Colorado pikeminnow and razorback sucker that prefer flowing river conditions and whose designated critical habitat occurs in these inflow areas (see **Tables TA 8-3** and **TA 8-4** in **Section TA 8.2.2**, Environmental Consequences, Issue 1). The most important threat associated with reservoir operations is the establishment and spread of nonnative piscivorous fish, particularly smallmouth bass, which can increase predation and competition pressures on native species such as humpback chub and other fishes targeted for recovery in the Colorado River Basin. Reservoir elevation is a key driver of these risks because it affects the likelihood that smallmouth bass are entrained through Glen Canyon Dam, the effectiveness of Piute Farms Waterfall on the San Juan River as a barrier to upstream fish movement, the extent of riverine critical habitat in the Colorado and San Juan River inflows, and the availability of shoreline habitat that favors nonnative fish reproduction. Accordingly, four primary impact indicators were evaluated: (1) smallmouth bass entrainment through Glen Canyon Dam and subsequent downstream expansion, (2) maintaining Lake Powell elevations below 3,666.5 feet to preserve Piute Farms Waterfall as a barrier to upstream movement of nonnative fish, (3) the extent of riverine critical habitat for Colorado pikeminnow and razorback sucker in the Colorado and San Juan River inflows, and (4) the amount of exposed shoreline habitat favorable for smallmouth bass spawning and recruitment.

Lake Powell elevation influences the extent of riverine critical habitat for Colorado pikeminnow and razorback sucker in the Colorado and San Juan River inflows. When the reservoir rises above approximately 3,598 feet in the Colorado River inflow and 3,600 feet in the San Juan River inflow, portions of designated critical habitat become inundated and converted from flowing river habitat to reservoir conditions (see **Tables TA 8-3** and **TA 8-4**). **Figures TA 8-1** and **TA 8-3** evaluate the robustness of each alternative in maintaining lake elevations below these thresholds and preserving

riverine habitat, while **Figures TA 8-2** and **TA 8-4** illustrate the hydrologic conditions under which alternatives may exceed these thresholds. Modeling results indicate that the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most effective at maintaining elevations below these thresholds and protecting riverine habitat and slightly outperforms the CCS Comparative Baseline. In contrast, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the least robust at maintaining these conditions because they more frequently produce higher Lake Powell elevations, which inundate riverine habitat. The Representative Preferred Alternative performs moderately across these indicators, maintaining elevations below these thresholds in about 40 percent of futures during the initial implementation period.

Reservoir elevation also determines whether Piute Farms Waterfall continues to function as a barrier to fish movement in the lower San Juan River. When Lake Powell elevations exceed approximately 3,666.5 feet, the waterfall becomes inundated, and fish from the reservoir, including predatory nonnative species, can move upstream into riverine habitats. **Figure TA 8-5** evaluates the robustness of each alternative in maintaining elevations below this threshold, while **Figure TA 8-6** identifies the flow conditions that could result in elevations exceeding the threshold. Modeling results show that maintaining this barrier throughout the full modeling period is difficult under all alternatives; however, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs best, followed by the CCS Comparative Baseline. The Representative Preferred Alternative maintains the barrier in approximately one third of futures over the full modeling period and in more than half of futures during the initial implementation period. Although the waterfall also prevents native fish such as Colorado pikeminnow and razorback sucker from returning upstream to historic habitats, maintaining the barrier is generally considered beneficial because it prevents upstream expansion of predatory nonnative fish.

Reservoir elevation affects the availability and types of shoreline habitat around Lake Powell, which in turn influences fish community composition and recreational fisheries. **Table TA 8-5** quantifies how shoreline habitat area changes with reservoir elevation. Higher reservoir levels inundate broad cobble, gravel, and vegetated shorelines that tend to support sportfish such as largemouth bass, bluegill, and crappie, whereas lower reservoir levels expose steep cliff and rockfall habitats that favor smallmouth bass spawning, growth, and recruitment. Modeling results indicate that most alternatives would increase the amount of exposed shoreline habitat relative to the CCS Comparative Baseline (see **Figure TA 3-6** in **TA 3**, Hydrologic Resources), conditions that may favor smallmouth bass population growth and increase the risk that individuals are entrained downstream, potentially increasing predation pressure on native fish populations below Glen Canyon Dam.

Maintaining October 1 Lake Powell elevations above approximately 3,570 feet reduces the likelihood that smallmouth bass occupy forebay areas where entrainment through Glen Canyon Dam is likely. **Figure TA 8-7** evaluates the robustness of each alternative in maintaining October 1 elevations above this threshold, while **Figure TA 8-8** shows the hydrologic conditions under which alternatives are vulnerable to elevations falling below the threshold. Modeling results indicate that the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform best in reducing entrainment risk. The remaining action alternatives and the CCS Comparative Baseline perform substantially worse. The Representative Preferred Alternative performs at an intermediate level, maintaining the elevation threshold in about 42 percent of futures during the first implementation period.

Lake Powell reservoir elevations influence native fish conservation outcomes through multiple interacting mechanisms, including nonnative fish establishment, riverine habitat availability, fish passage barriers, and shoreline habitat conditions. Different operational alternatives, therefore, involve trade-offs among reducing risks from nonnative fish, maintaining critical riverine habitat for endangered fish, preserving natural barriers to upstream fish movement, and sustaining reservoir fisheries under uncertain future hydrologic conditions.

Issue 2: Changes in water quantity, release timing, temperature, and quality from Glen Canyon Dam downstream through the Grand Canyon to Pearce Ferry.

The reach of the Colorado River from Glen Canyon Dam to Lake Mead has experienced substantial ecological change due to long-term modifications in flow magnitude, timing, temperature, and water quality associated with dam operations. These changes have influenced habitat conditions and fish populations throughout the Grand Canyon, affecting ESA-listed species such as humpback chub and razorback sucker, as well as other native species and sportfish, including flannelmouth sucker, bluehead sucker, and rainbow trout. Of particular concern is the potential establishment of nonnative piscivorous fish, especially smallmouth bass, which may be entrained through Glen Canyon Dam when Lake Powell elevations decline, and the warm epilimnion aligns more closely with dam penstocks. Entrainment modeling indicates that propagule pressure increases substantially when reservoir elevations fall below approximately 3,530 feet and persists until elevations fall below the minimum power pool of 3,490 feet, after which releases through river outlet works reduce invasion risk (Eppehimer et al. 2025). Maintaining Lake Powell elevations above approximately 3,570 feet at the start of the year substantially reduces the likelihood of entraining smallmouth bass and other undesirable nonnative species. Warmer releases associated with lower reservoir levels may also increase downstream water temperatures, potentially facilitating reproduction and establishment of warmwater nonnative fish that could increase predation and competition pressures on native species.

A combination of hydrologic, water quality, temperature, and biological indicators was used to evaluate these risks. River flows from CRSS were used to characterize hydrologic conditions affecting aquatic habitat, while a smallmouth bass population model integrating reservoir elevation, water temperature, inflow volumes, and outflows was used to estimate propagule pressure at Glen Canyon Dam and population growth rates (lambda) at several locations downstream, including Lees Ferry, the Little Colorado River confluence (RM 61), Havasu Creek confluence (RM 156), and Pearce Ferry (RM 281). Lambda values greater than 1 indicate increasing populations, while values less than 1 indicate declining populations. Key water temperature thresholds used in the analysis included 12 °C (53.6 °F), which supports humpback chub growth; 16 °C (60.8 °F), which promotes spawning of both humpback chub and smallmouth bass; and 20 °C (68 °F), which can cause thermal stress or mortality for trout species.

Water quality conditions were evaluated using modeled dissolved oxygen concentrations in dam releases (see **Figures TA 6-11** through **TA 6-14** in **TA 6**). Results indicate that minimum annual dissolved oxygen concentrations generally remain between approximately 4 and 7 mg/L under average hydrologic conditions but decrease under drier scenarios. Robustness analysis (**Figure TA 6-12**) shows that the Enhanced Coordination and Maximum Operational Flexibility alternatives are most effective at maintaining dissolved oxygen above the hypoxic threshold of 2 mg/L in at least 90 percent of years across modeled futures. Vulnerability analysis (**Figure TA 6-14**) indicates that the CCS Comparative

Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are more likely to produce undesirable conditions under hydrologic scenarios represented in the Drying with Variability ensemble, whereas the Enhanced Coordination and Maximum Operational Flexibility alternatives remain resilient under most modeled drought conditions.

Water temperatures important to native fish habitat were evaluated using historical monitoring data and modeled scenarios within the DMDU framework. Hourly temperature data from monitoring stations near the Little Colorado River and Diamond Creek for water years 2008 to 2025 were used to calculate the number of days per year exceeding biologically relevant thresholds of 12 °C and 16 °C (53.6 °F and 60.8 °F). These thresholds represent conditions that support humpback chub growth (12 °C [53.6 °F]) and spawning (16 °C [60.8 °F]). Historical patterns showed that most years experienced at least 110 days above these thresholds, which was adopted as a benchmark for thermally suitable conditions. Model outputs were then summarized using heatmaps and boxplots to evaluate how management alternatives influence temperature regimes along the river corridor from Lees Ferry to Pearce Ferry and how those conditions affect native fish, trout species, and nonnative predators such as smallmouth bass.

At Lees Ferry, temperature outcomes vary among alternatives and hydrologic conditions (**Figure TA 8-9**). Exceeding 12 °C (53.6 °F) generally promotes humpback chub growth, while temperatures above 16 °C (60.8 °F) promote smallmouth bass spawning and those above 20 °C (68 °F) can reduce rainbow trout survival. Under average hydrologic conditions, most alternatives produce similar temperature patterns, although the Enhanced Coordination and Maximum Operational Flexibility Alternatives result in fewer days exceeding the higher thresholds because they maintain cooler dam releases. Robustness analysis (**Figure TA 8-10**) indicates that the Enhanced Coordination Alternative performs best in maintaining temperatures below 20 °C (68 °F), followed by the Maximum Operational Flexibility Alternative. Vulnerability analysis (**Figure TA 8-11**) shows that most alternatives become susceptible to temperatures above 20 °C (68 °F) during extended drought conditions. The Representative Preferred Alternative performs moderately, meeting the preferred temperature threshold in fewer futures than the highest performing alternatives.

At the Little Colorado River confluence, water temperatures are generally warmer and more conducive to native fish growth than at Lees Ferry (**Figure TA 8-12**). Exceeding the 12 °C (53.6 °F) threshold promotes humpback chub growth, while exceeding 16 °C (60.8 °F) supports spawning but may also favor smallmouth bass. Robustness analysis (**Figure TA 8-13**) shows that the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs best at achieving the preferred threshold for humpback chub growth, while the Enhanced Coordination and Maximum Operational Flexibility alternatives perform worst because they maintain cooler water temperatures. However, analysis of the 16 °C (60.8 °F) spawning threshold (**Figure TA 8-14**) indicates that all alternatives perform poorly at achieving sustained mainstem spawning conditions for humpback chub. This result suggests that humpback chub spawning will likely remain concentrated in the Little Colorado River tributary rather than the mainstem.

Farther downstream at the Havasu Creek confluence, temperature conditions are generally warm enough to support humpback chub growth across most alternatives (**Figure TA 8-15**). Robustness results indicate that nearly all alternatives meet the threshold of at least 110 days above 12 °C (53.6 °F) in most futures (**Figure TA 8-16**). However, achieving temperatures above 16 °C (60.8 °F) for

extended periods, which could support humpback chub spawning but also promote smallmouth bass reproduction, is less common (**Figure TA 8-17**). The Enhanced Coordination and Maximum Operational Flexibility Alternatives produce fewer days above this threshold, limiting both native and nonnative spawning potential. The Representative Preferred Alternative performs strongly for the growth threshold but more moderately for spawning related temperature thresholds.

At Pearce Ferry, water temperatures are influenced more strongly by ambient air temperatures than by dam releases because of the long distance downstream from Glen Canyon Dam (**Figure TA 8-18**). As a result, differences among alternatives are smaller. All alternatives consistently exceed the 12 °C (53.6 °F) threshold needed for humpback chub growth (**Figure TA 8-19**), but conditions conducive to spawning (temperatures above 16 °C [60.8 °F]) vary more widely (**Figure TA 8-20**). Alternatives that maintain cooler upstream release temperatures, particularly the Enhanced Coordination and Maximum Operational Flexibility Alternatives, produce fewer days above the spawning threshold, which may reduce smallmouth bass reproduction but also limit opportunities for humpback chub spawning in the mainstem.

Temperature outcomes also influence smallmouth bass population growth and entrainment risk. Modeling of smallmouth bass population growth rates (lambda) indicates that the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform best at maintaining lambda below 1, indicating declining populations if established (**Figure TA 8-21**). The No Action Alternative and CCS Comparative Baseline perform worst in this regard. Vulnerability analysis (**Figure TA 8-22**) shows that prolonged dry hydrologic conditions increase the likelihood that smallmouth bass populations could grow.

Finally, entrainment modeling evaluates the number of smallmouth bass that may pass through Glen Canyon Dam and survive downstream (**Figure TA 8-23**). The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform best at limiting entrainment, whereas the other alternatives perform substantially worse. Vulnerability analysis (**Figure TA 8-24**) indicates that all alternatives could experience elevated entrainment during dry hydrologic conditions because low Lake Powell elevations align warm surface waters, where smallmouth bass reside, with dam penstocks. Overall, alternatives that maintain higher reservoir elevations and cooler release temperatures generally reduce smallmouth bass invasion risk but may also limit thermal conditions favorable for native fish growth and spawning, illustrating a key management tradeoff in temperature management below Glen Canyon Dam.

Overall, reservoir elevation, dam release temperature, and hydrologic variability strongly influence aquatic habitat conditions and fish population dynamics downstream of Glen Canyon Dam. Alternatives that maintain higher Lake Powell elevations generally produce cooler release temperatures, lower entrainment risk, and reduced growth in the smallmouth bass population, which benefits trout survival and helps limit the establishment of nonnative fish. However, these cooler conditions may also limit thermal opportunities for humpback chub growth and mainstem spawning. Conversely, alternatives that allow warmer water conditions may benefit native fish growth but also increase the risk of smallmouth bass reproduction and establishment. These results illustrate the tradeoffs among management alternatives in balancing native fish recovery, control of nonnative predators, and maintenance of recreational fisheries under uncertain future hydrologic conditions.

Issue 3: Lower reservoir elevations have reduced lake habitat and extended river inflows, including about 30 miles on the Colorado River and 20 miles on the Virgin River, with similar extensions observed at Las Vegas Bay, Echo Bay, and other locations. How will these inflow changes affect the quantity and quality of lake, wetland, and riverine inflow habitats?

The Lower Colorado River Basin from Lake Mead to the SIB has experienced ecological changes driven by fluctuations in reservoir elevations and tributary inflows, which affect the quantity and quality of aquatic habitat for native, nonnative, and recreationally important fish species. Lower Lake Mead elevations reduce littoral shoreline habitat used by sportfish and razorback sucker, while simultaneously extending riverine inflow habitats along the Colorado River, Virgin River, and other tributaries. These changes may alter the extent of designated critical habitat for razorback sucker and influence the distribution and movement of native fishes such as humpback chub and razorback sucker. Reservoir elevation also affects fish passage at Pearce Ferry Rapid, which functions as a natural barrier to upstream fish movement under lower lake levels but becomes inundated at elevations above approximately 1,090 feet. When the rapid is submerged, both native and nonnative fish may move upstream from Lake Mead into the Grand Canyon. Conversely, elevations below approximately 1,000 feet would compromise hydropower generation. To evaluate these conditions, the analysis considered indicators including monitoring data on sportfish catch, shifts in native fish distribution and abundance, and changes in the availability and quality of shoreline and inflow spawning habitats. Monitoring datasets from Arizona Game and Fish Department (AZGFD), Nevada Department of Wildlife (NDOW), and the LCR MSCP were integrated with DMDU modeling results to evaluate how alternative management strategies may affect reservoir elevations, aquatic habitats, and fish community dynamics.

Two key elevation thresholds were evaluated in the analysis. The first threshold is Lake Mead elevation of 1,090 feet, above which Pearce Ferry Rapid becomes inundated and no longer functions as a barrier to upstream fish passage. Robustness analysis (**Figure TA 8-25**) evaluates the percentage of modeled futures in which Lake Mead remains below 1,090 feet for at least 90 percent of months, a threshold based on recent historical conditions, during which the reservoir remained below this elevation approximately 94 percent of the time between 2016 and 2026. Results show that the No Action Alternative performs best, followed by the CCS Comparative Baseline. Among action alternatives, the Basic Coordination Alternative performs best. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives perform the worst. The Representative Preferred Alternative meets the threshold in 20 percent of futures over the full modeling period and in approximately 39 percent of futures during the first implementation decade (2027–2039). Vulnerability analysis (**Figure TA 8-26**) indicates that several alternatives, including the Representative Preferred Alternative, become vulnerable to elevations exceeding 1,090 feet under relatively moderate 10-year average flows of approximately 12.4 maf or wetter, conditions that occur in most traces of the Drying with Variability ensemble. In contrast, the No Action Alternative and CCS Comparative Baseline are less vulnerable and would generally exceed the threshold only under wetter conditions.

The analysis also evaluated the potential for lake elevations to fall below the lowest elevation observed during the recent historical period (1,040.92 feet in July 2022), which serves as a proxy for maintaining shoreline habitats that have historically supported the current fish community. Robustness analysis

(**Figure TA 8-27**) evaluates the percent of modeled futures in which Lake Mead remains at or above this elevation for at least 90 percent of months. Results show that the No Action Alternative performs worst, while the CCS Comparative Baseline and Basic Coordination Alternatives perform modestly better. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives perform substantially better with the Supply Driven Alternative (LB Pro Rata approach) performing best. The Representative Preferred Alternative meets this threshold in 26 percent of futures across the full modeling period, although performance is lower during the initial decade (17 percent). Vulnerability analysis (**Figure TA 8-28**) indicates that most alternatives become vulnerable to elevations falling below 1,040.92 feet under 10-year average flows between approximately 10.9 and 11.7 maf or drier; conditions that are comparable to or slightly drier than the historically observed minimum 10-year average of 11.8 maf.

Overall, reservoir elevation strongly influences aquatic habitat availability and fish community dynamics in Lake Mead and downstream reaches. Alternatives that maintain lower reservoir elevations are more effective at sustaining Pearce Ferry Rapid as a barrier to upstream fish movement, which may help limit the spread of nonnative species into the Grand Canyon but also restrict the movement of native fishes such as the razorback sucker. Conversely, alternatives that maintain higher lake levels improve the likelihood of sustaining shoreline spawning and nursery habitats that support the existing Lake Mead fish community, but increase the potential for fish passage across Pearce Ferry Rapid. If reservoir elevations remain within the historical range observed between 2008 and 2026, the current fish assemblage and habitat conditions are expected to persist. However, prolonged periods outside this historical range, particularly sustained low-elevation conditions, may reduce shoreline spawning habitats and increase ecological stress for aquatic species in the Lake Mead ecosystem.

Issue 4: How would modifications in water quantity, timing, temperature, and quality released from Hoover Dam affect the lower Colorado River, including LCR MSCP reaches 2 through 6 (Hoover Dam to Davis Dam and Lake Mohave, Davis Dam to Parker Dam and Lake Havasu, Parker Dam to Cibola Gage, Cibola Gage to Imperial Dam and Imperial Reservoir, and Imperial Dam to the NIB)?

Hoover Dam operations may influence aquatic habitats and fish populations in the Lower Colorado River from Hoover Dam downstream to Imperial Dam, including reaches managed under the LCR MSCP. Although ESA mitigation measures are already in place through previous consultations, this EIS assesses how different operational alternatives may affect river flows, timing, temperature, and water quality under NEPA. Changes in these factors could influence habitats and population dynamics of endangered species such as razorback sucker and bonytail, as well as other native fishes, including flannelmouth sucker and desert pupfish. Modified flow regimes may affect the extent of backwater and riverine habitats, the location and suitability of razorback sucker spawning areas, and the stability of constructed desert pupfish refuge ponds if flows fall outside historical bounds. Reduced flows could also allow predatory nonnative fish, such as flathead catfish, to expand upstream from the Cibola gage toward Imperial Dam, increasing the predation risk to native fishes. The analysis relies on monitoring data from agencies including AZGFD, NDOW, the California Department of Fish and Wildlife, Reclamation, the LCR MSCP, and U.S. Fish and Wildlife Service (FWS), with the assumption that fisheries management practices, such as stocking of listed species, continue as they have since 2008.

A primary indicator evaluated in the analysis is whether monthly releases from Hoover Dam remain within the range observed during the Interim Guidelines period (2008–2025), representing the recent historical flow regime to which aquatic communities have experienced. Robustness analysis (**Figure TA 8-29**) evaluates the percent of modeled futures in which releases remain within this historical range for 100 percent of months. Results show that the No Action Alternative, CCS Comparative Baseline, and Basic Coordination Alternative are the most robust. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs moderately worse, while the Enhanced Coordination Alternative performs similarly. The Maximum Operational Flexibility Alternative performs the worst. Despite these differences, all alternatives maintain releases within the historical range in more than 92 percent of months across the full modeling period. Decadal analysis shows similar rankings, with the No Action, CCS Comparative Baseline, and Basic Coordination Alternatives meeting the threshold in roughly 75–88 percent of futures, while other alternatives perform somewhat lower but still maintain releases within historical bounds for more than 90 percent of months.

Additional analysis of monthly release magnitudes (**Figure TA 8-30**) compares annual minimum and maximum releases across hydrologic conditions. Under Wet Flow categories, most alternatives produce similar distributions of minimum and maximum releases, indicating comparable operational responses during high inflow periods. However, the Supply Driven Alternatives (both LB Priority and LB Pro Rata approaches) tend to produce higher annual maximum monthly releases than other alternatives. As hydrologic conditions become drier, differences among alternatives become more apparent. The No Action Alternative, Basic Coordination Alternative, and CCS Comparative Baseline maintain relatively higher minimum releases during critically dry conditions, indicating continued higher downstream flows even during drought. In contrast, the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven Alternatives (both LB Priority and LB Pro Rata approaches) generally result in lower minimum releases during dry periods because these alternatives implement larger shortage reductions to conserve storage in Lake Mead. Even under critically dry conditions, minimum monthly releases remain above the historical reference threshold of 220 kaf in approximately 90 percent or more years for most alternatives, except the Maximum Operational Flexibility Alternative, which falls below that threshold more frequently. Results for the Representative Preferred Alternative fall within the range observed across other alternatives, with median annual minimum and maximum releases remaining within historical bounds under both dry and critically dry conditions.

Operational differences among alternatives produce only modest changes in Hoover Dam release patterns relative to the historical flow regime experienced between 2008 and 2025. Alternatives that maintain higher release volumes during drought conditions, such as the No Action and Basic Coordination Alternatives, may accelerate declines in Lake Mead storage but maintain relatively stable downstream flows. Alternatives that reduce releases during drought conditions may help maintain reservoir elevations while still providing flows within the historical range experienced by aquatic species. Because downstream impoundments such as Lake Mohave and Lake Havasu operate under guide curves that maintain relatively stable elevations across alternatives, and because modeled releases remain largely within historical ranges, aquatic habitats within the LCR MSCP reaches are expected to remain generally similar to recent historical conditions. Under these circumstances, fish community composition and population dynamics downstream of Hoover Dam would likely remain comparable to those observed during the 2008–2025 period, assuming continued fisheries management and habitat restoration efforts.

Summary Comparison of Alternatives

The analysis compares several proposed alternatives for the Colorado River downstream of Glen Canyon Dam using hydrologic modeling, ecological indicators, temperature thresholds, and assessments of ecosystem vulnerability and resilience. A full summary of those findings can be found in **Figure TA 8-31** in **Section TA 8.2.6**, Summary Comparison of Alternatives. Key findings show that the Enhanced Coordination and Maximum Operational Flexibility Alternatives are most robust in maintaining cooler water temperatures, maintaining higher dissolved oxygen levels, and controlling nonnative species like smallmouth bass. However, they may restrict native fish spawning and growth. In contrast, the No Action Alternative and the CCS Comparative Baseline better preserve riverine habitats above Lake Powell and prevent upstream movement of nonnative fish from Lake Powell and Lake Mead; this would benefit endangered species such as Colorado pikeminnow and razorback sucker but reduce lake habitat for sportfish. For Lake Mead and downstream habitats, the No Action Alternative and the CCS Comparative Baseline maintain lower lake elevations that help contain nonnative fish; however, they may also limit native fish access to new habitats. Most alternatives support stable flows and fish communities downstream of Hoover Dam, though the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are less robust in maintaining desirable release patterns. The Representative Preferred Alternative typically falls within the middle of the range of outcomes across issues. Each alternative involves trade-offs between supporting native endangered species, controlling nonnative fish, and maintaining recreational fisheries.

3.9 Vegetation Including Special Status Species

3.9.1 Affected Environment

This analysis categorizes vegetation into marsh, woody riparian, and upland habitat types (collectively referred to as terrestrial habitats) throughout the analysis area, which includes Lake Powell, Glen Canyon Dam to Lake Mead, Lake Mead, and Hoover Dam to the SIB. For additional information on the affected environment, including a list of special status species, please reference **TA 9**, Vegetation Including Special Status Species, and **Attachment 1**, Special Status Plant Species, in **TA 9**. **Table TA 9-1** in **Section TA 9.1**, Affected Environment, provides the approximate acreages of marsh, woody riparian, and upland habitats by reach. Wetlands in the analysis area are typically characterized by marsh habitat, but could also occur in woody riparian habitats.

Marsh habitats occur in areas that are consistently flooded and are typically found in the transition zone between open water and upland ecosystems. Marsh vegetation is sensitive to drought on short timescales, seasonally to annually, and has been found to decrease in cover, species diversity, and productivity when water availability shifts from perennial to intermittent (Stromberg et al. 2005, 2007; Friedman et al. 2022). Woody riparian habitats occur where water is consistently available and periodic flooding occurs. Woody riparian vegetation typically has deeper root systems capable of accessing alluvial groundwater and is not dependent on surface water flows (Stromberg et al. 2013). This vegetation type is sensitive to drought on longer timescales, on an annual to decadal scale, depending on the species (Shafroth et al. 2002). Upland habitats occur in areas without consistent water availability, where vegetation depends on precipitation.

Lake Powell

Short-term and long-term fluctuating water elevations influence Lake Powell's shoreline vegetation. The median annual water elevation fluctuation during the 2007 Interim Guidelines period (between 2008 and 2025) was 31.45 feet (see **Figure TA 9-1** in **Section TA 9.1**, Affected Environment). The drought-induced drawdown of Lake Powell since 2011 has reduced the lake's perimeter and exposed approximately 59,000 acres of formerly submerged land (Root and Jones 2022). Recently exposed sites below full pool of Lake Powell shows a higher percentage and cover of nonnative species, with prickly Russian thistle (*Salsola tragus*) being extremely abundant (Arens 2023). However, native shrubs are outcompeting nonnative plants on sites that have been exposed for more than 3 years; these shrubs are providing diverse ecosystems, including hanging gardens and cryptobiotic crusts, where natural flow patterns are reestablishing (Arens 2023, NPS 2026). As water levels continue to drop, newly established vegetation may begin to decline (Kasprak et al. 2026). Two special status plant species are present in the Lake Powell reach and could be affected by operations (**Attachment 1** in **TA 9**, Vegetation Including Special Status Species).

Glen Canyon Dam to Lake Mead

Marsh, woody riparian, and upland habitats from Glen Canyon Dam to Lake Mead are influenced by the peak magnitudes, daily fluctuations, and seasonal patterns of river flows. Most evidence indicates that vegetation composition, structure, distribution, and function are closely tied to ongoing Glen Canyon Dam operations (Reclamation 2016; Palmquist et al. 2023). Marsh and woody riparian vegetation have expanded in this reach since Glen Canyon Dam was completed in 1963 (Sankey et al. 2015). The greatest area of vegetation expansion between 2002 and 2013 was woody riparian vegetation on sandbars in the active channel (Durning et al. 2021). The availability of water at low river elevations from consistent base flows can promote vegetation establishment, whereas prolonged periods of peak flow may inhibit vegetation establishment. When inundation frequency increases by 5 percent or more, vegetation expansion was unlikely to occur (Sankey et al. 2015).

Twenty special status plant species are present in the Grand Canyon to Lake Mead reach and could be affected by operations (**Attachment 1** in **TA 9**, Vegetation Including Special Status Species).

Lake Mead

Similar to Lake Powell, short- and long-term fluctuations in water elevation affect Lake Mead's shoreline vegetation. The median annual water elevation fluctuation between 2008 and 2025 was 16.19 feet (see **Figure TA 9-3** in **Section TA 9.1**). The drawdown of Lake Mead from 1998 to 2011 reduced the lake's perimeter by more than 400 kilometers (250 miles) and exposed more than 61,776 acres of formerly submerged land (Engel et al. 2014). Long-term fluctuations allow the establishment of woody riparian vegetation, including the nonnative and invasive tree tamarisk (*Tamarix* spp.); however, as lake levels continue to fall, tamarisk may begin to show drought stress and mortality when water levels fall below their roots.

Overall, native species cover has been found to be greatest on surfaces that have been exposed for a longer period of time (Engel et al. 2014). Native vegetation at Lake Mead has been positively influenced by defoliation from the tamarisk leaf beetle (*Diorhabda* spp.) (beetle). Twenty-one special status plant species are present in the Lake Mead reach and could be affected by operations (**Attachment 1** in **TA 9**, Vegetation Including Special Status Species).

Hoover Dam to the Southerly International Boundary (SIB)

The LCR MSCP planning area identifies 14 land cover types, including five woody riparian types that are divided into multiple structural types. The marsh land cover type is divided into seven compositional types based on plant composition and vegetation structure (Reclamation 2004; see **Table TA 9-2** in **Section TA 9.1**). Since the beetle's release in 2006, its range has expanded downstream from Lake Mead along the lower Colorado River; by 2019, large beetle populations were detected along the Imperial stretch of the lower Colorado River. In 2020, beetles were present, and defoliation was documented in or around all LCR MSCP study areas (Reclamation 2021). In 2024, beetles were documented to the SIB (McLeod and Pellegrini 2021; Mahoney et. al 2022; RiversEdge West 2025).

In 2024, Reclamation contracted RiverRestoration.Org to map backwater areas (water, marsh, and non-marsh) in the LCR MSCP planning area and to conduct a change analysis between the 2024 effort and a 2000 backwater mapping effort (RiverRestoration.Org 2025). The study found an overall decrease in marsh area between Davis Dam and Morelos Dam from 2000 to 2024. Nine special status plant species are present in the Hoover Dam to SIB reach and could be influenced by operations (**Attachment 1** in **TA 9**, Vegetation Including Special Status Species).

3.9.2 Environmental Consequences

Figures referenced in this section and a description of how to interpret the results of the analysis are provided in **Section TA 9.2**.

Methodology

There are no long-term vegetation monitoring datasets available for Lake Powell, Lake Mead, or Hoover Dam to the SIB that would support quantitative habitat modeling, as was done for the Glen Canyon Dam to Lake Mead section; therefore, a qualitative approach was used to determine the predicted differences in marsh and woody riparian vegetation among the alternatives. As noted in **Section 3.9.1**, Affected Environment, marsh and woody riparian vegetation are affected by water level fluctuations on short (annual) and long (5-year) timescales. Therefore, changes in water elevation over 1-year and 5-year periods were used as proxies to represent potential changes to marsh and woody riparian vegetation.

To determine the changes in water elevation under each alternative, CRSS was applied within the DMDU framework to show maximum variability within 1 year and over 5 years in the robustness heat map figures. A 5-year period was selected to represent longer-term variability in water level fluctuations. The modeled variability from CRSS and the DMDU framework were then compared to historic conditions to determine whether variability would remain the same, increase, or decrease for each alternative. For the purposes of this analysis, historic conditions extend from water year (WY) 2008–2025 (the 2007 Interim Guidelines period). Refer to **Section 3.2**, Analysis Methods, for additional information on DMDU and **Appendix E**, DMDU Overview and Approach, for an overview of how to interpret the DMDU robustness heatmaps.

The DMDU calculations are based on the alternatives meeting a preferred minimum performance, defined by a threshold applied to model output values and a frequency over time. If a modeled future meets both the threshold and frequency, it is considered a successful future. For Lake Powell vegetation, the thresholds correspond to the median observed variability in water elevation over 1 year

(for marsh vegetation) and 5 years (for woody riparian vegetation). The CCS Comparative Baseline data displayed on each figure represent the modeled outcome if current management strategies are continued into the future. This information is included for comparative purposes between the alternatives and the modeled future of the analysis area.

Since vegetation can tolerate a range of environmental conditions, failing to meet the threshold criteria once over the full modeling period is not necessarily detrimental to the habitat's establishment or growth over the long term. Therefore, the analysis focuses on the number of times that the model meets the criteria over a 10-year window for marsh vegetation and a rolling 10-year window for woody riparian vegetation.

The GCMRC conducted hydrologic niche modeling for several species on the fixed-site sandbars for each alternative and used these models to estimate the acres of habitat suitability for each species (Butterfield and Palmquist 2026). The data used for this modeling were collected from 2014 to 2019 (Palmquist et al. 2018a) and can be accessed in the associated data release (Palmquist et al. 2022). In addition to habitat suitability, changes to native species richness, proportion native cover, and total native vegetation cover were estimated by combining the modeled habitat suitability. The hydrologic niche modeling includes HFEs. For a detailed analysis of frequency and duration of HFEs under each alternative, see **TA 5**, Geomorphology and Sediment.

Figures presented for this reach are conditional box plots. Refer to **Section 3.2**, Analysis Methods, for additional information on DMDU and **Appendix E**, DMDU Overview and Approach, for an overview of how to interpret the DMDU conditional box plots. The hydrologic niche modeling results used to create these figures can be accessed in the associated data release (Butterfield and Palmquist 2026). The dashed lines included in **Figure TA 9-9** through **Figure TA 9-13**, in **TA 9**, are reference lines to the 50th percentile of modeled 'historical' period, which were modelled using 2000-2025 hydrology under CCS Comparative Baseline using a dry-initial condition (see **Section 3.2.6** for an explanation of initial conditions).

As with Lake Powell, changes in water elevation from historical conditions were used as a proxy to determine potential impacts on marsh and woody riparian vegetation under each alternative for Lake Mead. The same methods for Lake Mead were used as described for Lake Powell.

As with Lake Powell and Lake Mead, the change in water elevation was used as a proxy to determine potential impacts on marsh and woody riparian vegetation under each alternative for the Hoover Dam to SIB reach. However, for this reach, water releases were used to represent changes from historical conditions rather than water elevation. Releases from Hoover Dam, Davis Dam, and Parker Dam were modeled, as releases from these dams determine the amount of water available downstream. Davis Dam and Parker Dam were found to have similar trends as Hoover Dam; therefore, only Hoover Dam results are discussed in detail. The impacts as described in the Hoover Dam to SIB section apply to the entire reach.

Impact Analysis Area

The Lake Powell reach includes Lake Powell up to full pool (water surface elevation 3,700 feet). The Glen Canyon Dam to Lake Mead reach extends from Glen Canyon Dam (RM -15.6) to RM 240. The Glen Canyon Dam to Lake Mead reach begins at Glen Canyon Dam, includes the Colorado River

through Grand Canyon, and ends where Lake Mead at full pool occurs at RM 240. The analysis area for this reach extends to the 45,000-cfs modeled stage elevation, corresponding to the maximum controlled flood releases under the current HFE protocol; the analysis area is considered the active floodplain of the Colorado River in this reach under LTEMP (Reclamation 2016)**.** The section from Glen Canyon Dam to Lake Mead is divided into the following three sub-reaches to account for vegetation community changes (Palmquist et al. 2018b): Marble Canyon (RM -15.6 to RM 60), Eastern Grand Canyon (RM 60 to RM 161), and Western Grand Canyon (RM 161 to RM 240).

The Lake Mead reach extends from RM 240 in the Grand Canyon to Hoover Dam. The analysis area for this reach includes the full pool of Lake Mead (water surface elevation 1,229 feet). The Hoover Dam to SIB reach is aligned with the LCR MSCP planning area. As described in **TA 8**, Biological Resources – Fish and Other Aquatic Resources, there are seven reaches within the LCR MSCP planning area. For vegetation analysis, the analysis area includes LCR MSCP reaches 2 through 7 (Reclamation 2004). Reach 1 in the LCR MSCP planning area includes Lake Mead up to the full pool, which is addressed separately as Lake Mead. The analysis area includes the full pool of Lake Mohave and Lake Havasu and the Colorado River's historical floodplain.

Assumptions

The assumptions used for the analysis of impacts are provided in **Section TA 9.2.1**, Methodology.

Impact Indicators

The following impact indicators were used:

- A change in the median and interquartile ranges from modeled historical conditions (Glen Canyon Dam to Lake Mead reach)
- Changes in water fluctuations within a single year compared with historical conditions (Lake Powell, Lake Mead, and Hoover Dam to SIB reaches)
- Changes in water fluctuations in the preceding 5 years compared with historical conditions (Lake Powell, Lake Mead, and Hoover Dam to SIB reaches)

Issue 1: How would changes in the management of the Colorado River impact vegetation, including special status species

Lake Powell. For all alternatives except for the Enhanced Coordination Alternative and the Maximum Operation Flexibility Alternative, increased variability in the first decade (2027–2039; **Figure TA 9-7** in **TA 9**) compared to modeled historic conditions, indicated by a lower percentage of futures meeting the level of performance, would result in changes in marsh vegetation. Whether an area experiences an increase or a decrease in marsh habitat in response to changed conditions is mostly dependent on local topography, but generally an increase in variability is expected to result in a decrease in marsh vegetation due to more frequent dewatering and inundation. In the first decade, the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative are the most robust, meeting the minimum level of performance in 81 percent and 80 percent of futures, respectively. CCS Comparative Baseline and No Action Alternative meet it in 49 percent and 36 percent of futures, respectively.

In the first decade, cover of prickly Russian thistle may increase due to the increased area of upland habitat created during water elevation fluctuations. Cover of prickly Russian thistle would be expected

to decrease in the later decades if variability also decreases, reducing areas vulnerable to invasive species establishment on an annual basis. Native vegetation can re-establish over time, particularly in areas exposed for more than 3 years (Arens 2023).

In the later decades (2040–2049 and 2050–2060; **Figure TA 9-7** in **TA 9**), the Enhanced Coordination Alternative is the most robust, meeting the minimum level of performance in 92 percent and 90 percent of futures, respectively. CCS Comparative Baseline and No Action Alternative meet it in 54 percent and 48 percent, and 51 percent and 53 percent of futures, respectively. As variability becomes closer to historic conditions for Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative (as indicated by a higher percentage of futures meeting the level of performance), marsh vegetation may re-establish to a similar historical extent under those alternatives.

For the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative under the Critically Dry Flow Category Lake Powell has a modeled WY minimum median elevation of approximately 3,520 feet and 3,512 feet, respectively (see **Table TA 3-4** in **Section TA 3.2**, Environmental Consequences, in **TA 3**, Hydrologic Resources); these median elevations are 38 and 46 feet below, respectively, the minimum 2024 water elevation of 3,558 feet (see **Figure TA 3-1** in **Section TA 3.1**, Affected Environment). Under the Average Flow Category, Lake Powell has a WY modeled minimum median elevation of approximately 3,613 and 3,605 feet for the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative, respectively (see **Table TA 3-4** in **Section TA 3.2**); these median elevations are approximately 55 and 47 feet higher than the minimum 2024 water elevation. This indicates higher modeled elevations under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative under all but the critically dry modeled conditions. If water elevations gradually rise with similar levels of variability to historical conditions (**Figure TA 9-7**), marsh vegetation is expected to continue to reestablish along the new water line over time. If water elevations rise, some of the side canyons that were exposed as Lake Powell receded may reflood, which would inundate the native plant communities that had reemerged.

If water elevations stay the same or gradually fall with similar variability to historical conditions (**Figure TA 9-7**), marsh vegetation may reestablish to a similar extent along the new water line over time. Under these alternatives, plant communities in the side canyons would remain exposed.

Whether water elevations rise, fall, or remain the same, if variability resembles historical conditions under the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative in the later decades, marsh vegetation **(Figure TA 9-7)** and woody riparian vegetation **(Figure TA 9-8)** is expected to continue to reestablish along the new water line over time. For alternatives that have more variability than historical conditions (**Figure TA 9-7, Figure TA 9-8**), marsh and woody riparian vegetation may reestablish to a smaller extent along the new water line over time. Where variability eliminates or prevents the establishment of marsh habitat, woody riparian or upland habitat may become the dominant habitat type. Whether an area experiences an increase or a decrease in marsh or woody riparian habitat in response to changed conditions is largely dependent on local topography, but generally an increase in variability is expected to result in a decrease in woody riparian vegetation.

The trends and type of impacts on woody riparian vegetation are the same as those described for marsh vegetation for Lake Powell (**Figures TA 9-7** and **TA 9-8**).

Glen Canyon Dam to Lake Mead Suitable Habitat Area – Marsh. Figure TA 9-9 compares the amount of modeled marsh habitat for each alternative by Grand Canyon sub-reach. Marsh vegetation includes bulrushes (*Schoenoplectus* spp.), rushes (*Juncus* spp.), field horsetail (*Equisetum arvense*), and common reed (*Phragmites australis*).

In Marble Canyon and Eastern Grand Canyon, under the Average Flow Category, Moderately Wet Flow Category, and Dry Flow Category, the medians are near modeled historic conditions (dashed line) and the interquartile ranges are relatively restricted and overlap the modeled historic conditions (**Figure TA 9-9**) for all alternatives, indicating that the amount of habitat suitable for marsh species would likely be similar to historic conditions under these categories. Under the Critically Dry Flow Category, the Maximum Operational Flexibility Alternative, Supply Driven Alternative, and Representative Preferred Alternative medians and interquartile ranges are completely above modeled historic conditions (dashed line), indicating that suitable habitat for marsh species may increase under the Critically Dry Flow Category for those alternatives. Under the Wet Flow Category, the medians and interquartile ranges are mostly below modeled historic conditions (dashed line) for all alternatives, suggesting there would likely be less suitable marsh habitat under all alternatives.

Further downstream in Western Grand Canyon, wider interquartile ranges suggest greater uncertainty in the amount of modeled suitable marsh habitat. The general trends follow that of Marble Canyon and Eastern Grand Canyon, but with more differentiation in the Moderately Wet and Dry Flow Categories; there would likely be similar levels of marsh habitat under the Average Flow Category, less marsh habitat under the Wet and Moderate Wet Flow Categories, and more marsh habitat under the Dry and Critically Dry Flow Categories. Under the Average, Dry, and Critically Dry Flow Categories, the CCS Comparative Baseline and Enhanced Coordination Alternative have wider interquartile ranges than the other alternatives, suggesting greater uncertainty.

The decrease in suitable habitat for marsh species under the Wet Flow Category for all sub-reaches and all alternatives may occur because higher water levels may reduce the overall available terrestrial habitat in the river's active channel (Sankey et al. 2015). The similarity or increase in suitable habitat for marsh species under the Critically Dry Flow Category (4.46–10.0 maf) and the Dry Flow Category for all sub-reaches and all alternatives may be because decreasing water levels increase the amount of exposed shoreline habitat.

Glen Canyon Dam to Lake Mead Suitable Habitat Area – Woody Riparian. Figure TA 9-10 compares the amount of modeled woody riparian habitat for each alternative by Grand Canyon sub-reach. Woody riparian vegetation includes seepwillow (*Baccharis* spp.), arrowweed (*Pluchea sericea*), honey mesquite (*Prosopis glandulosa*), and coyote willow (*Salix exigua*).

Across all three sub-reaches, similar interquartile ranges would suggest woody riparian suitable habitat would respond in a similar way across all alternatives under each Flow Category. However, the wide interquartile ranges suggest a high amount of uncertainty about how vegetation would respond under each of the modeled conditions and alternatives in all three sub-reaches.

Similar to marsh habitat, under the Average, Moderately Wet Flow, Wet Flow, and Dry Flow Categories, there is less suitable habitat for woody riparian species, as indicated by the median remaining below the modeled historic conditions under all sub-reaches and across all alternatives except for the No Action Alternative and Enhanced Coordination Alternative in the Dry Flow

Category. For some alternatives, the interquartile range expands above the modeled historic conditions (dashed line), indicating uncertainty about how vegetation would respond. Under the Critically Dry Flow Category, the medians are typically above the modeled historic conditions (dashed line), indicating a likely increase in suitable habitat for woody riparian vegetation under all alternatives except for the Maximum Flexibility Alternative. However, the large interquartile ranges extend far above as well as below the modeled historic conditions (dashed line) under all reaches and for all alternatives except for the No Action Alternative, indicating the variability is too high to predict whether there would be more or less suitable habitat for woody riparian species under these alternatives. The No Action Alternative remains above the modeled historical conditions for all three sub-reaches. This may be because under the No Action Alternative, there would be less water available, compared with the other alternatives, and thus more exposed shoreline that can support woody riparian species.

Similar to marsh habitat, the decrease in suitable habitat for woody riparian species under the Moderately Wet Flow Category and Wet Flow Category for all sub-reaches and all alternatives may be because higher water levels reduce the overall available terrestrial habitat (Sankey et al. 2015). Whereas suitable habitat for woody riparian species may increase under the Critically Dry Flow Category; this expansion would occur near river level on areas recently exposed by lower water levels. Suitable habitat for both woody riparian and marsh species may overlap in these recently exposed areas, where these habitat types would compete near the river. In areas near the top of the active floodplain, decreasing water levels may provide an opportunity for an increase in upland habitat due to disconnection from the river.

Glen Canyon Dam to Lake Mead Suitable Habitat Area – Arrowweed. Figure TA 9-11 compares arrowweed suitable habitat under each alternative by Grand Canyon sub-reach. Across all three reaches, all alternatives show similar trends: the generally similar and overlapping interquartile ranges suggest arrowweed would respond in a similar way across all alternatives. Arrowweed would respond similarly to marsh and woody riparian habitat: there would be less arroweed suitable habitat under wetter conditions and more arrowweed suitable habitat under drier conditions.

Glen Canyon Dam to Lake Mead – Native Species Richness. Figure TA 9-12 compares the predicted count number of native species (native species richness) under each alternative by Grand Canyon sub-reach. Native species richness includes all habitat types and does not distinguish between marsh, woody riparian, and upland. Across all three sub-reaches, all alternatives show similar trends: The wide and generally similar interquartile ranges suggest native species richness would respond in a similar way across all alternatives.

Under all alternatives, sub-reaches, and flow categories, the median is below the modeled historic conditions (dashed line). For some modeled conditions, the interquartile range is above the modeled historic conditions, indicating uncertainty in how vegetation would respond. Since most of the interquartile range is still below the modeled historic conditions, native species richness may decrease under all modeled conditions. However, given the large interquartile ranges, it is difficult to predict how each alternative may respond. Similar to marsh habitat, the Western Grand Canyon reach has larger interquartile ranges than Marble Canyon and Eastern Grand Canyon, indicating greater uncertainty further downstream.

Species richness at the fixed-site sandbars declined from 2014 to 2019. This trend was driven by low species richness in 2019 (Palmquist et al. 2023). The low species richness in 2019 was likely caused by the HFE that occurred in fall 2018 and the lack of monsoon precipitation in summer 2019. Native species richness may decrease under wet hydrologic conditions because HFEs would be a more frequent occurrence and may decrease under the Critically Dry Flow Category due to a lack of precipitation. Disturbance created by HFEs can also positively impact native species richness, as some species require periodic disturbance. Native species richness may also decrease under the Critically Dry Flow Category due to a lack of HFEs. Under all conditions, a combination of these hydrologic and climatic factors may be driving the variable interquartile ranges.

Glen Canyon Dam to Lake Mead – Proportion Native Species Cover. Figure TA 9-13 compares the proportion of native species cover under each alternative by Grand Canyon sub-reach. The proportion native species cover includes all habitat types and does not distinguish between marsh, woody riparian, and upland vegetation. Across all three sub-reaches, all alternatives show similar trends: The generally wide and similar interquartile ranges in each sub-reach suggest the proportion of native cover would respond in a similar way across all alternatives.

Similar to native species richness, the proportion of native species cover has large interquartile ranges across all modeled conditions and all alternatives. This indicates a large amount of uncertainty in how vegetation would respond under various conditions. Under all reaches, under the Wet, Moderately Wet, Average, and Dry Flow Categories modeled conditions, the median is below the modeled historic conditions (dashed line) for all alternatives except for the No Action Alternative and Basic Coordination Alternative under Average and Dry Flow Categories. Since most of the interquartile ranges are below the modeled historic conditions, the proportion of native cover may decrease under Wet, Moderately Wet, Average, and Dry Flow Category conditions under all alternatives and all sub-reaches. However, given the large interquartile ranges, it is difficult to predict how vegetation may respond under each of the modeled conditions, alternatives, and sub-reaches.

For all sub-reaches, under the Critically Dry Flow Category modeled conditions, the median and interquartile range is above the modeled historic conditions (dashed line) under all alternatives except for the Maximum Operational Flexibility Alternative. This suggests that under the Critically Dry Flow Category modeled conditions, the proportion native cover may stay similar to historic conditions or increase under most alternatives. However, given the large interquartile ranges, it is difficult to predict how vegetation may respond under each alternative.

Encroachment of riparian vegetation into the exposed active channel and into the bare sand of sandbars has been found to be driven by seepwillows, which are a native species (Durning et al. 2021). The proportion of native species cover may decrease under all conditions except for the Critically Dry Flow Category due to the lack of bare sand available for native species, particularly seepwillows, to colonize. The proportion of native cover may increase under the Critically Dry Flow Category because of receding water levels and subsequent increase in available sand.

Glen Canyon Dam to Lake Mead – Annual Total Vegetation Cover. Figure TA 9-14 compares the annual total vegetation cover under each alternative by Grand Canyon sub-reach. Annual total vegetation cover includes all habitat types and does not distinguish between marsh, woody riparian, and upland. Across all three reaches, all alternatives show similar trends: The generally similar and

overlapping interquartile ranges suggest annual total vegetation cover would respond in a similar way across all alternatives.

Under the Average Flow Category, across all three sub-reaches, the median for each alternative overlaps or nearly overlaps the modeled historic conditions (dashed line), and the interquartile ranges are relatively small. This indicates that annual total vegetation may be similar to historic conditions under the Average Flow Category.

Across all three sub-reaches, under the Wet Flow Category and Moderately Wet Flow Category, the median and interquartile ranges are at or below the modeled historic conditions (dashed line) for all alternatives except for the interquartile range of the No Action Alternative in the Moderately Wet Flow Category, although the median remains below historic conditions. This suggests that there would be less annual total vegetation cover under the Wet and Moderately Wet Flow Categories under all sub-reaches and all alternatives. Under the Dry Flow Category, the medians are above historic conditions (dashed line) for all alternatives except the CCS Comparative Baseline and Enhanced Coordination Alternative. Under the Critically Dry Flow Category the median and interquartile ranges are above the modeled historic conditions (dashed line) for all sub-reaches and all alternatives except for the CCS Comparative Baseline. This indicates that there may be more annual total vegetation cover under Critically Dry Flow Category.

Similar to the discussions above under *Suitable Habitat Area*, the decrease in annual total vegetation cover under the wet and moderately wet modeled conditions for all sub-reaches and all alternatives may be because higher water levels reduce the overall available terrestrial habitat (Sankey et al. 2015). Conversely, annual total vegetation cover may increase under the Dry and Critically Dry Flow Categories, likely on areas recently exposed by lower water levels. Fewer to no HFEs under the Dry and Critically Dry Flow Categories could also lead to higher vegetation encroachment.

High Flow Experiments

HFEs influence vegetation dynamics in this reach depending on geomorphic setting, duration, and flow volume. HFEs are dependent on sufficient storage and sediment conditions at Lake Powell. Alternatives that prioritize retaining higher levels in Lake Powell are more likely to result in HFEs, which could influence modeled vegetation responses in this reach. The role of HFEs on shaping vegetation in this reach are described in greater detail in the 2024 LTEMP SEIS (Reclamation 2024c).

Lake Mead. In the first decade, all alternatives are equally non-robust, meeting the minimum level of performance in 0 percent of futures. For all alternatives, the increased variability from historical conditions in the first decade (2027–2039; **Figure TA 9-15**) of the analysis may result in decreased cover of marsh vegetation. In later decades (2040–2049 and 2050–2060; **Figure TA 9-15**) when variability becomes closer to historical conditions for the Basic Coordination Alternative and Maximum Operational Flexibility Alternative, marsh vegetation may reestablish to a more similar extent compared to the other alternatives. Both of these alternatives are more robust than the CCS Comparative Baseline and No Action Alternative, which meet the minimum level of performance in 16 percent and 14 percent, and 10 percent and 10 percent of futures, respectively. Similar to Lake Powell, when conditions are more variable, cover of nonnative species, such as prickly Russian thistle, may increase; if variability decreases, native cover may reestablish.

As shown in **Figure TA 3-11** (see **TA 3.2**), the interquartile ranges for all alternatives for the Average Flow Category are above the 2024 WY minimum of 1,061 feet except for the No Action Alternative. The interquartile ranges under the Dry Flow Category are closer to the 2024 WY minimum compared to the Average Flow Category, and the interquartile ranges overlap with the 2024 WY minimum for all alternatives under the Critically Dry Flow Category. This suggests that Lake Mead is likely to lower under drier conditions. Conversely, under the Moderately Wet and Wet Flow Categories, the interquartile ranges shift to be higher than the 2024 WY minimum of 1,061 feet (**Figure TA 3-11**, see **TA 3.2**), suggesting that Lake Mead would rise under wetter conditions.

Similar to Lake Powell, whether water elevations rise, fall, or remain the same, if there are similar levels of variability to historical conditions under the Basic Coordination Alternative, Maximum Operational Flexibility Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) in the later decades (**Figure TA 9-15**), marsh vegetation is expected to continue to reestablish along the new water line over time. For alternatives with greater variability than historical conditions (**Figure TA 9-15**), marsh vegetation may reestablish to a smaller extent along the new water line over time. Where variability eliminates or prevents the establishment of marsh habitat, woody riparian or upland habitat may become the dominant habitat type.

Similar to Lake Powell, the first decade of modeling for woody riparian vegetation is influenced by historical data (**Figure TA 9-16**). All alternatives meet the minimum level of performance in 12 percent or less of futures. The later decades (2040–2049 and 2050–2060; **Figure TA 9-16**) begin to trend towards more similar variability compared to historic conditions, but variability still remains high. The Basic Coordination Alternative and the Maximum Operational Flexibility Alternative are more similar to historic conditions, meeting the minimum level of performance in 26 percent and 50 percent and 22 percent and 52 percent of futures, respectively. Both of these alternatives are more robust than the CCS Comparative Baseline and No Action Alternative, which meet the minimum level of performance in 20 percent and 22 percent, and 20 percent and 24 percent of futures, respectively.

In later decades (2040–2049 and 2050–2060; **Figure TA 9-16**), when variability becomes more similar to historical conditions for the Basic Coordination Alternative and Maximum Operational Flexibility Alternative, woody riparian vegetation may reestablish to a more similar extent as existing conditions compared to other alternatives. Where variability eliminates or prevents the establishment of woody riparian habitat, upland habitat may become the dominant habitat type.

Figures TA 9-15 and **TA 9-16** suggest that annual variability in Lake Mead water elevations may be higher, especially in the early decade of the modeling period; however, the variability on a 5-year basis may overall be closer to historical conditions, generally benefiting woody riparian vegetation.

Hoover Dam to the SIB. Similar to Lake Powell and Lake Mead, the first decade of modeling for marsh vegetation is influenced by historical data (**Figure TA 9-17**). In the first decade, the Basic Coordination Alternative is the most robust, meeting the minimum level of performance in 60 percent of futures. CCS Comparative Baseline Alternative and No Action Alternative meet it in 55 percent and 6 percent of futures, respectively. For all alternatives, the increased variability from historic conditions in the first decade (2027–2039; **Figure TA 9-17**) may result in decreased marsh vegetation cover.

In later decades (2040–2049 and 2050–2060; **Figure TA 9-17**), all alternatives trend towards more similar variability compared to historic conditions. All alternatives meet the minimum level of

performance in 78 percent or more of futures. The CCS Comparative Baseline and No Action Alternative meet it in 63 percent and 61 percent, and 63 percent and 55 percent of futures, respectively. As variability becomes closer to historical conditions, marsh vegetation may reestablish to a similar extent. Where variability eliminates or prevents establishment of marsh habitat, woody riparian or upland habitat may become the dominant habitat type.

During the 2007 Interim Guidelines period, the annual volume of the Colorado River below Hoover Dam averaged 9.185 maf (see **Section TA 3.1**). For all alternatives under the Average and Dry Flow Categories the interquartile ranges of the modeled annual volume are below 9.185 maf (**Table TA 3-21** and **Figure TA 3-27** in **Section TA 3.2**). This suggests that the annual flow volume below Hoover Dam may decrease under all alternatives under the Average and Dry Flow Categories. The 2007 Interim Guidelines reduced the average annual releases from Hoover Dam by approximately 1.014 maf from prior operating guidelines (**Section TA 3.1**). As described in **Section TA 9.1**, the recent change analysis indicates marsh vegetation generally decreased from 2000 to 2024 (RiverRestoration.Org 2025). If water releases decrease with higher levels of variability, compared with historical conditions (**Figure TA 9-17**), marsh vegetation is expected to continue to decrease over time under Average and Dry Flow Categories. If water releases decrease with similar levels of variability as historical conditions (**Figure TA 9-17**), marsh vegetation is expected to decline at a rate similar to existing conditions under Dry and Critically Dry Flow Categories.

Similar to Lake Powell and Lake Mead, the first decade of modeling for woody riparian vegetation is influenced by historical data (**Figure TA 9-18**). In the first decade, all alternatives are equally non-robust, meeting the minimum level of performance in 0 percent of futures. Increased variability from historic conditions in the first decade (2027–2039; **Figure TA 9-18**) may result in decreased woody riparian vegetation cover due to inconsistent water availability.

In later decades (2040–2049 and 2050–2060; **Figure TA 9-18**), alternatives trend towards variability more similar to historic conditions. The Basic Coordination Alternative is the most robust, meeting the minimum level of performance in 45 percent and 40 percent of futures, respectively. The CCS Comparative Baseline and No Action Alternative meet it in 30 percent and 27 percent, and 29 percent and 26 percent of futures, respectively. The CCS Comparative Baseline and No Action Alternative meet it in 17 percent and 12 percent, and 21 percent and 19 percent of futures, respectively. This increased variability may result in decreased riparian vegetation cover under all alternatives, but to a lesser extent under the Basic Coordination Alternative and No Action Alternative. Where variability eliminates or prevents woody riparian habitat establishment, upland habitat may become the dominant habitat type.

Summary Comparison of Alternatives

Table TA 9-4 in **Section TA 9.2** provides a comparison of alternatives that are most and least similar to historical conditions for each reach.

For Lake Powell marsh and woody riparian vegetation, the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative would result in vegetation most similar to historical conditions. The Maximum Operational Flexibility Alternative would also result in vegetation most similar to historical conditions for Lake Mead's marsh and woody riparian vegetation. However, for the Hoover Dam to the SIB reach, the Maximum Operational Flexibility Alternative and the Enhanced

Coordination Alternative would result in vegetation least similar to historical conditions, which would result in larger changes in vegetation, compared with historical conditions, for that reach. Similarly, the Basic Coordination Alternative would result in conditions least similar to historical conditions for Lake Powell, but would be closest to historical conditions for Lake Mead and Hoover Dam to the SIB. This suggests that no single alternative would result in vegetation similar to historical conditions across all reaches.

For all reaches, multiple alternatives provide variability more similar to historical conditions than the CCS Comparative Baseline, except for the Hoover Dam to SIB reach, where only the Basic Coordination Alternative would result in variability more similar to historical conditions. This suggests that a change in management from current strategies would benefit a large portion of the analysis area; however, it would not benefit the Hoover Dam to SIB reach unless the Basic Coordination Alternative is selected.

For the Glen Canyon Dam to Lake Mead reach, the alternative that would result in vegetation most similar to historical conditions depends strongly on the flow categories. Across all alternatives, all sub-reaches, and all evaluated criteria (the suitable habitat area, native species richness, proportion of native species cover, and annual total vegetation cover), the interquartile ranges often overlap. When the interquartile ranges overlap, it is difficult to determine whether one alternative is truly different from another. Therefore, no single alternative emerged as the best or worst for retaining vegetation similar to historical conditions.

Under all alternatives for Lake Powell, Lake Mead, and Hoover Dam to the SIB, the first decade would experience more variability, which would result in a reduction in marsh and woody riparian habitat compared with historical conditions. All alternatives would see conditions return closer to historical conditions in the second and third decades, which may result in vegetation reestablishing to a similar extent. Where variability eliminates or prevents the establishment of marsh, woody riparian, or upland habitat, there may be a shift to one of the other habitat types.

3.10 Terrestrial Wildlife Including Special Status Species

3.10.1 Affected Environment

This section provides an overview of the general terrestrial wildlife typically found within marsh, woody riparian, and upland habitats in the analysis area, as described in **Section 3.9**, Vegetation Including Special Status Species, including invertebrates, amphibians, reptiles, birds, and mammals. This section also includes special status species, which are defined here as those listed as BLM sensitive species in the overlapping Arizona, California, Utah, and Nevada BLM field offices; species covered under the LCR MSCP; and species listed as threatened, endangered, or proposed for listing by the FWS (BLM 2017, 2018, 2019, 2023; LCR MSCP 2022; FWS 2025). **Attachment 1** in **TA 10**, Terrestrial Wildlife Including Special Status Species, provides a table of the species considered in this document, including their listing status, the river reaches they typically inhabit, and the habitat types most important to their life histories. **Attachment 1** in **TA 10** was developed with input from cooperating agencies and local experts. A full description of the wildlife and special status species that use each of the habitat types is provided in **Section TA 10.1**, Affected Environment, in **TA 10**.

In addition to analyzing the impacts on wildlife in the analysis area as defined in **Section 3.9**, Vegetation Including Special Status Species, impacts are also evaluated for the LCR MSCP conservation areas. These areas were established to provide habitat for species listed under the ESA or that may become listed under the ESA and that use habitat along the Colorado River from Lake Mead down to the SIB (LCR MSCP 2025). The Colorado River in this area has been highly modified by several dams and water diversions, which have affected the growth and establishment of marsh and woody riparian habitat (see **Section 3.9.1**, Affected Environment). The LCR MSCP Habitat Conservation Plan (HCP) and subsequent ESA consultations identified the impacts on marsh, woody riparian, upland, and backwater habitats predicted from existing and anticipated future river operations, and the program established the conservation areas and off-river land acquisitions to mitigate for these losses and provide reliable suitable habitat for wildlife (LCR MSCP 2025). There are 18 conservation areas aimed at conserving 27 species, with a goal of creating 5,940 acres of cottonwood/willow, 1,320 acres of honey mesquite, 568 acres of marsh, and 484 acres of backwater habitats. In addition to the conservation areas, several wildlife refuges and lands managed for wildlife and recreation are present below Hoover Dam. These include Havasu National Wildlife Refuge, Bill Williams River National Wildlife Refuge, Cibola National Wildlife Refuge, Imperial National Wildlife Refuge, Gooseflats Wildlife Area, Lake Mead National Recreation Area, and Mittry Lake Wildlife Management Area.

Section 3.9, Vegetation Including Special Status Species, describes the marsh, woody riparian, and upland habitat types, which are used in this section to determine the affected environment and environmental impacts on wildlife, including special status species. For additional information on the wildlife species considered in this analysis by habitat type, please reference **Section TA 10.1**, Affected Environment, in **TA 10**, Terrestrial Wildlife Including Special Status Species.

3.10.2 Environmental Consequences

Methodology

This Terrestrial Wildlife section relies on the outcomes of the vegetation analysis, the methodology for which is outlined in the Methodology subsection of **Section 3.9.2**, Environmental Consequences.

Impact Analysis Area

The analysis area is the same as described in the Impact Analysis Area subsection of **Section 3.9.2**, Environmental Consequences.

Assumptions

- Upland wildlife species, including special status species, that do not rely directly on the Colorado River or on woody riparian and marsh vegetation influenced by elevation or flows are not included in the impact analysis because changes in operations would not impact these species.
- The evaluation of impacts on wildlife, including special status species, are driven by impacts on vegetation modeling in **Section 3.9** (DMDU-based vegetation analysis).

Impact Indicators

These indicators align with the DMDU figures in **Section 3.9**.

- For terrestrial wildlife species using marsh habitat, changes in water fluctuations within a single year compared with historical conditions
- For terrestrial wildlife species using woody riparian habitat, changes in water fluctuations in the preceding 5 years compared with historical conditions
- For terrestrial wildlife species using upland habitat, changes in water fluctuations over either the preceding single year or preceding 5 years compared with historical conditions

Issue 1: How would changes in the management of the Colorado River impact terrestrial wildlife species habitat availability, including special status species?

Lake Powell

As discussed in **Section 3.11.2**, Environmental Consequences, Lake Powell's surface water elevations fluctuate on a short-term (annual) and long-term (5-year) scale, which causes changes in water availability and which results in the establishment, reestablishment, or loss of upland, marsh, and woody riparian habitat over time. Wildlife, including special status species (hereafter collectively referred to as wildlife), that currently use the Lake Powell analysis area have adapted to these changing conditions.

Under all alternatives, modeling indicates a greater range of variability in Lake Powell's surface elevations compared with historic conditions for both marsh and woody riparian habitat in the first decade (2027–2039) (**Figure TA 9-7** and **Figure TA 9-8** in **TA 9**, Vegetation Including Special Status Species). As described in **Section TA 9.2**, Environmental Consequences, in **TA 9**, Vegetation Including Special Status Species, this greater variability would result in changes in the vegetation extent compared with existing conditions and could decrease vegetation cover. While Lake Powell would continue to support at least some upland, marsh, and woody riparian habitat, the location of conditions suitable to support each of these habitat types is likely to change. Areas that currently support marsh, woody riparian, or upland habitat could transition to one of the other habitat types. Side-canyons that have been exposed due to lower water levels have had an increase in native vegetation, which likely provides suitable wildlife habitat for a range of wildlife species. An increase in water levels could result in the loss of suitable habitat in these areas.

With increased variability, wildlife would have to adapt to changing habitat availability on a larger scale than under historical conditions. For those species capable of moving long distances, such as large mammals, bats, birds, and some amphibians, reptiles, and invertebrates, this change in habitat availability would likely have fewer long-term impacts, provided that suitable habitat is available within their dispersal or migratory range. Habitat transitions could also result in the range expansion or contraction of some species, including into new reaches, as they adapt to changing habitat availability. For less mobile species, such as some small mammals, amphibians, reptiles, and invertebrates, the transition from one habitat type to another may impact foraging, breeding, or sheltering behaviors, which can impact survival and reproduction. Decreased survival and reproduction on a large scale can result in a decreased population size. Smaller local populations are more vulnerable to changes in the environment, which can lead to even greater reductions in population size and an increased risk of the loss of local populations.

During the second decade (2040–2049) and third decade (2050–2060), modeling indicates a range of variability more similar to historical conditions under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative compared with the other alternatives as well as compared with the first decade (2027–2039; **Figure TA 9-7** and **Figure TA 9-8** in **TA 9**, Vegetation Including Special Status Species). This would result in habitat variability similar to what is currently on the landscape; wildlife would need to adapt to changing habitat conditions at the same scale as historical conditions. For all other alternatives, variability would remain high in the second and third decades (as indicated by lower percentages of futures meeting the level of performance), and wildlife would continue to need to adapt to changing habitat availability on a larger scale compared with historical conditions.

In addition to the annual and 5-year changes in water elevation, modeling indicates Lake Powell would gradually rise in elevation over time under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative in all but the Critically Dry Flow Category (**Table TA 3-4** and **Figure TA 3-1** in **TA 3**, Hydrologic Resources). This would result in a shift of marsh and woody riparian vegetation along the new shoreline over time. The rise in water elevation would result in a marginal loss of upland habitat but is not likely to impact wildlife that use marsh or woody riparian habitat, as the shift would be gradual enough for vegetation to continue to reestablish along the new shoreline. Under all other alternatives, modeling indicates water levels would remain the same or decrease in elevation. Similarly, vegetation would reestablish along the lower shoreline as the water elevations change over time. As water elevations lower, the distance to water for upland species would increase. However, given the ability for vegetation to adapt to changing water levels, this change in water elevation, either to a higher elevation under the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative or to a similar or lower elevation under all other alternatives, would not likely impact foraging, breeding, or sheltering behaviors for wildlife. Lower water levels can raise the risk of harmful algal blooms. This risk applies to all alternatives except the Enhanced Coordination and Maximum Operational Flexibility Alternatives and under all conditions except for the Critically Dry Flow Category. This could impact wildlife directly through increased toxicity exposure or indirectly through reductions in habitat quality and quantity.

While monarch butterflies (*Danaus plexippus plexippus*) primarily use woody riparian habitat for migration, they also use marsh and upland habitat regularly. Given the shifting availability of marsh, woody riparian, and upland habitat, and the ability to use features from all three habitat types, monarch butterflies are likely to be able to find suitable habitat under all alternatives in the Lake Powell analysis area. Species-specific impacts will be addressed in future ESA Section 7 Biological Opinions (BOs).

Glen Canyon Dam to Lake Mead

Similar to Lake Powell, the Glen Canyon Dam to Lake Mead reach experiences fluctuating water levels that cause changes in water availability, which results in the establishment, reestablishment, or loss of upland, marsh, and woody riparian habitat over time. Wildlife in the Glen Canyon Dam to Lake Mead analysis area have had to adapt to these changing conditions in the past.

As shown in **Figure TA 9-9** and **Figure TA 9-10** in **TA 9**, Vegetation Including Special Status Species, the amount of suitable habitat for marsh and woody riparian habitat across all three sub-reaches of the Glen Canyon Dam to Lake Mead reach is modeled to respond similarly under all alternatives, and the wide interquartile ranges in **Figure TA 9-10** in **TA 9**, Vegetation Including Special Status Species,

indicate that future acreages of woody riparian habitat are difficult to predict. For marsh and woody vegetation, for all alternatives and sub-reaches, there is less suitable habitat under the Wet and Moderately Wet Flow Categories and more suitable habitat under the Dry and Critically Dry Flow Categories compared to modeled historical conditions. The Western Grand Canyon sub-reach has wider interquartile ranges, which suggests greater uncertainty in how vegetation will respond under the various alternatives. Woody vegetation has larger interquartile ranges than marsh vegetation, and therefore greater uncertainty. The amount of habitat available for wildlife species, including southwestern willow flycatcher (*Empidonax traillii extimus*) and yellow-billed cuckoo (*Coccyzus americanus*), is affected primarily by modeled conditions rather than by the alternatives. Species-specific impacts will be addressed in future ESA Section 7 BOs.

Similar patterns are apparent for native species richness, proportion of native species cover, and annual total vegetation cover (**Figures TA 9-12**, **TA 9-13**, and **TA 9-14** in **TA 9**, Vegetation Including Special Status Species). Increased species richness, proportion of native species cover, and annual total vegetation cover would be beneficial to wildlife species for foraging and breeding habitat. However, increases in each of these factors are driven by the modeled conditions rather than by the alternatives, with additional habitat available under the Critically Dry Flow Category. This is likely due to encroachment of vegetation into areas exposed by lower water levels.

With potentially decreasing water levels at Lake Powell, the temperature of releases from Glen Canyon Dam could increase, increasing the potential for harmful algal blooms in the Glen Canyon Dam to Lake Mead reach. Harmful algal blooms could impact wildlife directly through increased toxicity exposure or indirectly by reducing habitat quality and quantity (see **TA 6**, Water Quality).

Lake Mead

Similar to Lake Powell, Lake Mead experiences fluctuating water levels on an annual and 5-year time scale that cause changes in water availability, which results in the establishment, reestablishment, or loss of upland, marsh, and woody riparian habitat over time. Wildlife in the Lake Mead analysis area have had to adapt to these changing conditions in the past.

As described for Lake Powell, the first decade (2027–2039) exhibits higher variability compared with historical conditions under all alternatives, which would result in changes in habitat availability on a larger scale compared with existing conditions (**Figure TA 9-7** and **Figure TA 9-8** in **TA 9**, Vegetation Including Special Status Species). Marsh and woody riparian vegetation is expected to decrease in response to the increase in variability.

Wildlife species that are capable of moving longer distances would be less likely to be affected by increased variability, provided that suitable habitat is available within their dispersal or migratory range. Even for species that are highly mobile, there may be energetic costs to finding suitable habitat in a fragmented landscape if the distance between suitable habitat locations is outside their typical movement patterns. Increased energetic costs can impact survival and reproduction. Species that are less mobile may experience impacts on foraging, breeding, or sheltering behaviors, which can also impact survival and reproduction. Decreased survival and reproduction through increased energetic costs while searching for suitable habitat or through impacts on foraging, breeding, or sheltering behaviors can result in a decreased population size. Smaller local populations are more vulnerable to

changes in the environment, which can lead to even greater reductions in population size and an increased risk of the loss of local populations.

Unlike Lake Powell, at Lake Mead the second decade (2040–2049) and third decade (2050–2060) exhibit variability similar to historical conditions for the Basic Coordination Alternative and Maximum Operational Flexibility Alternative, rather than the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative. However, the impacts on wildlife would be the same as described under Lake Powell for the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative. That is, wildlife would need to adapt to changing habitat conditions at a rate more similar to historical conditions under the Basic Coordination Alternative and Maximum Operational Flexibility Alternative and would need to adapt to changing habitat conditions on a larger scale for the remaining alternatives.

As described in **Section TA 9.2**, Environmental Consequences, in **TA 9**, Vegetation Including Special Status Species, for all alternatives, Lake Mead elevations could rise, fall, or remain the same compared with existing conditions under all alternatives (**Figure TA 3-11** in **TA 3**, Hydrologic Resources). Similar to Lake Powell, whether the water elevations increase, decrease, or stay the same compared with existing conditions, wildlife would likely be able to adapt to these slower changes and follow the vegetation as it reestablishes along the shoreline. Should water elevations decrease under any of the alternatives, the lowering of the water elevation in Lake Mead could increase the potential for harmful algal blooms, which could impact wildlife directly through increased toxicity exposure or indirectly through reduced habitat quality and quantity.

Listed threatened and endangered species with potential to occur in the Lake Mead analysis area consist of southwestern willow flycatcher, yellow-billed cuckoo, Yuma Ridgway's rail (*Rallus obsoletus yumanensis*), and Mojave desert tortoise (*Gopherus agassizii*). Impacts have been previously assessed in the LCR MSCP HCP, 2007 Final EIS, and 2004 SEIS and associated BOs. Additional ESA Section 7 and Section 10 processes are ongoing, and additional impacts will be disclosed in future BOs and HCPs.

Southwestern willow flycatcher and yellow-billed cuckoo rely on woody riparian habitat, which has modeled increased variability and therefore decreased habitat availability in the first decade compared with historical conditions. These species are capable of moving long distances to access suitable habitat, although southwestern willow flycatchers exhibit local site fidelity and most readily colonize sites that are near existing breeding sites. The loss of suitable breeding habitat in a river reach could result in southwestern willow flycatchers being slow to recolonize the area even if suitable habitat redevelops. For both species, if water levels fluctuate or rise to the extent that habitat is unavailable, then impacts on nesting may occur.

Yuma Ridgway's rails rely on marsh habitat, which may also experience increased variability and therefore decreased habitat availability in the first decade compared with historical conditions. Yuma Ridgway's rails are also capable of moving long distances to access suitable habitat, although the readiness with which they colonize new areas far from established breeding sites is unclear. For all three species, as variability returns closer to historical conditions in the second and third decades for the Basic Coordination Alternative and Maximum Operational Flexibility Alternative, availability of suitable habitat would likely be similar to historical conditions.

Mojave desert tortoises rely on upland habitat. While upland habitat availability is modeled to change under all alternatives in each of the decades, Mojave desert tortoises would have suitable habitat available upslope and would be capable of moving away from rising water levels. Survivorship would depend on the quantity and quality of available forage in the areas they relocate to. As water levels fluctuate, upland habitat loss would be equal to the areas of change unless water fluctuations stabilize and upland vegetation is able to reestablish. Decreased survival and reproduction on a large scale can result in a decreased population size. Smaller local populations are also more vulnerable to changes in the environment, which can lead to even greater reductions in population size and an increased risk of the loss of local populations.

As described for Lake Powell, monarch butterflies are likely to find suitable habitat under each alternative and are unlikely to be affected.

Hoover Dam to SIB

Similar to Lake Powell and Lake Mead, the Hoover Dam to SIB reach experiences fluctuating water levels on an annual and 5-year timescale that causes changes in water availability, which results in the establishment, reestablishment, or loss of upland, marsh, and woody riparian habitat over time. Wildlife in the Hoover Dam to SIB analysis area had to adapt to these changing conditions in the past.

The LCR MSCP HCP and subsequent BOs set habitat creation goals to mitigate for predicted impacts from covered river operations including flow reductions, water delivery and diversion, changes in point of diversion, generation of hydropower, and operation and maintenance activities in the LCR MSCP planning area (Reclamation 2004; FWS 2005, 2018, 2022, 2024). A summary of the habitat creation goals and habitat created toward those goals as of 2025 (LCR MSCP 2025) are included as **Table 3-5**. Habitat creation goals assumed the predicted habitat impacts from reductions in flow and changes in points of diversion up to 2.083 mafy may occur annually until 2055 and would be permanent, even if impacts never actually occur. Habitat would be created to replace it in LCR MSCP conservation areas. This includes a prediction that all existing cottonwood-willow land cover supported by the river and river connected groundwater would be lost due to flow-related covered activities (with the exception of habitat at Topock Marsh and Lake Havasu). Impacts on marsh from flow reductions from 2.083 mafy to 3 mafy were predicted to be short term in duration and the habitat would recover when inundated again (FWS 2024).

These habitat creation goals are the minimum amount of land cover to be created to meet the habitat requirements for the listed and unlisted species covered by the program. Habitat created by the LCR MSCP will be designed in an integrated mosaic and managed for more than one covered species, including habitat elements for each species.

Table 3-5
Summary of Habitat Creation Goals and Habitat Acres Created from Lake Mead to the SIB

Habitat Type	Habitat Creation Goal (Acres)	Habitat Created through 2025 (Acres)
Marsh	568	362
Woody Riparian (cottonwood-willow only)	5,940	4,954
Woody Riparian (honey mesquite only)	1,320	2,046
Woody Riparian (total)	7,260	7,000

Sources: For habitat creation goals, Reclamation 2004; FWS 2005, 2022, 2024. For habitat created through 2025, LCR MSCP 2020, 2025.

Table 3-6 and **Table 3-7** detail the number of acres affected, habitat created, and habitat creation commitments. Although it is unknown exactly how many acres of habitat will be affected over the next 30 years, referencing the number of acres affected over the last 20 years, the amount of habitat present in the reaches (**Table TA 9-1** in **TA 9**), and how those acres were mitigated allows for a greater understanding of future implications. Future impacts and habitat creation commitments will be included in ESA Section 7 BOs and Section 10 HCPs.

Table 3-6
Summary of Federal and Nonfederal Flow-Related Impacts Included in 2004, 2018, 2022, and 2024 HCPs and BOs

Species	Federal and Nonfederal Flow-Related Impacts (Acres)				
ESA Section 7 Consultation	2004 BO and HCP	Additional Impacts in 2018 Biological Assessment, BO, and HCP	Additional Impacts in 2022 Biological Assessment and BO	Additional Impacts in 2024 Biological Assessment and BO	Total
Yuma Ridgway's rail	133	N/A	7	84	224
Southwestern willow flycatcher	1,784	N/A	0	0	1,784
Yellow-billed cuckoo	1,425	N/A	0	0	1,425
Mojave desert tortoise	0	N/A	0	0	0
Northern Mexican gartersnake	N/A	1,081	7	84	1,172

Under all alternatives, all LCR MSCP conservation areas would retain their water entitlements. During shortage conditions, conservation areas with lower priority water rights (4th to 6th level priorities) may not receive their deliveries. Conservation areas are managed for the appropriate habitat type considering their water priority level and historic shortages decisions. During periods of shortage, there may be a reduction in habitat quality for areas with dense overstory and understory. When insufficient water is available, regardless of cause, to maintain established land cover types as habitat for one or more covered species, the Program Manager would coordinate with the FWS to prioritize

the distribution of available water among created habitats to ensure that the greatest benefits for covered species would be provided. As water becomes available, the conservation areas would be managed to improve conditions. Currently, the Cibola Valley Conservation Area is the only LCR MSCP conservation area with 4th to 6th level priority water rights. Impacts on habitat quality if 4th to 6th level priority water rights may be minimized if groundwater is available to the roots of some or all of the vegetation. Current depth to groundwater in the Cibola Valley Conservation Area is approximately 10 feet.

As described for Lake Powell and Lake Mead, the first decade (2027–2039) exhibits high levels of variability compared with historical conditions for all alternatives, which would result in changes in habitat availability on a larger scale compared with existing conditions, especially for woody riparian habitat (**Figure TA 9-17** and **Figure TA 9-18** in **TA 9**, Vegetation Including Special Status Species). Marsh and woody riparian habitat are modeled to decrease in the first decade in response to increased variability. Wildlife species that are capable of moving longer distances are less likely to be affected by the increased variability. Similar to Lake Mead, in the Hoover Dam to SIB reach wildlife species could experience decreased population levels or localized loss of populations if the increased variability results in increased energy expenditure to find suitable habitat or impacts foraging, breeding, and sheltering behaviors.

Table 3-7
ESA Section 7 Habitat Creation Commitments and Habitat Created 2005–Present

Species	Section 7 Habitat Creation Conservation and Mitigation Commitments (Acres)					LCR MSCP Land Cover Created for the Species (2005–2025) (Acres)
	2004 BO	2018 BO	2022 BO	2024 BO	Total	All[14] Created and Creditable
Yuma Ridgway's rail	512	N/A	15	41	568	362
Southwestern willow flycatcher	4,050	N/A	0	0	4,050	945
Yellow-billed cuckoo	4,050	N/A	0	0	4,050	2,553
Mojave desert tortoise	230 acres of existing habitat protection[15]	N/A	0	0	230	230 acres purchased

In the later decades (2040-2049 and 2050-2060), for the Hoover Dam to SIB reach, all alternatives meet the minimum level of performance in 78 percent or more of futures for marsh habitat (**TA 9**,

[14] Lower Colorado River Multi-Species Conservation Program. 2025. Final Implementation Report, Fiscal Year 2026 Work Plan and Budget, Fiscal Year 2024 Accomplishment Report. Bureau of Reclamation, Boulder City, Nevada. Table 1-8
[15] Net loss in habitat is fully mitigated by protecting 230 acres of desert tortoise habitat in accordance with mitigation requirements in the document entitle "Compensation for Desert Tortoise" (Desert Tortoise Compensation Team 1991).

Vegetation Including Special Status Species, **Figure TA 9-17**). For woody riparian habitat, the Basic Coordination Alternative is the most robust. The impacts on wildlife would be the same as described for Lake Powell and Lake Mead; wildlife would need to adapt to changing habitat conditions at a rate more similar to historical conditions under the Basic Coordination Alternative and would need to adapt to changing habitat conditions on a larger scale for the remaining alternatives. This could impact wildlife through changes in foraging, breeding, or sheltering behaviors, which can impact survival and reproductive rates of individuals. Decreased survival and reproduction on a large scale can have population-level impacts.

Under all alternatives, flows from Hoover Dam to SIB are modeled to decrease under the Average and Dry Flow Categories (**Table TA 3-21** and **Figure TA 3-27** in **TA 3**, Hydrologic Resources). As described in **Section TA 9.2**, Environmental Consequences, in **TA 9**, Vegetation Including Special Status Species, a recent change analysis found that marsh vegetation decreased from 2000 to 2024 (RiverRestoration.org 2025). With a higher level of variability and decreased releases, marsh vegetation is modeled to continue to decrease over time and be replaced by either upland habitat or woody riparian habitat. Wildlife species that use marsh habitat in the Hoover Dam to SIB reach are modeled to experience greater levels of habitat loss than under historical conditions if future conditions are dry or average. This habitat loss could impact wildlife species' ability to forage, breed, nest, and shelter in the area, causing them to relocate or possibly experience reduced survival rates. The potential for decreased water levels in Lake Mead could also result in water with increased temperatures being released from Hoover Dam. This could increase the potential for harmful algal blooms, which impact marsh and woody riparian vegetation, and could impact wildlife directly through increased toxicity exposure or indirectly through reductions in habitat quality and quantity.

Federal, state, and tribal managed habitat areas, such as Cibola National Wildlife Refuge, depend on water from the Colorado River to ensure functional habitat for wildlife. If water in the river drops below the level at which water is able to properly flow through diversion structures or pumps are able to function, there may be impacts on habitat unless another method is used to transport water to the managed habitat areas. If a prolonged period of dryness occurs, woody riparian and marsh vegetation may begin to desiccate; however, the extent to which this will occur is unknown.

Listed threatened and endangered wildlife species that have the potential to occur in the Hoover Dam to SIB analysis area are southwestern willow flycatcher, yellow-billed cuckoo, Yuma Ridgway's rail, northern Mexican gartersnake, and Mojave desert tortoise. Impacts have been previously assessed in the LCR MSCP HCP, 2007 Final EIS, and 2004 SEIS and associated BOs. Additional ESA Section 7 and Section 10 processes are ongoing, and additional impacts will be disclosed in future BOs and HCPs. Migrant and transient southwestern willow flycatchers and yellow-billed cuckoos could be affected by the general availability of woody riparian vegetation in which they forage and shelter, which is modeled to decrease in the first decade (2027–2039) under all alternatives (**Figure TA 9-17** and **Figure TA 9-18** in **TA 9**, Vegetation Including Special Status Species). In the second (2040–2049) and third (2050–2060) decades, decreased cover of woody riparian vegetation is modeled under all alternatives, but to a lesser extent under the Basic Coordination Alternative, CCS Comparative Baseline, and the Representative Preferred Alternative (**Figure TA 9-12** and **Figure TA 9-13** in **TA 9**, Vegetation Including Special Status Species). Breeding southwestern willow flycatchers have been present in recent years at Topock Marsh, while breeding yellow-billed cuckoos are found in LCR

MSCP conservation areas and other restored habitats. Woody riparian vegetation in these areas could be affected by the alternatives if they result in shortage allocation reductions of water deliveries. Alternatives that enhance habitat near established populations would benefit species such as the southwestern willow flycatcher that show fidelity to breeding sites. Reductions in water allocations to the conservation areas could reduce the amount of woody riparian habitat available for yellow-billed cuckoo breeding.

Decreased cover of marsh vegetation may occur in the first decade for all alternatives, which could affect the Yuma Ridgway's rail by reducing the amount of habitat available for breeding, feeding, and sheltering. Under all alternatives, marsh vegetation may reestablish in the second and third decades to an extent similar to recent conditions. However, under dry to average future conditions, water is modeled to decrease over time under all alternatives, which could reduce the amount of habitat available to Yuma Ridgway's rails for breeding, feeding, and sheltering.

The most recent confirmed northern Mexican gartersnake sightings have been in Topock Marsh in the Havasu National Wildlife Refuge. Marsh vegetation at Topock Marsh could be affected by the alternatives if they result in shortage allocation reductions of water deliveries. Northern Mexican gartersnakes are less capable of moving long distances. Should a northern Mexican gartersnake be present in marsh habitat experiencing higher levels of variability that results in the loss of that marsh habitat, as is possible in the first decade under all alternatives, northern Mexican gartersnakes may not be able to find suitable replacement habitat, which could cause local loss of populations. In the second and third decades, all alternatives would have conditions similar to historical conditions, which may support northern Mexican gartersnakes in a manner similar to existing conditions. Mojave desert tortoises are likely to be able to move to upland habitat as the habitat conditions change over time.

Water levels are modeled to decrease under all alternatives under Average and Dry Flow Categories. This may result in additional upland habitat for the Mojave desert tortoise. As at Lake Powell and Lake Mead, the monarch butterfly is likely to find suitable habitat under each alternative and is unlikely to be affected.

Summary Comparison of Alternatives

Changes in reservoir elevations and flow variability can alter the extent and location of marsh, woody riparian, and upland habitats that support terrestrial wildlife, including special status species. These habitat shifts affect wildlife by changing the availability of areas used for foraging, breeding, sheltering, and migration. While highly mobile species may relocate to suitable habitat, less mobile species may experience reduced survival or reproduction if habitat availability declines or becomes fragmented, which can reduce population sizes or lead to the loss of local wildlife. For Lake Powell, the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative would result in wildlife habitat availability most similar to historical conditions (**Table TA 9-1** in **TA 9**, Vegetation Including Special Status Species). The Maximum Operational Flexibility Alternative would also result in wildlife habitat availability most similar to historical conditions for Lake Mead. However, for Hoover Dam to the SIB, the Maximum Operational Flexibility Alternative and Enhanced Coordination Alternative would result in wildlife habitat availability least similar to historical conditions, with subsequent impacts on wildlife foraging, breeding, or sheltering behaviors, which can reduce reproduction and survival of individuals. Similarly, the Basic Coordination Alternative would result in wildlife habitat least similar to historical conditions for Lake Powell, but it would be closest to historical conditions for Lake Mead

and Hoover Dam to the SIB. Therefore, no single alternative would result in wildlife habitat availability similar to historical conditions across all reaches. For all reaches, multiple alternatives provide variability more similar to historical conditions than the CCS Comparative Baseline except for the Hoover Dam to SIB reach, where only the Basic Coordination Alternative would result in variability more similar to historical conditions for woody riparian vegetation. This suggests that a change in management from current strategies would benefit a large portion of the analysis area but would not benefit woody riparian vegetation in the Hoover Dam to SIB reach unless the Basic Coordination Alternative was selected.

Under all alternatives, the first decade (2027–2039) would experience more variability, which would likely result in a reduction in marsh and woody riparian habitat and, therefore, an increase in impacts on wildlife compared with historical conditions. All alternatives would see conditions return closer to historical conditions in the second decade (2040–2049) and third decade (2050–2060), which would likely result in wildlife habitat reestablishing to a similar extent. Where variability eliminates or prevents the establishment of marsh, woody riparian, or upland habitat, there may be a shift to one of the other habitat types.

For the Glen Canyon Dam to Lake Mead reach, the alternative that would result in wildlife habitat availability most similar to historic conditions depends strongly on flow categories. Under the Dry Flow Category and Critically Dry Flow Category, some differences among the alternatives emerge, presumably because there are greater differences in the lowest flows, the median flows, and peak flows under those conditions. However, across all alternatives, all sub-reaches, and all evaluated criteria (suitable habitat area, native species richness, proportion of native species cover, and annual total vegetation cover), the interquartile ranges of the alternatives often overlap. When the interquartile ranges overlap, it is difficult to say whether one alternative is truly different from another. Therefore, no single alternative emerged as the best or worst for retaining wildlife habitat similar to historic conditions.

For all reaches, a decrease in water elevation or flow could increase water temperatures, which would increase the potential for harmful algal blooms. Harmful algal blooms can cause direct impacts on wildlife through increased toxicity or indirect impacts through decreases in habitat quality and quantity. Under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternative, there would be increased water levels in Lake Powell in all but the Critically Dry Flow Category, which would result in the lowest potential for harmful algal blooms. For Lake Mead, all alternatives may result in a lowered elevation, which could increase the potential for harmful algal blooms in Lake Mead and in the Hoover Dam to SIB reach.

3.11 Cultural Resources

3.11.1 Affected Environment

Cultural resources are the physical evidence of past or present cultures, including archaeological sites, historic-era buildings and structures, objects, trails, landforms, and other places of traditional, cultural, or religious importance. Cultural resources can be human-made or natural features and are, for the most part, unique, finite, and nonrenewable.

A Class I cultural resources record search was conducted for the study area in Arizona, California, Nevada, and Utah (Tremblay et al. 2024a, 2024b; Eddy et al. 2024; Winslow et al. 2024; Eskenazi 2024). Reclamation is consulting with the Arizona, California, Nevada, and Utah State Historic Preservation Officers (SHPOs), land managing agencies, affected tribes, and other consulting parties to develop a project-specific programmatic agreement under Section 106 of the NHPA and its implementing regulations (36 CFR 800.14). As part of the development of the programmatic agreement, Reclamation, the SHPOs, land managing agencies, affected tribes, and other consulting parties have defined the area of potential effect (APE). For this analysis, the NEPA study area coincides with the APE which also follows the Class I search area.

The study area for the analysis runs from the northern extent of Lake Powell to the SIB and consists of the Colorado River channel from bank to bank except from Glen Canyon Dam to Lake Mead, where it stretches from canyon rim to canyon rim, as well as a 0.5-mile buffer on either side of the riverbank or canyon rim. For additional information on regulatory considerations, including a detailed summary of Section 106 of the National Historic Preservation Act and its implementing regulations under 36 CFR 800, please reference **Section TA 11.1**, Affected Environment, in **TA 11**, Cultural Resources.

Identification Efforts

The Class I records search identified archaeological resources, built environment resources, specially designated cultural resources (National Historic Landmarks [NHLs], National Heritage Areas [NHAs], and National Historic Trails [NHTs]), cultural landscapes, and traditional cultural places (TCPs) within the study area. For additional information on data sources and the types of data collected for each state in the study area, please reference **Section TA 11.1.1**, Identification Efforts, in **TA 11**, Cultural Resources. The Class I records search shows that much of the study area has not been surveyed for cultural resources. Because survey coverage for both Lake Powell and Lake Mead is very low, there is potential for additional undocumented sites to exist in the study area. Data were compiled in August 2023, and the 2023 datasets were incorporated into the analysis. Additionally, the NPS provided updated archaeological site counts for Lake Powell and Lake Mead (including Grand Canyon-Parashant NM) in March 2026, which supplemented the August 2023 dataset for the reservoirs. Therefore, the site counts used in the analysis do not reflect later agency database updates in the study area outside the reservoirs.

This section analyzes impacts on archaeological sites, built environment resources, and specially designated cultural resources. Impacts on tribal resources, tribal perspectives on cultural landscapes, and TCPs are analyzed in **TA 13**, Tribal Resources.

Class I Results

The results of the Class I records search, as summarized below, include archaeological and built environment resources as well as specially designated cultural resources identified in the study area by state. For a more detailed summary on the results of the comprehensive Class I records search for each state, please reference **Section TA 11.1.4**, Class I Results, in **TA 11**, Cultural Resources.

Survey coverage of the study area is variable by state but is overall very low, ranging from 2 or 3 percent in Arizona, 5 percent in Nevada, 11 percent in California, and 37 percent in Utah. Because of the low coverage, the numbers of archaeological sites presented below do not reflect the total number

of sites in the study area and are likely only a small fraction of the sites that are present. However, the sites that have been recorded give an overall picture of resources that may be found in the study area and are used in the analysis as a representative data set for what may be present in unsurveyed areas.

Arizona

The 2023 Class I records search initially identified a total of 4,246 archaeological sites in the study area in Arizona. This number included both NPS and non-NPS data, accounting for duplicates between the two datasets (see **Table TA 11-1** in **TA 11**, Cultural Resources). Non-NPS data contained 1,246 previously recorded sites in the study area. The updated site counts provided by NPS in March 2026 totaled 4,135 sites, which includes sites that overlap from the non-NPS dataset (see **Table TA 11-1** and **Table TA 11-3** in **TA 11**, Cultural Resources). The NPS dataset represents a wide range of cultural affiliations and site functions across three NPS park units (GCNP, Lake Mead NRA, and Glen Canyon NRA) (see **Table TA 11-4** and **Table TA 11-5** in **TA 11**, Cultural Resources). For the built environment, 49 previously evaluated resources were identified in the study area in Arizona. Of these, 43 are listed in the National Register of Historic Places (NRHP); these non-NHL resources consist of 8 districts (that is, groupings of resources), 26 buildings, 6 structures, 1 object, and 2 sites. The remaining 6 resources, all districts, are NRHP-eligible (see **Table TA 11-13** in **TA 11**, Cultural Resources). Additionally, 16 unevaluated but notable built environment resources (5 districts, 1 building, 9 structures, and 1 site) were also identified and may be eligible for the NRHP based on extensive research conducted for the Class I records search (see **Table TA 11-14** in **TA 11**, Cultural Resources).

Specially designated cultural resources identified in the study area in Arizona include nine NHLs, most of which are in GCNP, along with Hoover Dam NHL (also in Nevada) and Yuma Crossing NHL (also in California). Yuma Crossing NHL also encompasses the Yuma Crossing NHA (the only NHA identified in the study area), which is only on the Arizona side of the Colorado River. The Armijo Route of the Old Spanish NHT corridor (also in Utah and Nevada), the Juan Bautista de Anza NHT corridor, and the recently designated Butterfield Overland NHT corridor (both of which also cross into California) also cross the study area in Arizona, although there is no known physical evidence of any of these trails (see **Table TA 11-18** in **TA 11**, Cultural Resources).

California

A total of 493 previously recorded archaeological sites are found within the study area in California (see **Table TA 11-6** in **TA 11**, Cultural Resources) along with 63 built environment resources (three districts, a regional park, and various buildings, structures, roads, and transmission lines) (see **Table TA 11-15** and **Table TA 11-16** in **TA 11**, Cultural Resources). Yuma Crossing NHL is the only NHL in the study area in California, and there are no NHAs because the Yuma Crossing NHA designation only includes portions of the NHL on the Arizona side of the river. For the portions of the Juan Bautista de Anza NHT and Butterfield Overland NHT that cross the study area in California, there is no physical evidence of original trail segments known to exist in the study area.

Nevada

In the Nevada study area, 664 archaeological sites have been previously recorded in the NPS and non-NPS datasets (99 non-NPS [Nevada Cultural Resources Inventory System only] and 565 NPS) (see **Table TA 11-7** and **Table TA 11-8** in **TA 11**, Cultural Resources). Research identified 159 previously documented built environment resources (districts, individual buildings, structures, sites, and objects),

of which 98 are associated with the construction and ongoing operation of the NRHP-listed Hoover Dam Historic District (also an NHL) on the Nevada side of the Colorado River. In addition to those resources associated with Hoover Dam, there is 1 NRHP-listed structure in Lake Mead NRA (Willow Beach Gauging Station), 26 associated with the development of recreation around Lake Mead and Lake Mohave within Lake Mead NRA, and 3 associated with Davis Dam. The remaining 29 built environment resources include 23 documented on an individual basis (apart from Hoover and Davis Dams and established recreation areas in Lake Mead NRA) and 6 for which no information was available from corresponding archives (see **Table TA 11-17** in **TA 11**, Cultural Resources). Hoover Dam NHL (also in Arizona) and the Mojave Road route of the Old Spanish NHT corridor (also in Arizona and Utah) are the only two specially designated cultural resources in the study area in Nevada. There is no evidence of the Old Spanish NHT identified in the study area.

Utah

A total of 1,384 previously recorded archaeological sites (366 non-NPS and 1,018 NPS) were identified in the study area in Utah (see **Table TA 11-10** and **Table TA 11-11** in **TA 11**, Cultural Resources) along with one built environment resource (NRHP-eligible Hite Crossing Bridge). The Armijo Route of the Old Spanish NHT corridor is the only specially designated cultural resource in the study area in Utah, and, like other NHT corridors, there are no known segments of original trail identified in the study area.

3.11.2 Environmental Consequences

Impacts on cultural resources could result from changes in lake levels or river flows from the annual releases. Direct impacts, which are those immediate in place and time, could occur from processes like wave action or wet-dry cycling, and also include visual, auditory, and atmospheric impacts. Indirect impacts occur later in time and/or farther away in terms of distance and could include easier access to newly exposed archaeological sites that were previously underwater. Impacts on cultural resources analyzed in this section only include those impacts resulting from Reclamation's management of annual releases from Glen Canyon and Hoover Dams, which influence reservoir elevations, river flows, and aeolian (wind-borne) transport. The analysis emphasizes cultural resources within 20 meters (66 feet) of the river corridor because they are the most likely to be affected by changes in river flows.

Methodology

Archaeological Resources

Potential impacts on archaeological resources were evaluated using three approaches: 1) site counts (by elevation) compared to modeled lake levels; 2) a USGS/NPS-developed preservation risk model (Caster et al. 2026); and 3) a USGS aeolian (wind-blown sand) transport model (Kelley et al. 2026; Salter and Grams 2026). Elevations for all sites identified in the Class I records search at Lake Powell and Lake Mead were calculated and used to identify those sites that are at elevations subject to changes in water levels. However, due to the low Class III survey coverage, there are doubtless more sites to be found. Along the river corridor, the analysis considers sites identified within 20 meters (66 feet) of the river corridor (bank to bank). A 20-meter (66-foot) distance is used because the variability of elevation along the river corridor is too great to efficiently sort thousands of sites by elevation. For additional information on these methods, as well as the development of the preservation risk model and the models for wind-deposited sediment, please reference **Section TA 11.2.1**, Methodology, in **TA 11**, Cultural Resources.

Built Environment Resources

Because built environment resources are generally less vulnerable to operational impacts than archaeological resources, which are finite, fragile, and nonrenewable, no modeling was conducted specifically for built environment resources. The primary built environment resources identified in the study area consist of major water management infrastructure constructed as part of Reclamation projects like Glen Canyon Dam, Hoover Dam, and Davis and Parker Dams as well as the smaller dams and the various canals and levee systems in the lower reaches of the Colorado River. These facilities represent critical infrastructure essential to Colorado River operations. None of the alternatives would involve decommissioning, removal, or substantial alteration of these facilities. Accordingly, implementation of the alternatives would not be expected to affect the historic integrity or significance of these resources. Based on this assessment, no direct or indirect impacts are anticipated on built environment resources constituting critical water management facilities, and they are not carried forward for detailed analysis.

There are also built environment resources around the reservoirs and immediately along the river corridor—particularly those developed in response to the creation of Lake Powell and Lake Mead or to provide access to or means across the river in the Grand Canyon—that are not considered critical infrastructure for river operations. As such, these types of properties were designed or located in consideration of fluctuating water levels around both the reservoirs and the river corridor. Therefore, impacts on NRHP-listed or -eligible built environment resources would occur where uncharacteristic water levels and river flows exceed historical ranges. For additional information on methodology for built environment resources, please reference **Section TA 11.2.1**, Methodology, in **TA 11**, Cultural Resources.

Specially Designated Cultural Resources

No modeling was undertaken for NHLs, NHAs, or NHTs. The one NHA identified in the study area (Yuma Crossing) coincides with the Arizona portion of the Yuma Crossing and Associated Sites NHL; therefore, it is analyzed as an NHL. There are no confirmed segments of original trail in the study area for the three NHTs. Impacts on NHLs, as the only specially designated cultural resources identified in the study area, could occur only if river flows are outside the historical range.

Impact Analysis Area

The impacts analysis area consists of the Colorado River corridor from the upper limits of Lake Powell in Utah through the Grand Canyon in Arizona and Lake Mead in Arizona, and from Hoover Dam to the SIB.

Assumptions

- Once a resource has been inundated by a reservoir, being continuously inundated thereafter is more conducive to preservation than repeated cycles of inundation and exposure (that is, wet-dry cycling and wave action).
- Repeating cycles of inundation and exposure of resources by the reservoirs or the river are damaging to archaeological resources.
- The covering of resources by wind-deposited river-sourced sediment is conducive to preservation.

- While HFEs were considered in the aeolian transport model as part of the individual vegetation and sandbar models, actual HFE frequency may differ from that assumed or predicted in the modeling.
- Impacts on cultural resources can be characterized based on projected minimum and end-of-year lake elevations for very wet through very dry conditions and river flow volumes.
- Cultural resources that have not been previously inundated would not be inundated under the CCS Comparative Baseline, the No Action Alternative, or any action alternatives (that is, no cultural resources located above reservoir spillway elevations or above the levels of current river flows would be inundated).
- The limit of physical impacts on cultural resources by the river is constrained to resources within the river corridor (bank to bank) or within 20 meters (66 feet) of the river.
- Where previous survey coverage is absent within the study area, there may be sites that have not yet been identified that could be affected under the CCS Comparative Baseline, the No Action Alternative, or the action alternatives.
- The Class I records search conducted for the study area in Arizona, California, Nevada, and Utah serves as a representative dataset for the purposes of analysis.
- Lake Mohave and Lake Havasu would continue to follow their target end-of-the-month elevation schedules ("rule curve") (see **TA 3**, Hydrologic Resources), therefore, no cultural resource impacts are expected at these reservoirs.

Impact Indicators

- Projected monthly and end-of-year lake elevations that may expose cultural resources to damage from wave action, wet-dry cycling, or increased ease of access
- Projected WY and CY dam releases resulting in potential river-flow changes that leave cultural resources susceptible to damage from erosion, wet-dry cycling, or increased ease of access
- Projected availability of sediments along the river that may be transported by wind and deposited on archaeological sites

Issue 1: How will any changes in dam operations affect (1) lake elevations at Lake Powell and Lake Mead and (2) river flows downstream, which may affect cultural resources?

Lakes

This section summarizes the potential for archaeological resources to be exposed and, therefore, experience potential impacts from exposure, using the distribution of previously recorded archaeological sites by elevation and the hydrologic modeling results for Lake Powell and Lake Mead elevations. The following summary incorporates the discussion of hydrologic modeling as presented in **TA 3**, Hydrologic Resources. For additional information on the technical details related to Issue 1, please reference **Section TA 11.2.2**, Issue 1, in **TA 11**, Cultural Resources.

Because survey coverage varies across the study area and much of the site location data was recorded prior to modern GPS/GIS technology, precise site counts are not feasible for analysis. Site counts therefore represent a sample used to characterize the overall level of sensitivity within the study area. Representative site counts by elevation were compiled from Class I data using associated elevations based on critical conditions for each lake. For Lake Powell, the critical elevations considered for the

analysis are 3,700 feet (the top of the Glen Canyon Dam spillway) to 3,490 feet (the minimum power pool) (see **Table TA 3-2** in **TA 3**, Hydrologic Resources). For Lake Mead, these associated elevations are 1,221 feet (the top of the Hoover Dam Spillway) down to 950 feet (the minimum power pool) (see **Table TA 3-5** in **TA 3**, Hydrologic Resources). Archaeological sites identified in the Lake Powell and Lake Mead dataset were distributed by elevation range (see **Table TA 11-19** and **Table TA 11-20** in **TA 11**, Cultural Resources). Overall, survey coverage for both lakes is very low (around 3 percent), which means the numbers in these tables greatly underrepresent the total number of sites present. There are no NRHP-listed or NRHP-eligible built environment resources within the elevation range for Lake Powell (3,700–3,490 feet). There is one NRHP-eligible district (Echo Bay Developed Area) within the elevation range for Lake Mead (1,221–950 feet); its historic boat ramp falls between 1,221 and 1,100 feet.

The analysis for both Lake Powell and Lake Mead as presented here focuses on average and dry to critically dry flow conditions (Average, Dry, and Critically Dry Flow Categories). For discussion related to wet flow conditions (Wet Flow Category), please refer to **TA 11.2.2**, Issue 1, in **TA 11**, Cultural Resources.

Lake Powell

This section references **Figure TA 3-6** in **TA 3.2.1**, Issue 1, and **Tables TA 3-3** and **TA 3-4** at the end of **TA 3**, Hydrologic Resources. The following discussion uses the known number of sites within the Lake Powell dataset provided by NPS staff (see **Table TA 11-19** in **TA 11**). Survey coverage at Lake Powell is calculated to be 3.3 percent of the area below full pool, meaning the number of sites in the Lake Powell data set represents a fraction of the total number of sites present. For additional information on these tables and figures as they were incorporated into the analysis of cultural resources, please reference **Section TA 11.2.2**, Issue 1, in **TA 11**, Cultural Resources.

In general, when the level of Lake Powell is at the top of the Glen Canyon Dam spillway (3,700 feet), all 857 archaeological sites in the Lake Powell dataset (as well as any undiscovered sites below this elevation) would be inundated. Conversely, water levels dropping to minimum power pool could expose up to all 857 archaeological sites (depending on how many of those in the Lake Powell dataset remain above 3,490 feet), leaving them vulnerable to impacts. Again, it is important to note that, because some areas at Lake Powell have not been surveyed, all of the modeled scenarios have the potential to impact undiscovered archaeological resources. Sites exposed at higher elevations may be less vulnerable to impacts from wet-dry cycling and wave action, but ease of access to them may increase depending on their location. Elevations for Lake Powell are assessed based on minimum WY and EOWY elevations.

Under the Average Flow Category, the modeled scenarios begin to diverge in performance. Minimum WY median elevations for the CCS Comparative Baseline and the No Action Alternative fall around and just below 3,550 feet, potentially exposing at least 316 known archaeological sites, along with any undiscovered sites, within and above the 3,540–3,560-foot zone. EOWY median elevations for the CCS Comparative Baseline and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) are around 3,570 feet, while the No Action Alternative is just above 3,580 feet. At these elevations, at least 280 known sites, along with any undiscovered sites above 3,570 feet within the 3,580–3,560-foot zone, could be vulnerable if water levels drop. The Basic Coordination and Representative Preferred Alternatives perform somewhat better, with minimum WY median elevations

of approximately 3,560 feet and 3,570 feet, respectively, potentially exposing up to 316 known sites. The EOWY median elevations are higher at around 3,590 feet for the Basic Coordination Alternative and just below 3,600 feet for the Representative Preferred Alternative, potentially exposing at least 249 known sites and any additional sites above 3,590 feet within the 3,600–3,580-foot zone.

The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform best under average conditions. Minimum WY median elevations are around 3,610 feet and 3,600 feet, respectively, which would expose between 197 and 249 known sites. EOWY median elevations are around 3,630 feet for the Enhanced Coordination Alternative and 3,620 feet for the Maximum Operational Flexibility Alternative. At these elevations, the Enhanced Coordination Alternative could expose at least 138 known sites (plus any sites above 3,630 feet within the 3,640–3,620-foot zone), while the Maximum Operational Flexibility Alternative could expose up to 197 known sites. These two alternatives also have the narrowest interquartile ranges for both median elevation metrics. Additional sites would be exposed as water levels decline further and conditions become drier, depending on site elevation.

For the Critically Dry Flow Category, the CCS Comparative Baseline, the No Action Alternative, and the action alternatives struggle to maintain key Lake Powell elevations. Minimum WY and EOWY median elevations for the CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives fall below 3,490 feet (minimum power pool), with the No Action Alternative declining to just below 3,440 feet. Under these conditions, at least 415 known archaeological sites (approximately 48 percent of the Lake Powell dataset) along with any undiscovered sites, could be exposed and vulnerable. Additional sites may be affected as elevations fall below 3,490 feet, depending on the distribution of the 442 recorded sites below 3,500 feet. The 3,500 foot elevation is important because it provides an approximate 10-foot buffer to protect critical infrastructure, water supply, and hydropower operations, which are critically impacted at an elevation of 3,490 feet (see **Section TA 3.2.1**, Issue 1, in **TA 3**, Hydrologic Resources).

The Representative Preferred Alternative performs slightly better under critically dry conditions, with a minimum WY median elevation just above 3,490 feet. This would still leave at least 415 known sites exposed above 3,500 feet but could protect additional sites if present above the minimum power pool elevation. The EOWY median elevation for this alternative is just below 3,510 feet, which would inundate more sites below this level within the 3,520–3,500-foot zone. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform the best compared to the others. Minimum WY median elevations are approximately 3,520 feet and 3,510 feet, respectively, with EOWY median elevations around 3,560 feet and 3,550 feet. Relative to these EOWY elevations, both alternatives could expose at least 316 known sites and any undiscovered sites down to around 3,560 feet, with the Maximum Operational Flexibility Alternative potentially exposing additional sites above 3,550 feet within the 3,560–3,540-foot zone. Interquartile ranges for the Enhanced Coordination Alternative indicate that it has the greatest potential to limit site exposure under critically dry conditions, with the upper bound of the EOWY median elevation (75th percentile) reaching approximately 3,600 feet and potentially limiting exposure to 249 known sites.

Lake Mead

This section references **Figure TA 3-11** in **TA 3.2.1**, Issue 1, and **Tables TA 3-6** and **TA 3-7** at the end of **TA 3**, Hydrologic Resources. The following discussion uses the known number of sites within

the Lake Mead dataset provided by NPS staff. Survey coverage at Lake Mead is calculated to be 2.8 percent of the area below full pool meaning the number of sites in the Lake Mead data set represents a fraction of the total number of sites present. For additional information on these tables and figures as they were incorporated into the analysis of cultural resources, please reference **Section TA 11.2.2**, Issue 1*,* in **TA 11**, Cultural Resources.

In general, when water-level elevations are at or above 1,221 feet, all 310 archaeological sites in the dataset would be inundated. Conversely, if water levels drop to 950 feet, all 310 sites in the Lake Mead dataset would be exposed, depending on the elevations of sites below 961 feet (see **Table TA 11-20** in **TA 11**, Cultural Resources). Because very little of Lake Mead was surveyed prior to the construction of Hoover Dam in the early 1930s and, as a result, undiscovered archaeological resources are likely to be present in unsurveyed areas, such resources could be affected under any of the modeled scenarios. Elevations for Lake Mead are assessed based on minimum CY and EOCY elevations.

Under the Average Flow Category, the modeled scenarios begin to diverge in performance with respect to minimum CY and EOCY median elevations. As lake levels decline, additional sites may be exposed depending on elevation. The No Action Alternative performs the most poorly, with minimum CY and EOCY median elevations just below 970 feet and just below 980 feet, respectively. These elevations would expose at least 301 known archaeological sites in the Lake Mead dataset as well as sites below this elevation within the 981–961-foot zone, including any undiscovered sites that may be present. The CCS Comparative Baseline performs somewhat better than the No Action Alternative, with a minimum CY median elevation of about 1,030 feet and an EOCY median elevation around 1,040 feet. However, these elevations could still leave at least 286 known archaeological sites, along with any undiscovered sites present, vulnerable to impacts from exposure. The Basic Coordination Alternative has a minimum CY median elevation just above 1,050 feet and an EOCY median elevation just above 1,060 feet, leaving at least 280 known archaeological sites (and any undiscovered sites present) exposed. The corresponding interquartile ranges, from approximately 1,130 feet at the upper limit down to around 1,000 feet, could leave between 227 and 296 known sites vulnerable to impacts from exposure, depending on elevation.

The Representative Preferred Alternative performs slightly better, with a minimum CY median elevation just above 1,090 feet and an EOCY median elevation just above 1,100 feet, potentially exposing at least 265 known archaeological sites along with any undiscovered sites present. The Enhanced Coordination Alternative has a minimum CY median elevation around 1,100 feet and an EOCY median elevation around 1,110 feet, which could expose between 245 and 265 known sites, depending on elevation. The interquartile ranges for this alternative are similar for both minimum CY and EOCY elevations, ranging from around 1,130 feet down to about 1,060 feet and from around 1,140 feet down to around 1,070 feet, respectively. Within these ranges, between 227 and 280 known sites could be exposed, depending on elevation and the presence of undiscovered sites. The Maximum Operational Flexibility Alternative has a minimum CY median elevation just below 1,120 feet and an EOCY median elevation just below 1,130 feet, potentially exposing between 227 and 245 known sites, along with any undiscovered sites present. The interquartile range for this alternative is the largest among the modeled scenarios, ranging from around 1,180 feet, which could leave up to 142 known sites exposed, down to just above 1,040 feet, which could expose up to 286 known archaeological sites and any undiscovered sites also present above these elevations.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs the best under average hydrological conditions. The LB Priority approach has minimum CY and EOCY median elevations around 1,140 feet and 1,150 feet, respectively, which could expose between 196 and 227 known sites as well as any undiscovered sites present. The LB Pro Rata approach performs slightly better, with a minimum CY median elevation just above 1,150 feet and an EOCY median elevation around 1,160 feet. These elevations could expose at least 196 known sites as well as sites present above 1,150 feet within the 1,161–1,141-foot zone. Interquartile ranges for the Supply Driven Alternative vary, with the LB Pro Rata approach ranging from just below 1,190 feet (75th percentile) to just below 1,070 feet (25th percentile), and the LB Priority approach ranging from around 1,180 feet (75th percentile) to just below 1,060 feet (25th percentile). Within these ranges, between 85 and 275 known sites could be exposed under the LB Pro Rata approach and between about 142 and 280 known sites under the LB Priority approach, depending on elevation and the presence of undiscovered sites.

As hydrological conditions become critically dry, the modeled scenarios maintain the same relative performance but shift downward collectively by roughly 100 feet in elevation within the Critically Dry Flow Category. For Lake Mead, the 975-foot elevation is important because it provides a 25-foot buffer for water supply and hydropower to stay above minimum power pool (see **Section TA 3.2.1**, Issue 1, in **TA 3**, Hydrologic Resources). Under these conditions, the elevation at which sites are vulnerable to wet-dry cycling and wave action would be lowest across all scenarios. The CCS Comparative Baseline has a minimum CY median elevation around 930 feet, while the No Action Alternative declines further to around 900 feet, both well below the Lake Mead minimum power pool elevation of 950 feet. The EOCY median elevation for the CCS Comparative Baseline is around 960 feet, while the No Action Alternative declines to around 930 feet. At these elevations, up to all 310 known archaeological sites in the Lake Mead dataset, along with any undiscovered sites that may be present, could be exposed depending on the elevations of the four known sites below 961 feet. The Basic Coordination Alternative performs somewhat better, with a minimum CY median elevation just above 970 feet and an EOCY median elevation around 980 feet. The Representative Preferred Alternative performs slightly better, with a minimum CY median elevation around 980 feet and an EOCY median elevation just above 990 feet. Despite these slightly higher elevations, both alternatives could still leave at least 296 known sites (more than 95 percent of the sites in the Lake Mead dataset) along with any undiscovered sites present, exposed during critically dry conditions.

The Enhanced Coordination Alternative has minimum CY and EOCY median elevations around or just above 1,000 feet, with interquartile ranges extending from approximately 1,050 feet down to around 950 feet. Depending on the elevations of the four known sites below 961 feet, this alternative could still leave up to all 310 known sites exposed. The Maximum Operational Flexibility Alternative has similar median elevations, with minimum CY and EOCY values just above 1,010 feet and around 1,000 feet, respectively. These elevations could leave between 291 and 296 known sites (and any undiscovered sites) vulnerable to impacts. The interquartile ranges extend from around 1,060 feet down to approximately 970 feet, potentially exposing between about 280 and 301 known sites depending on the elevations of sites within the 981–961-foot zone.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) also performs slightly better compared to other scenarios. The LB Priority approach has minimum CY and EOCY median elevations around 1,010 feet, while the LB Pro Rata approach reaches the highest median elevations under critically dry conditions at or just below approximately 1,030 feet. Even so, between 286 and 291

known sites could still be exposed based on median elevations. Examination of the upper limits of the interquartile ranges indicates that some additional sites could remain inundated, with upper elevations around or just above 1,070 feet for the LB Priority approach (potentially exposing at least 275 known sites) and around 1,090 feet for the LB Pro Rata approach (potentially exposing at least 265 known sites). However, both scenarios would still leave at least 85 percent of the archaeological sites in the Lake Mead dataset, along with any undiscovered sites present, exposed above the water level and therefore vulnerable to impacts.

For the Echo Bay Developed Area, modeled scenarios with minimum CY and EOCY median elevations below 1,100 feet would expose portions of the boat ramp; however, this exposure would occur outside the NRHP-eligible district boundary. Modeled scenarios with elevations above 1,100 feet could partially inundate the ramp, with full submersion occurring at higher elevations along the ramp, which extends up to approximately 1,221 feet. These conditions would be more likely under the Supply Driven Alternative because the interquartile ranges for minimum CY and EOCY elevations under the LB Priority approach extend up to around 1,090 feet. Reservoir elevations exceeding 1,221 feet could affect recreation area infrastructure within the district boundary.

Preservation Risk Modeling

Preservation risk modeling results were compared with the 90th percentile values of modeled values for WY 2008 to 2025 (i.e., the 2007 Interim Guidelines period); the 90th percentile risk value is 2.72 for Lake Powell and 2.24 for Lake Mead (see **Figure TA 11-1** in **TA 11**, Cultural Resources; Caster et al. 2026). If preservation risk exceeds these threshold values, impacts on archaeological sites may occur at levels beyond those expected under historical conditions for the specific reservoir. For the purposes of this analysis, "historical conditions" coincide with the 2007 Interim Guidelines period (WY 2008–2025).

For Lake Powell under the Average Flow Category, the CCS Comparative Baseline and the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives all have preservation risk median values at the 2.72 threshold. The Representative Preferred Alternative has a slightly lower median value of 2.69, followed by the Maximum Operational Flexibility Alternative at 2.65 and the Enhanced Coordination Alternative at 2.52. The Maximum Operational Flexibility and Enhanced Coordination Alternatives share the same interquartile range, from 2.65 (75th percentile) to 2.24 (25th percentile), under average hydrological conditions. The Representative Preferred Alternative has the narrowest interquartile range, from 2.72 to 2.65, while the No Action Alternative shows the greatest variation, ranging from 3.23 to 2.24. Overall, under average modeled conditions, preservation risk values generally remain at or near the 2.72 threshold, indicating that impacts on archaeological sites, if they occur, would not exceed those expected under similar average conditions historically.

Under the Critically Dry Flow Category for Lake Powell, preservation risk median values for the CCS Comparative Baseline and all alternatives exceed the 2.72 threshold. The No Action Alternative has the highest median preservation risk value at 3.71, followed by the Basic Coordination Alternative at 3.42 and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) at 3.39. The Representative Preferred Alternative has a median value of 3.23, while both the Maximum Operational Flexibility and Enhanced Coordination Alternatives have median values of 3.10; however, the interquartile range for the Enhanced Coordination Alternative drops to 2.71 at the lower bound. Because lower preservation risk values indicate better performance, median values below 2.72 would

suggest impacts comparable to historical conditions. Under critically dry conditions, however, all median values exceed this threshold, indicating elevated preservation risk relative to historical conditions.

For Lake Mead under the Average Flow Category, the No Action Alternative has the highest preservation risk median value at 2.70. The CCS Comparative Baseline follows at 2.31, and the Basic Coordination Alternative at 2.26, both above the Lake Mead preservation risk threshold of 2.24, indicating greater risk to archaeological sites than would be expected under similar historical conditions. The Enhanced Coordination Alternative has a median value just below the threshold at 2.22, followed by the Representative Preferred Alternative at 2.20 and the Maximum Operational Flexibility Alternative at 2.18. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has the lowest median preservation risk value at 2.03. Interquartile ranges for the CCS Comparative Baseline, the No Action Alternative, and all action alternatives extend above the 2.24 threshold, including the Representative Preferred Alternative at 2.31. The lower bounds of these ranges generally fall below the threshold, except for the No Action Alternative, which remains above it at 2.35.

Under the Critically Dry Flow Category for Lake Mead, preservation risk median values for all scenarios exceed the 2.24 threshold. The No Action Alternative performs the worst with a median value of 3.07, followed by the CCS Comparative Baseline at 3.00. All action alternatives have lower median values but remain above the threshold, including the Basic Coordination Alternative at 2.64, the Representative Preferred Alternative at 2.38, the Enhanced Coordination Alternative at 2.36, and both the Maximum Operational Flexibility and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives at 2.35. Because none of the scenarios fall below the 2.24 threshold, impacts on archaeological sites under critically dry conditions would exceed those anticipated under similar historical conditions.

Figure TA 11-2 and **Figure TA 11-3** in **TA 11**, Cultural Resources, compare alternatives by showing the percentage of futures in which the preservation risk is below 2.72 for Lake Powell and 2.24 for Lake Mead in at least 90 percent of months. The 2.72 and 2.24 preservation risk values represent the 90th percentile of modeled historical values for WY 2008–2025 (the 2007 Interim Guidelines period), which includes the period of significant reservoir storage loss. To reiterate, if the preservation risk is above those values, impacts on archaeological sites may be greater than expected under historical conditions.

For Lake Powell, over the full modeling period, the Enhanced Coordination Alternative would be the most robust, meeting the 2.72 risk threshold in 47 percent of futures. The Maximum Operational Flexibility Alternative would be less robust, meeting the 2.72 threshold in 28 percent of futures, followed by the No Action and Basic Coordination Alternatives at 17 percent, the Representative Preferred Alternative at 16 percent, and the CCS Comparative Baseline at 15 percent. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) meets the preferred level of performance in 14 percent of futures. This relational pattern is consistent if the full modeling period is broken out into shorter periods, including the first decadal period from 2027–2039 where the Enhanced Coordination Alternative also performs the best at 30 percent whereas the CCS Comparative Baseline performs the worst at 10 percent. It is important to note that 2027, as the beginning of the first 10-year interval, is anticipated to have low reservoir elevations and, therefore, the

modeling for this breakout (2027–2039) shows very low percentages of futures met for the preferred minimum of performance across the CCS Comparative Baseline, the No Action Alternative, and all other action alternatives. See **Figure TA 11-2** in **TA 11** (Cultural Resources) for robustness modeled for 2040–2049 and 2050–2060 at Lake Powell.

For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would be the most robust by meeting the 2.24 risk threshold in 24 percent of futures over the full modeling period. The CCS Comparative Baseline and No Action Alternative meet the preferred minimum of performance in only 6 and 13 percent of futures, respectively. The Maximum Operational Flexibility Alternative would meet the threshold in 19 percent of futures, followed by the Enhanced Coordination Alternative at 15 percent, the Representative Preferred Alternative at 14 percent, and the Basic Coordination Alternative at 10 percent. If the modeling period is broken out, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) can be seen to meet the threshold for only 5 percent of futures in the first decadal period (2027–2039), followed by the CCS Comparative Baseline, the Maximum Operational Flexibility Alternative, and the Representative Preferred Alternative, all three of which meet the preferred level of performance in only 3 percent of futures. The Basic Coordination and Enhanced Coordination Alternatives meet the threshold 2 percent of the time while the No Action Alternative is at 1 percent for the 2027–2039 modeling period. See **Figure TA 11-3** in **TA 11** (Cultural Resources) for robustness modeled for 2040–2049 and 2050–2060 at Lake Mead.

Overall, the Enhanced Coordination Alternative is the most robust for Lake Powell for the full modeling period and the first decadal modeling period (2027–2039), followed by the Maximum Operational Flexibility Alternative. For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust, followed by the Maximum Operational Flexibility Alternative for the full modeling period. Looking at only the 2027–2039 modeling period, while the Supply Driven Alternative (both LB Priority and Pro Rata approaches) still remains the most robust at 5 percent, the CCS Comparative Baseline, Representative Preferred Alternative, and Maximum Operational Flexibility Alternative are all equally, but lesser, robust for the first 10-year period at 3 percent.

River Flows

This section references the discussion presented in **Section TA 3.2.4**, Issue 4, as presented in **TA 3**, Hydrologic Conditions, with additional references to other sections as appropriate. The analysis focuses on Average Flow and Critically Dry Flow Categories. In all categories except the Critically Dry Flow Category, the high end of the results range has been cut off to improve comparisons in the average and drier flow conditions.

For the purposes of analyzing potential impacts related to changes in river flow, archaeological sites that may be physically affected are those located along or immediately adjacent to the river, where erosion caused by moving water may occur. As with the Lake Powell and Lake Mead datasets discussed above, variable survey coverage and older locational data must be taken into account. To identify the number of archaeological sites, built environment resources, and specially designated cultural resources that may be affected by changes in flow, sites with all or portions of their boundaries in the river corridor (bank to bank) or within 20 meters (66 feet) of the river corridor were identified from the

overall dataset using a GIS. For additional information on the cultural resources identified along the river by reach, please reference **Section TA 11.2.2,** Issue 1 in **TA 11**, Cultural Resources.

For all reaches, the impacts from changes in river flow would include water erosion from river currents during higher releases and flows but may also include exposure from lower water levels where either dam release or flow volumes are reduced; however, these impacts are only considered in this analysis when volumes fall outside the parameters of past releases or flows.

Glen Canyon Dam to Lake Mead

This section summarizes the potential for cultural resources to be affected by river flows below Glen Canyon Dam and references the median and interquartile WY release volumes (in maf) from the dam illustrated in **Figure TA 3-21** in **Section TA 3.2.3** and in **Table TA 3-14** at the end of **TA 3**, Hydrologic Resources. Since 2008 with the implementation of the 2007 Interim Guidelines, releases from Glen Canyon Dam have been in the range of around 7.0 maf to around 12.5 maf, averaging around 8.7 maf (see **Section TA 3.1.3**, Lake Powell and Glen Canyon Dam, in **TA 3**, Hydrologic Resources). In general, WY releases from Glen Canyon Dam that fall outside the historical range of around 7.0–12.5 maf have greater potential to impact known cultural resources within 20 meters (66 feet) of the river as well as on undiscovered resources that may be present along the river corridor. In addition, higher WY release volumes can increase erosion along the river corridor, even when releases remain in this historical range.

River flows from Lake Powell to Lake Mead primarily consist of controlled releases from Glen Canyon Dam. WY releases from the dam in the Average Flow Category would generally fall within the range of past annual release volumes as neither the CCS Comparative Baseline, No Action Alternative, nor the action alternatives (including the Representative Preferred Alternative) have median volumes that fall below 7.9 maf in the Average Flow Category. Therefore, there would be no additional impacts because none of the modeled scenarios would deviate from the established range. In the Average Flow Category, the interquartile range for the Enhanced Coordination Alternative would be the only modeled scenario that deviates from the range of past release volumes (7.0 maf up to 12.5 maf), as it is modeled to potentially drop to around 6.9 maf (25th percentile). Reductions in the volume of WY releases would affect river flows, thereby potentially exposing the Steamboat Charles Spenser. The same drops in river flows, resulting from reduced WY releases from Glen Canyon Dam, would not be detrimental to the one known historic property within 20 meters (66 feet) of the river because the boundary of the Lees Ferry and Lonely Dell Historic District extends into the river channel.

In the Critically Dry Flow Category, median WY release volumes for the CCS Comparative Baseline, No Action Alternative, and all action alternatives would fall below 7.0 maf, to as low as around 5.1 maf under the Enhanced Coordination Alternative. Under the critically dry hydrologic conditions, the No Action Alternative would perform better than the others relative to the upper limits of the interquartile ranges (75th percentile), which are around 7.7 maf for the CCS Comparative Baseline and around 8.2 maf for the No Action Alternative. The Representative Preferred Alternative has one of the narrowest interquartile range under critically dry hydrological conditions, with an upper limit around 6.0 maf, which is still below the bottom of the range of past flow volumes at 7.0 maf. All the modeled scenarios could impact the Steamboat Charles Spenser if the reduced volumes of these WY releases cause the river to drop below previous water levels. On the other hand, these same potential

drops in river water level would protect the only NRHP-listed property within 20 meters (66 feet) of the river (the Lees Ferry and Lonely Dell Historic District), as previously discussed.

Hoover Dam to Davis Dam

This section summarizes the potential for cultural resources to be affected by river flows below Hoover Dam to Davis Dam and refers to the median and interquartile CY release volumes from Hoover Dam as illustrated in **Figure TA 3-25** in **Section TA 3.2.3** and **Table TA 3-19** at the end of **TA 3**, Hydrologic Resources. Since 2008, CY releases from Hoover Dam have been in the range of around 8.5 maf to around 9.6 maf, averaging around 9.2 maf (see **Section TA 3.1.7**, Hoover Dam to Lake Mohave, in **TA 3**, Hydrologic Resources). In general, CY releases from Hoover Dam that fall outside the historical range of around 8.5 to around 9.6 maf have greater potential to impact known cultural resources within 20 meters (66 feet) of the river as well as on undiscovered resources that may be present along the river corridor. For the Average Flow Category, the No Action Alternative is the only modeled scenario under which median CY release volume would remain within the 8.5–9.6 maf range for previous release volumes below Hoover Dam in this reach at around 8.6 maf. The CCS Comparative Baseline falls just under previous release volumes at around 8.3 maf. The action alternatives would not perform as well, with the median CY releases for the Basic Coordination Alternative in the Average Flow Category around 8.0 maf, followed by the Representative Preferred Alternative at around 7.9 maf, the Maximum Operational Flexibility Alternative at around 7.8 maf, the Supply Driven Alternative (LB Priority and LB Pro Rata approaches) at around or just below 7.7 maf, and the Enhanced Coordination Alternative at just below 7.6 maf. Where impacts on archaeological sites result from erosion caused by moving water, these may be less likely to occur if the reduced CY release volumes cause the river to drop below previous water levels. The same drops in river water levels would not be detrimental to NRHP-listed Willow Beach Gaging Station.

For the Critically Dry Flow Category, median CY release volumes would be well below previous volume ranges under the CCS Comparative Baseline, No Action Alternative, and all action alternatives, which would fall below 8.0 maf, down to as low as around 6.4 maf for the Maximum Operational Flexibility Alternative, with the Enhanced Coordination Alternative slightly higher at around 6.5 maf. Again, relative to impacts on archaeological sites that may be subject to erosion caused by moving water, the ranges of all the modeled scenarios may be less likely to physically affect archaeological sites if the reduced CY release volumes cause the river to drop below previous water levels. Likewise, these same potential drops in river water level would not impact the NRHP-listed Willow Beach Gaging Station previously discussed.

Within this reach is Lake Mohave, which is operated under a rule curve that maintains end-of-month target elevations between 630 feet and around 646 feet and which has been kept relatively constant at around 641 feet since 2008 (see **Section TA 3.1.7**, Hoover Dam to Lake Mohave, in **TA 3**, Hydrologic Resources). There are no anticipated impacts on any known cultural resources around the reservoir in this portion of the reach, regardless of scenario, because Lake Mohave would continue to be operated under the existing rule curve.

Below Davis Dam

No impacts under the CCS Comparative Baseline, No Action Alternative, and all action alternatives are expected below Davis Dam. Davis and Parker Dams will continue to be operated under the current rule curves that determine end-of-month target elevations for Lake Havasu (see **Section TA**

3.1.8, Davis Dam to Lake Havasu, in **TA 3**, Hydrologic Resources). Imperial Dam is operated to maintain a nearly constant elevation to meet water delivery requirements for major diversions to California and Arizona (see **Section TA 3.1.10**, Cibola Gage to Imperial Dam, in **TA 3**). Additionally, the river below Imperial Dam is characterized by several stretches of mechanically channelized river corridor.

Issue 2: How will changes in dam operations affect sediment availability for aeolian transport to protect archaeological sites in the Grand Canyon?

This section references **Section TA 11.2.3**, Issue 2, in **TA 11**, Cultural Resources, as well as **Section TA 9.2.2**, Issue 1, in **TA 9**, Vegetation Including Special Status Species, and **Section TA 5.2.5**, Issue 4, in **TA 5**, Geomorphology and Sediment. As discussed in S**ection TA 11.2.1**, Methodology, in **TA 11**, the aeolian transport model looks at favorable conditions for wind-deposited sand to be present to protect archaeological sites over long periods of time using projected vegetation cover and exposed sand area or sandbar volume (Butterfield and Palmquist 2026; Kelley et al. 2026; Salter and Grams 2026). The vegetation and sandbar volume modeling used is from the Marble Canyon sub-reach from Lees Ferry to the Little Colorado River. The exposed sand modeling was conducted for the portion of the river from Lees Ferry to Bright Angel Creek. Although the analyses are limited to these reaches, the results provide general insight into sediment and vegetation responses that may also occur in other portions of the river corridor with similar geomorphic and hydrologic conditions.

Overall, less annual total vegetation cover is better for aeolian sand transport because it leaves available sand exposed to be picked up by the wind. As discussed in **Section TA 9.2.2**, Issue 1, and seen in **Figure TA 9-14** in **TA 9**, Vegetation Including Special Status Species, for all modeled scenarios in wet and moderately wet conditions there would be less annual total vegetation cover (below modeled historical conditions, indicated by the dashed line in **Figure TA 9-14**) from higher water levels and longer HFEs. As conditions grow drier, water flows diminish, and HFEs are shorter, annual total vegetation cover thereby increases (see **Figure TA 9-14** in **TA 9**). In dry and critically dry conditions, total annual vegetation cover increases and differentiation between alternatives can be seen. For the Critically Dry Flow Category, the medians and interquartile ranges are above the modeled historical conditions (dashed line) for all sub-reaches and all alternatives except the interquartile range for the CCS Comparative Baseline, which drops just below the dashed line (see **Figure TA 9-14** in **TA 9**). This indicates that there may be more annual total vegetation cover, especially under critically dry flows.

As discussed in **TA 5**, for an HFE to be triggered, enough sand needs to be available in Marble Canyon and enough water needs to be available in Lake Powell (as measured by water level), with both the required amounts of sand and water being dependent on the selected HFE duration. Additionally, HFE releases can only be implemented when Lake Powell water levels are at or above 3,500 feet, with sandbar deposition occurring most rapidly during the first 4 days of an HFE event. Lastly, sandbar volume modeling uses the assumption that HFEs are implemented as often as possible (see **Section TA 5.2.1**, Modeling Criteria and Assumptions). For the aeolian transport model, increased exposed sandbar volume means more sand is available to protect archaeological sites. In general, as conditions get drier and the amount of water flowing through the river decreases, exposed sandbar volume increases (see **Section TA 5.2.5**, Issue 4, in **TA 5**, Geomorphology and Sediment). Differences in performance among the alternatives also increase as hydrological conditions become drier, with the

Enhanced Coordination and Maximum Operational Flexibility Alternatives performing the best for the Critically Dry Flow Category (see **Figure TA 5-12** in **Section TA 5.2.5**).

The results of the WY average of exposed sand area modeling are seen in **Figure TA 11-4** (see **TA 11**, Cultural Resources), with the 90th percentile and median (50th percentile) of modeled sand areas depicted as two dashed lines. As with exposed sandbar volume, increased exposed sand area is beneficial for the aeolian transport of sand to protect archaeological sites. In the Average Flow Category, median exposed sand area is around the 90th percentile (upper dashed line) and the median (50th percentile, lower dashed line) of modeled sand area (in million square meters). As conditions become drier, all modeled scenarios perform similarly with modeled median exposed sand area above the observed median, with the No Action, Enhanced Coordination, and Maximum Operational Flexibility Alternatives having slightly higher median values than the CCS Comparative Baseline and the other action alternatives, particularly in the Critically Dry Flow Category. Under critically dry conditions, the Maximum Operational Flexibility Alternative has the most variability with the greatest interquartile range.

The above three models are used in the aeolian sand modeling. **Figure TA 11-5** in **TA 11**, Cultural Resources, shows the results of the aeolian sand modeling, in which some futures meet one of two criteria: either the annual sand area is greater than the median observed sand area over the last 20 years and the vegetation cover area is less than median observed area over the last 20 years or the sandbar volume is greater than 1.5 times the initial condition. Based on previous studies and as shown in the table (in the highlighted row), those criteria being met at least 1 out of every 3 years is the optimal condition for enough sand to be available for aeolian transport.

Over the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would be the most robust at meeting the preferred minimum performance in 19 and 18 percent of futures, respectively, followed by the No Action Alternative only in 14 percent of futures. The Basic Coordination Alternative meets the preferred minimum of performance in only 9 percent of futures, with the Representative Preferred Alternative meeting it in only 6 percent of futures. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the least robust, meeting the preferred minimum performance in only 3 percent of futures, with the CCS Comparative Baseline only slightly higher at 4 percent of futures. If the year interval is lengthened to 1 out of 4, 5, or 6 years, the models perform in a similar overall pattern, with the Enhanced Coordination Alternative performing the best until reaching 1-out-of-6-year interval when the No Action Alternative performs the best over the full modeling period.

If the modeling period is broken out for the first 10 years, the No Action Alternative performs the best, meeting the preferred minimum performance in 38 percent of futures for the highlighted interval, followed by the Enhanced Coordination Alternative at 35 percent of futures in the first decadal period (2027–2039), followed by the Maximum Operational Flexibility Alternative at 30 percent of futures. The Basic Coordination Alternative and the CCS Comparative Baseline meet the preferred minimum of performance in 18 percent and 19 percent of futures, respectively, followed by the Representative Preferred Alternative at 17 percent. The Supply Driven Alternative (both the LB Priority and LB Pro Rata approaches) performs with only 9 percent of futures meeting the minimum preferred performance. Due to aeolian transport favoring drier conditions because more useable sand is available and the beginning of the first decadal period (2027-2039) is anticipated to have low

reservoir elevations, the modeling for this breakout (2027–2039) depicts more modeled futures meeting the preferred minimum of performance across the CCS Comparative Baseline, the No Action Alternative, and all action alternatives than over the full modeling period. Refer to **Figure TA 11-5** in **TA 11** (Cultural Resources) for robustness modeled for 2040–2049 and 2050–2060 relative to multi-model aeolian transport condition.

The overall results seem to indicate an increase in the percentage of futures over time, which may correlate to increased available sand over time; however, the perceived increase is driven by an increase in sandbar volume over time in the modeling with the understanding that HFEs would continue as planned. In reality, the decision to conduct HFEs depends on annual review and the actual HFE frequency may differ from that assumed or predicted in the modeling.

Summary Comparison of Alternatives

The Enhanced Coordination and Maximum Operational Flexibility Alternatives would perform better for Lake Powell in terms of maintaining water levels in drier conditions that would expose fewer archaeological sites and protect more through inundation. Because the continuous inundation of archaeological sites is more conducive to preservation than repeating cycles of inundation and exposure due to the risks of wave action, changes in lake elevations that may expose previously inundated resources to impacts such as wet-dry cycling and wave action are the biggest concern. As conditions become drier at Lake Powell, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would perform the best in the Average Flow Category with median water elevations from around 3,600 feet to around 3,630 feet. They also would perform best in the Critically Dry Flow Category; however, between 3,510 feet and 3,560 feet for these two action alternatives, potentially leaving (at minimum) between 316 and 381 archaeological sites and any undiscovered sites above these elevations exposed. The Enhanced Coordination Alternative is the most robust in terms of the preservation risk model, meeting the minimum preferred performance in 47 percent of futures, followed by the Maximum Operational Flexibility Alternative at 28 percent of futures over the full modeling period. This relational pattern is consistent if the full modeling period is broken out into shorter ranges, including the first decadal period (2027–2039) where the Enhanced Coordination Alternative also performs the best at 30 percent of futures, followed again by the Maximum Operational Flexibility Alternative at 25 percent of futures.

For Lake Mead, however, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would perform the best in the Average Flow Category, followed by the Enhanced Coordination and Maximum Operational Flexibility Alternatives. Projections indicate that the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would have median elevations between 1,140 feet and 1,160 feet, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives would have median elevations between 1,100 feet and 1,130 feet, respectively, during average hydrological conditions. Recalling that lower reservoir levels means that more sites will be exposed, in the Critically Dry Flow Category, all scenarios would result in the exposure of at least 306 known archaeological sites (all but four in the Lake Mead dataset) as well as any undiscovered sites. However, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would have the potential to expose fewer sites with upper interquartile ranges up to around 1,030 feet. In addition, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would be the most robust for Lake Mead with respect to preservation risk, with 24 percent of the modeled futures

meeting the 2.24 threshold over the full modeling period, followed by the Maximum Operational Flexibility Alternative with 19 percent of futures. When examining the first decadal period (2027–2039) at Lake Mead, the percentage of futures meeting the preferred minimum of performance drops drastically. This is because the anticipated water levels for Lake Mead in 2027 are expected to be low and for this reason, robustness modeling shows a substantial drop in performance. For this first 10-year period, the Supply Driven Alternative (both LB Priority and LB Pro Rata) continues to perform the best, but only at 5 percent of futures, followed by the CCS Comparative Baseline, the Maximum Operational Flexibility Alternative, and the Representative Preferred Alternative, all three of which meet the preferred level of performance in only 3 percent of futures.

Overall, for Lake Powell, the Enhanced Coordination and the Maximum Operational Flexibility Alternatives perform better in drier conditions and have the greatest potential to expose fewer known sites (therefore protecting more through inundation) while, for Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) followed by the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform better in drier conditions. The Representative Preferred Alternative falls in the middle for both lakes. The No Action and Basic Coordination Alternatives have the least potential to protect archaeological sites at both lakes.

Complicating these conclusions are modeling results for releases from both Glen Canyon Dam (WY releases) and Hoover Dam (CY releases), which show that, in the reaches between Glen Canyon Dam and Lake Mead and Hoover Dam to Lake Mohave, the median dam release volumes for both would drop lower under the Enhanced Coordination and Maximum Operational Flexibility Alternatives specifically in the Critically Dry Flow Category than compared to the CCS Comparative Baseline, the No Action Alternative, and the other action alternatives. Under all the modeled scenarios, the Steamboat Charles Spenser could be affected if the reduced volumes of the WY releases from Glen Canyon Dam cause the river to drop below previously observed water levels. On the other hand, these same potential drops in river water level may provide some protection from river currents for resources within 20 meters (66 feet) of the river.

Below Davis Dam, few to no impacts (regardless of flow category) are expected because the dams below Lake Mohave are operated under guidelines that maintain lake elevations or target water deliveries, and there are several stretches of channelized banks.

Relative to sediment availability for aeolian transport in the Grand Canyon, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would have the best outcome for increasing the availability of sand for wind transport to protect archaeological sites. Both alternatives have a similar percentage of futures meeting the preferred minimum of performance (in at least 1 out of every 3 years) at 19 and 18 percent, respectively. Although this seems to be a small percentage, these two action alternatives perform better than the CCS Comparative Baseline, the No Action Alternative, and the other action alternatives, all of which meet the preferred minimum of performance in 9 percent or fewer of futures.

3.12 Paleontological Resources

3.12.1 Affected Environment

Overview and Study Area

This section summarizes the paleontological resource environment of Lake Powell, Lake Mead, and the lower Colorado River corridor. The full detailed analysis of the paleontological resources' affected environment can be reviewed in **TA 12**, Paleontological Resources. Paleontological resources include any fossilized remains, traces, or imprints of organisms preserved in rock. The Paleontological Resources Preservation Act of 2009 (PRPA; 16 USC 470aaa–470aaa-11) and its implementation rule (43 CFR 49) require Department of the Interior agencies to preserve, manage, and protect paleontological resources on lands administered by Reclamation, the NPS, the BLM, and the FWS. The PRPA ensures these federally owned resources are available for current and future generations to enjoy and study as part of America's national heritage.

The study area for paleontological resources stretches from the northern extent of Lake Powell to the SIB in California via the Colorado River. It covers approximately 1 million acres across Utah, Arizona, Nevada, and California. This area includes known and unknown resources in Lake Powell and Lake Mead.

It is important to note that the resources within fluctuating water levels are vulnerable to wave action; those resources above water are at risk from visitation impacts. The PRPA requires federal protection, but the ongoing exposure of these resources highlights the need for more effective preservation efforts. The PRPA also requires Department agencies to develop plans for inventory and monitoring using scientific principles and expertise. These plans must emphasize interagency coordination and collaborative efforts, when possible.

Potential Fossil Yield Classification System

The study area was mapped using the BLM's Potential Fossil Yield Classification (PFYC) system. This system assigns ranks to geologic units based on the relative abundance of vertebrate or other fossils and the sensitivity of those fossils to adverse impacts. For more information on how the PFYC system was created and is regularly updated, please refer to **Section TA 12.1.1**, Study Area, in **TA 12**, Paleontological Resources. **Table 3-8**, below, depicts the acreages of PFYC ranks within the study area. Geologic units with a higher potential for containing paleontological resources are assigned a higher number. Approximately 27 percent of the mapped area is classified as high/very high potential (PFYC 4-5). Maps of the study area can be found in **Section TA 12.1.1** (**Map TA 12-1** through **Map TA 12-8**).

Table 3-8
Acres of PFYC Classes in the Study Area

PFYC Class	Total Acres
1 (very low)	70,500
2 (low)	154,600
3 (moderate)	103,600
4 (high)	179,300

PFYC Class	Total Acres
5 (very high)	24,200
U (unknown)	113,700
W (water)	373,100
Total acres	**1,019,000**

Source: Reclamation GIS 2025; NWS GIS 2023.
*PFYC data do not cover the entire study area, especially in the waterbodies and portions of the Colorado River.

Key Drivers and Trends

Fluctuating water levels in both Lake Powell and Lake Mead pose significant threats to paleontological resources, including fossils and trackways preserved in sedimentary rocks. In reservoirs, cycles of inundation and exposure weaken softer rocks, such as sandstone, making them more susceptible to erosion. As water levels recede, previously submerged fossils are exposed to environmental factors like wind, sun, and temperature changes, which accelerate degradation. While sediment deposition can temporarily protect some sites, the exposure of fossil-rich layers as water levels recede increases the likelihood of weathering, fragmentation, and disturbance from human activity.

Human activity further exacerbates these challenges because exposed fossil sites attract recreational use, leading to soil compaction, vegetation damage, and unauthorized fossil collection. Water-related impacts, such as flooding, controlled reservoir releases, and increased river erosion, also threaten fossil preservation by accelerating the removal of fossil-bearing sediments. While erosion can reveal new paleontological resources, it simultaneously increases the risk of their loss. The study area, characterized byon steep topography and high recreational use, faces elevated erosion rates, making the balance between discovery and preservation increasingly challenging.

Erosion is the primary agent that exposes paleontological resources on the surface to then await discovery and documentation. Lake Powell and Lake Mead are interconnected; adjustments of water releases at Lake Powell have a downstream effect on Lake Mead. The impacts on paleontological resources due to natural processes are the same at both reservoirs, but the intensity of impacts and the resources affected vary. Paleontological resources in Glen Canyon NRA are largely more understood and considered to be highly scientifically important. Most of the area is ranked PFYC 4 (high) or PFYC 5 (very high), including the shorelines (BLM GIS 2025). In Lake Mead NRA, the paleontological resources are less understood, and much of the shoreline is mapped as PFYC U (unknown; BLM GIS 2025). Therefore, the erosion concerns at Lake Powell are extremely high, as these conditions are affecting geologic units with high and very high paleontological value.

Reservoirs and Colorado River Corridor Overview

Lake Powell and Glen Canyon Dam

Lake Powell and Glen Canyon Dam make up most of Glen Canyon NRA, which spans southern Utah and northern Arizona and contains one of the most extensive sedimentary records on the Colorado Plateau. This record represents approximately 300 million years of geologic history and chronicles significant events, including the assembly and breakup of Pangea, the evolution of inland seas, and the incision of the Colorado River (Anderson et al. 2010).

Glen Canyon NRA staff is conducting a paleontological resources inventory survey; because of the size of the recreation area, the survey is being done in phases, with the latest phase completed in 2024. The three inventory reports provide the baseline data for a breadth of paleontological resources found within Glen Canyon NRA. Despite these efforts, natural processes such as erosion, mass wasting, and fluctuating water levels continue to expose and degrade fossil-bearing strata. Additionally, impacts from human intervention, such as vandalism, and unauthorized fossil collection, pose ongoing threats to resource preservation (Graham 2016; Santucci et al. 2009). In some areas, the buildup of sediment from dam operations may enhance fossil preservation by burial, while in others, it prevents discovery of those fossils. For more information about the paleontological resources in Glen Canyon NRA, please reference **Section TA 12.1.1**, Study Area.

Grand Canyon National Park

The Colorado River corridor of Grand Canyon National Park contains paleontological resources of exceptional scientific significance, spanning nearly 1.2 billion years of the earth's history. The river corridor is renowned for its dramatic display of geomorphic effects created by fluvial incision and its unique dry preservation of fossils from the Ice Age (Mead et al. 2020). The river channel serves as the physical axis along which the park's oldest and youngest fossil-bearing strata are exposed. The river channel is organized into two principal paleontological occurrences documented in the Grand Canyon National Park Centennial Paleontological Resource Inventory (Santucci and Tweet 2021): ancient body and trace fossils preserved within the canyon's deep bedrock formations, and Pleistocene and Holocene fossils recovered from dry caves and sediment deposits along the corridor walls.

The objective of the Grand Canyon National Park Centennial Paleontological Resource Inventory was to identify the scope, significance, distribution, and management issues associated with fossils in the park (Santucci and Tweet 2021). The river corridor presents particular management challenges due to its difficult terrain and limited accessibility, and the inventory acknowledges that systematic survey of inner canyon fossil localities remains incomplete. Despite this, the Colorado River corridor constitutes one of the most scientifically valuable zones within Grand Canyon National Park.

Lake Mead and Hoover Dam

Lake Mead NRA covers 1.5 million acres of southeastern Nevada and northwestern Arizona. Lake Mead NRA showcases a stratigraphic record spanning more than 500 million years of geologic history, documenting the evolution of the southwestern margin of North America. The NPS completed a comprehensive paleontological resource inventory in 2018. This inventory established baseline data for fossil-bearing formations and identified areas with high fossil potential; the inventory is confidential.

Resources at Lake Mead NRA are vulnerable to the same natural processes and human impacts described at Glen Canyon NRA. Continued monitoring and research are recommended to protect resources at Lake Mead NRA.

Lower Colorado River Corridor

Reclamation completed a paleontological resource inventory for the lower Colorado River region in 2020, which contained the river corridor as it extends from southern Nevada to the Mexico border (Bonde and Slaughter 2020). The corridor contains a sedimentary geologic record spanning 500 million years. Although not fully continuous, the corridor includes units representative of most geologic periods.

Under current conditions, water-related impacts such as erosion and recreation threaten the preservation of paleontological resources in the lower Colorado River corridor. Flooding events and controlled releases of reservoir waters can submerge fossils or increase river velocity and erosion, consequently displacing fossils from their geologic units. Water systems with steep cliffs and undercutting are also subject to higher rates of erosion and potential resource loss than flatter areas. Water-based recreational opportunities may unintentionally invite theft, vandalism, or indirect disturbance to fossils.

3.12.2 Environmental Consequences

Methodology

In this section, impacts on paleontological resources include those resulting from Reclamation's management of the water in Lake Powell and Lake Mead. Two types of analyses are used to evaluate impacts: preservation risk modeling, developed by the USGS and NPS, and aeolian transport-vegetative cover-HFE joint modeling, also developed by the USGS (Caster et al. 2026; Kelley et al. 2026). Additionally, PFYC data were used to analyze areas of high potential to contain fossils within the impact analysis area, and CRSS modeling of reservoir elevations was used to determine exposure risks.

The paleontological Preservation Hazard Model is informed by PFYC data and natural preservation hazards (slope erosivity, fetch distance, and water fluctuations) (Caster et al. 2026). To analyze this model using the DMDU framework, the model summarizes 10-foot elevation bins in Lake Powell and 5-foot elevation bins in Lake Mead so that each elevation from full pool to empty has a preservation risk rank. Next, projected monthly lake elevations are related to those elevation bins to estimate the preservation risk rank. As lake elevations drop, preservation risk generally increases. The model assumes that all resources have value, and dense resources and high erosion potential represent the highest risk; those with low erosion potential and no predicted resources represent the lowest risk.

Impact Analysis Area

The impact analysis area for paleontological resources consists of the Colorado River corridor from the upper limits of Lake Powell in Utah, through the Grand Canyon and Lake Mead in Arizona, and from Hoover Dam to the SIB.

Assumptions

The paleontological resource results are direct outputs from the Preservation Hazard Model and Joint Model. The impact analysis area includes known, unknown, and predicted resources and does not identify specific localities.

Impact Indicators

Four impact indicators were used to assess the impacts on paleontological resources due to operational activities: end-of-year lake elevations, changes in river flows, paleontological preservation risk rank, and the increase or decrease in sandbar building and the availability of windblown sediments to protect exposed resources.

Issue 1: How would fluctuations in water levels due to changes in dam operations (primarily in Lake Powell and Lake Mead) impact the exposure, erosion, and degradation of paleontological resources, including fossils and trackways?

For a detailed analysis of how the alternatives and CCS Comparative Baseline influence the preservation risk rank and impact the exposure, erosion, and degradation of paleontological resources, please reference **Section TA 12.2.2**, Issue 1.

This analysis references the modeling of paleontological preservation risk at the reservoirs. The model defines a historically derived threshold that is the 90th percentile risk rank from 2008 to 2024 LTEMP values. Exceeding this value means that a larger percentage of potential resources are exposed to erosion risks than what has happened since the reservoirs were filled. A higher number means a higher risk. The threshold at Lake Powell is a preservation risk rank of 2.93; the 2.93 threshold is a reference line based on past conditions (2008-2024) used to judge when risk is unusually high. The threshold at Lake Mead is 2.33.

Lake Powell

Reference **Table TA 12-4** and **Figures TA 12-4**, **12-5**, and **12-6** for the full modeling results of the preservation risk at Lake Powell. As shown in **Figure TA 12-4**, the Maximum Operational Flexibility Alternative and the Enhanced Coordination Alternative have similar ranges that are around or below the threshold in the Average Flow Category (12.0–14.0 maf). However, the Enhanced Coordination Alternative has a median risk value that is approximately 14 percent lower than what is modeled for the Maximum Operational Flexibility Alternative (2.45 and 2.85, respectively). In the Dry Flow Category (10.0–12.0 maf), the Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative perform similarly well, although all alternatives exceed the historically derived threshold under the Critically Dry Flow Category (4.46–10.0 maf).

Focusing on trends in the drier hydrologic conditions, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs similarly to the CCS Comparative Baseline; the medians and ranges are above the threshold in the Dry and Critically Dry Flow Categories, although the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) exhibits slightly less variability. The No Action and Basic Coordination Alternatives also perform similarly, with medians higher than those of the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and CCS Comparative Baseline.

The Representative Preferred Alternative generally performs in the middle of the range of alternatives; it performs slightly better than the Supply Driven Alternatives (both LB Priority and LB Pro Rata approaches) and slightly worse than the Maximum Operational Flexibility Alternative. At Lake Powell, the Representative Preferred Alternative does not perform notably for preserving paleontological resources.

When looking across the full modeling period (which includes the full range of potential hydrologic futures, or modeled hydrologic scenarios), the Enhanced Coordination Alternative performs significantly better than all other alternatives and the CCS Comparative Baseline, maintaining a preservation risk rank below the historically modeled threshold in 36 percent of futures. This is a difference of greater than 10 percent between the Enhanced Coordination Alternative and the closest performing alternative, the Maximum Operational Flexibility Alternative (successful in 22 percent of

futures). Based on the planned length of the decision, it is notable that the performance of all alternatives worsens between the full modeling period and the 2027-2039 subperiod, except for the Representative Preferred Alternative, which actually improves from 12 percent to 13 percent of futures in which the threshold is met.

These trends are supported by the vulnerability analysis (**Figure TA 12-6**), which looks at flow conditions that could cause the preservation risk rank to exceed the threshold. The Enhanced Coordination Alternative results in undesirable performance when the 10-year average flow is below 11.2 maf. Approximately 75 percent of the reference hydrology traces include averages this low or lower. As a historical reference, the driest observed 10-year average for the Lees Ferry flow was 11.8 maf and occurred from 2012 to 2021. The CCS Comparative Baseline and Basic Coordination, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives performed the same, with paleontological resources becoming vulnerable at approximately 12.2 maf. For reference, the recently observed flow from 2016-2025 was 12.1 maf, meaning that these alternatives are vulnerable to conditions that have already occurred.

At Lake Powell, the Enhanced Coordination Alternative performs the best with respect to maintaining preservation risk ranks at or below the historically defined threshold, followed closely by the Maximum Operational Flexibility Alternative. The Representative Preferred Alternative generally performs in the middle of the alternatives, indicating that paleontological resources in Lake Powell would be subject to exposure, erosion, and degradation more frequently than what has been historically observed

Lake Mead

Reference **Table TA 12-4** and **Figures TA 12-7**, **12-8**, and **12-9** for the full modeling results of the preservation risk at Lake Mead. As shown in **Figure TA 12-7**, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and the Maximum Operational Flexibility Alternative perform almost identically in the Average Flow Category (12.0–14.0 maf), with similar median preservation risk ranks and an interquartile range at or below the 2008–2024 defined threshold. The Enhanced Coordination Alternative has a slightly greater median preservation risk, but it has a similar interquartile range to the other best-performing alternatives. The Representative Preferred Alternative performs similarly to the Enhanced Coordination Alternative, but it has greater variability and a larger proportion of its interquartile range above the historically defined threshold. Under all flow conditions, the No Action Alternative repeatedly exhibits the highest median and largest interquartile range, indicating that conditions would be unpredictable but more likely than not would result in greater risk to the preservation of paleontological resources.

Under the Dry and Critically Dry Flow categories, the Representative Preferred Alternative continues to perform similarly to the Enhanced Coordination Alternative, though it exhibits medians and interquartile ranges above the historically derived threshold. The Representative Preferred Alternative is outperformed by the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), which maintains an interquartile range below the threshold in both the Dry and Critically Dry Flow categories.

When looking across the full modeling period, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) was the most robust at achieving a risk rank of 2.3 in 90 percent of months, doing so in 35 percent of futures. The other action alternatives range between robustness of 2 percent

of futures (No Action Alternative) and 16 percent of futures (Maximum Operational Flexibility Alternative). However, it is notable that no alternatives achieve robustness in the 2027-2039 subperiod, with performance dropping significantly (greater than 10 percent) for the Supply Driven (both LB Priority and LB Pro Rata approaches), Maximum Operational Flexibility, and Enhanced Coordination Alternatives. The Representative Preferred Alternative is successful in 3 percent of futures between 2027 and 2039, indicating that paleontological resources would certainly be exposed and subject to erosion and degradation in Lake Mead during this time.

These trends are supported by the vulnerability analysis (**Figure TA 12-9**). Paleontological resources are the most vulnerable to risk under the CCS Comparative Baseline and the No Action Alternative. Undesirable performance occurs at 12.5 maf; nearly 100 percent of the reference hydrologic traces include average flows of 12.5 maf or lower. These two scenarios are vulnerable to conditions that have already occurred; the 10-year average flow at Lees Ferry from 2016 to 2025 was 12.1 maf. The Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives are vulnerable to increased risk to paleontological sites at flows of 12.2 maf, indicating that these resources are vulnerable to conditions that have already occurred. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would be vulnerable at flows of 11.6 maf; nearly 75 percent of all hydrologic traces are drier 11.6 maf.

At Lake Mead, paleontological resources would be the least vulnerable to exposure, erosion, and degradation under the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches). The Representative Preferred Alternative performs similarly but would result in greater instances of exposure and erosion. Given the length of the planned decision, paleontological resources in Lake Mead would almost certainly be subject to drier conditions than what has been historically observed, resulting in greater risk to preservation.

Issue 2: How would altered sediment transport, including both fluvial and aeolian deposition patterns, affect the preservation and stability of paleontological resources?

The preservation and stability of paleontological resources along the Colorado River corridor are closely tied to sediment dynamics, particularly the deposition and redistribution of fine sediments through fluvial and aeolian processes. Sediment burial helps protect surface-exposed resources from erosion, weathering, and human disturbance, while changes in the magnitude or timing of sediment delivery may either enhance or degrade preservation conditions. However, increased exposure of sandbars and sediment surfaces typically heightens the risk of erosion, weathering, and loss of fossil integrity, while sediment deposition and rapid burial may provide temporary protection from degradation. Frequent water level fluctuations that alternately expose and inundate sediments are generally detrimental to long-term preservation.

Fluvial Sediment Transport

This section presents a comparison of the No Action Alternative, CCS Comparative Baseline, and action alternatives with respect to the fraction of total sand mass transported by sandbar-forming flows. For more information, please reference **TA 5**, Geomorphology and Sediment.

As shown in **Figure TA 12-10** in **TA 12**, Paleontological Resources, the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform similarly, achieving sandbar-building conditions in 83 and 85 percent of futures, respectively. The Supply Driven (both LB Priority and LB Pro Rata

approaches) and Representative Preferred Alternatives are similarly robust (78 percent and 76 percent of futures, respectively). Sandbar-building conditions indirectly result in the preservation and stabilization of paleontological resources present in and around the sandbars. Fossils may be buried during sediment transport and protected from erosion and other types of degradation in the fluvial channel. It is likely that paleontological resources would be buried by fluvial sediment transport at a significant frequency under the Representative Preferred Alternative, resulting in better conditions for preservation.

In contrast, the No Action Alternative was successful in only 44 percent of futures; the CCS Comparative Baseline produced 36 percent of successful futures. Under the No Action Alternative, fossils and other paleontological resources would be indirectly affected by sandbar erosion between HFEs and not effectively reburied during sandbar-building events.

Aeolian Sediment Transport

This section presents a comparison of the No Action Alternative, CCS Comparative Baseline, and action alternatives with respect to favorable conditions for windblown sand to be present to protect paleontological resources over long periods of time. The model incorporates the vegetation, sandbar volume, and exposed sand area modeling. For more details, please reference **Section TA 12.2.1**, Methodology.

Figure TA 12-12 in **TA 12**, Paleontological Resources, shows the results of the aeolian sand modeling, in which the percentage of futures meet one of two criteria: Either the annual sand volume is greater than the median observed sand volume over the last 20 years and the vegetation cover area is less than the median observed area over the last 20 years, or the sandbar volume is greater than 1.5 times the initial condition. The highlighted row shows when those conditions are met at least 1 out of every 3 years, which is the optimal time frame for enough sand to be available for aeolian transport based on previous studies.

Over the full modeling period, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are the most robust; they meet the desired conditions of at least 1 out of every 3 years in 19 percent and 18 percent of futures, respectively. The No Action Alternative meets the desired conditions in 14 percent of futures, and the Representative Preferred Alternative meets the desired conditions in only 6 percent of futures. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the least robust, meeting the desired conditions in only 2 percent of futures. If the year interval is lengthened (that is, to 1 out of 4, 5, or 6 years), the models perform in a similar overall pattern, with the Enhanced Coordination and Maximum Operational Flexibility Alternatives performing the best.

When results are split out over intervals from 2027–2039, 2040–2049, and 2050–2060, the percentage of futures meeting the desired conditions increases for all alternatives. The robustness of the Representative Preferred Alternative increases from 6 percent of futures to 17 percent between 2027 and 2039. These results seem to indicate an increase in acceptability over time, which may correlate to increased available sand over time; however, the perceived increase is driven by an increase in sandbar volume over time in the modeling with the understanding that HFEs would continue as planned. In reality, the decision to conduct HFEs depends on the annual review.

It is notable that the Representative Preferred Alternative meets the desired conditions in 17 percent of futures between 2027 and 2039, indicating that the conditions required for aeolian transport will not occur frequently, exposing paleontological resources to erosion and other weathering mechanisms.

Issue 3: How would adjustments to dam operations and water levels alter human access to newly exposed fossil sites, and what are the potential risks of increased disturbance, unauthorized collection, and recreational impacts on paleontological resources?

This section summarizes the potential for paleontological resources to be exposed to increased levels of disturbance, unauthorized collection, and recreational impacts using the hydrologic modeling results for Lake Powell and Lake Mead elevations. This analysis incorporates the analysis of reservoir elevations detailed in **Section TA 3.2.1**, Issue 1: Reservoir Elevations, in **TA 3**, Hydrologic Resources**.** For a detailed analysis of how the alternatives and CCS Comparative Baseline influence the risk of human disturbance to paleontological resources, please reference **Section TA 12.2.4**, Issue 3.

Lake Powell

This section presents a comparison of the No Action Alternative, CCS Comparative Baseline, and action alternatives with respect to increased disturbance at, unauthorized collection of, and recreational impacts on paleontological resources at Lake Powell. For a more detailed analysis of recreation at Lake Powell, please refer to **TA 14**, Recreation.

As shown in **Figure TA 3-7** in **TA 3**, Hydrologic Resources, the alternatives perform similarly with respect to maintaining lake elevations and achieving desirable paleontological preservation risk ranks. The Maximum Operational Flexibility Alternative and the Enhanced Coordination Alternative are the most robust at staying above a 3,500-foot elevation in 100 percent of months over the full modeling period, doing so in 86 percent and 74 percent of futures, respectively. These results are similar to the robustness of both alternatives with regard to achieving the historically derived preservation risk threshold in 90 percent of months.

The No Action Alternative is the least robust at maintaining a 3,500-foot elevation in 100 percent of months, doing so in 20 percent of futures over the full modeling period. The No Action Alternative is only 71–80 percent robust at maintaining this elevation in 60 percent of months. The CCS Comparative Baseline, Basic Coordination Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) perform similarly, maintaining the 3,500-foot elevation in 100 percent of months in 29 percent, 25 percent, and 24 percent of futures, respectively.

The Representative Preferred Alternative meets this robustness criteria in 28 percent of modeled futures in the full modeling period. Based on the planned length of this alternative, it is important to note that it meets the preferred minimum performance level in 49 percent of futures between 2027 and 2039. Alternatives that keep Lake Powell at or above 3,500 feet more often will keep most sites below that level underwater (and protected) more of the time. Therefore, the risk of human disturbance would be for resources above 3,500 feet. The preservation risk rank historically derived threshold is achieved at approximately 3,500-foot elevation at Lake Powell. Under the Maximum Operational Flexibility Alternative, elevations at Lake Powell would be most consistently at or above 3,500 feet, which would result in the inundation of the most paleontological resources and the least amount of shoreline expansion for visitors to access resources.

Lake Mead

This section presents a comparison of the No Action Alternative, CCS Comparative Baseline, and action alternatives with respect to increased disturbance at, unauthorized collection of, and recreational impacts on paleontological resources at Lake Mead.

As shown in **Figure TA 3-12** in **TA 3**, Hydrologic Resources, the alternatives perform similarly with respect to maintaining lake elevations and achieving desirable paleontological preservation risk ranks. The Supply Driven Alternative (LB Pro Rata approach) and Maximum Operational Flexibility Alternative are similarly robust at keeping Lake Mead's elevation above 975 feet in 100 percent of months, doing so in 73 percent and 70 percent of futures, respectively. The Enhanced Coordination Alternative and the Supply Driven Alternative (LB Priority approach) are also similarly robust, maintaining Lake Mead's elevation above 975 feet in 65 percent and 61 percent of futures, respectively.

The Representative Preferred Alternative meets this robustness criteria in 50 percent of modeled futures in the full modeling period. Based on the planned length of this alternative it is important to note that it meets the preferred minimum performance level in 66 percent of futures between 2027 and 2039.

The No Action Alternative is the least robust, keeping Lake Mead elevation above 975 feet in 100 percent of months in 21 percent of futures over the full modeling period. Robustness of the CCS Comparative Baseline is 38 percent; robustness of the Basic Coordination Alternative is 50 percent.

Summary Comparison of Alternatives

Continuous inundation preserves paleontological resources better than repeated exposure to waves and wet-dry cycles. Changes in lake elevations that may expose previously inundated fossils and other resources are the biggest concern. When lake elevations drop, indirect impacts, such as those from human disturbance and recreational use, can also occur. For Lake Powell, the Enhanced Coordination Alternative performs best with regard to minimizing the preservation risk in all hydrologic conditions, except the Critically Dry Flow Category (4.46–10.0 maf), followed by the Maximum Operational Flexibility Alternative. Both alternatives exhibit median risk ranks that are at or below the threshold.

The Basic Coordination Alternative is the least effective action alternative with regard to meeting the paleontological preservation risk threshold at Lake Powell. This alternative becomes successful at the Moderately Wet Flow Category (14.0–16.0 maf), but it consistently exceeds the threshold at the Average Flow Category (12.0–14.0 maf) and drier. The No Action Alternative and CCS Comparative Baseline perform similarly to the Basic Coordination Alternative.

For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and the Maximum Operational Flexibility Alternative perform similarly and produce a median preservation risk rank around, or just above, the historically derived threshold in all hydrologic conditions except for the Critically Dry Flow Category (4.46–10.0 maf). All alternatives exceed the historical preservation risk conditions under the Critically Dry Flow Category (4.46–10.0 maf).

Under the Maximum Operational Flexibility Alternative, critical lake elevations would be maintained above 3,500 feet in Lake Powell and 975 feet in Lake Mead in 86 percent and 70 percent of futures, respectively. The operations proposed under the Maximum Operational Flexibility Alternative would

result in the least amount of time that paleontological resources below critical elevations are exposed to human disturbance and the associated impacts. The No Action Alternative would be the least robust at both reservoirs.

Under the Maximum Operational Flexibility Alternative, the paleontological preservation risk would be minimized to the greatest extent at both reservoirs. Paleontological resources that remain inundated would not be exposed to erosion, degradation, and the repeated cycles of inundation and exposure and wave action. The Enhanced Coordination Alternative would also minimize the paleontological preservation risk in the reservoirs, but it would do so more consistently at Lake Powell than at Lake Mead. Considering the amount of, and scientific importance of, paleontological resources present in Lake Powell, the Enhanced Coordination Alternative would be the most effective at minimizing the risk in this reservoir. The Enhanced Coordination Alternative would also be effective in Lake Mead, but not as effective as the Maximum Operational Flexibility Alternative.

The river corridor, from below Hoover Dam to the SIB, is not well mapped by the PFYC system. Classifications in the corridor are mostly PFYC W (water). While possible, the presence or impacts on scientifically important vertebrate fossils are not anticipated within the river corridor when compared with the potential for known or undiscovered fossils in the reservoirs. The Enhanced Coordination Alternative and the Maximum Operational Flexibility Alternative are the most robust alternatives with regard to sediment transport in the river corridor. Sediment transport would indirectly preserve and stabilize the known and unknown fossil localities.

Operations under the Maximum Operational Flexibility Alternative would indirectly create conditions that are most conducive to the preservation of paleontological resources in the analysis area, as indicated by this alternative's comparatively strong performance across the full suite of models.

For both Lake Powell and Lake Mead, the Representative Preferred Alternative generally performs somewhere in the middle of the action alternatives, never outperforming all alternatives in terms of paleontological resource risk reduction, fluvial and aeolian sediment transport, or maintaining significant lake elevations. Given the length of the planned decision, it is notable that paleontological preservation risk will likely be heightened under the Representative Preferred Alternative, as more resources will become exposed and eroded due to fluctuating reservoir levels and flows.

3.13 Tribal Resources

3.13.1 Affected Environment

The Colorado River, its canyons, and the associated ecosystems figure prominently in the cultural traditions of many tribal communities. For these tribes, the river and canyons are living entities consisting of sacred spaces, the homes of their ancestors, the residence of the spirits of their dead, and the source of culturally important resources. Indigenous worldviews do not separate cultural and natural environments as Western science often does; instead, they view all resources—whether considered cultural or natural in Western frameworks—as interconnected and interdependent. Many tribes see themselves as stewards of the Colorado River and its canyons, which are a vital part of the living and spiritual world. Caring for the river and the canyons is their responsibility. Tribal resources can include archaeological resources, archaeological structures, topographic features, habitats, plants,

wildlife, and minerals that Indigenous peoples, tribal nations, or other groups consider essential for the preservation of traditional culture and traditional values. For many tribes, the trails used to access the river are also considered culturally important landscape features. Tribal interests also include values and resources reflected in other sections in this Final EIS, including water for drinking and agriculture, recreational resources, and many other socioeconomic and environmental aspects that overlap other sections.

The traditional values of living communities can be manifested at locations called TCPs, Indian sacred sites, or cultural landscapes. Many tribes consider the Colorado River and its canyons to be a TCP. As described by NPS guidance on TCPs (NPS 2024b), a TCP is "a building, structure, object, site, or district that may be listed or eligible for listing in the National Register for its significance to a living community because of its association with cultural beliefs, customs, or practices that are rooted in the community's history and that are important in maintaining the community's cultural identity." Of the groups concerned, the Hualapai Tribe (Coulam 2011), Hopi Tribe (Hopi CPO 2001), Navajo Nation (Maldonado 2011), and Pueblo of Zuni (Dongoske 2011) have prepared NRHP nomination forms for the Colorado River and its canyons as a TCP. Reclamation is actively consulting with the tribes regarding the Colorado River and its canyons, including associated traditional ecological knowledge; Reclamation will incorporate that knowledge as it becomes available.

The study area for tribal resources is identical to that discussed in **TA 11**, Cultural Resources, and **TA 18**, Indian Trust Assets. It extends from the northern extent of Lake Powell to the SIB and consists of the Colorado River channel from bank to bank, except from Glen Canyon Dam to Lake Mead, where it stretches from canyon rim to canyon rim. The study area also includes a 0.5-mile buffer on either side of the riverbank or canyon rim. The study area coincides with the search area used for a Class I records search conducted for this EIS document (Tremblay et al. 2024a, 2024b; Eddy et al. 2024; Winslow et al. 2024; Eskenazi 2024).

The 14 Native American tribes listed here consider portions of the study area to be part of their homelands; the following eight tribes are associated directly with the Grand Canyon: A:shiwi (Zuni), Ndee (Western Apache), Diné (Navajo), Havasupai, Hualapai, Hopi, Nüümü (Southern Paiute), and Yavapai. Five tribes—the Cocopah, Pipa Aha Macav (Mojave), Piipaash (Maricopa), Quechan, and Xalchidom (Halchidhoma)—have homelands along the lower Colorado River where it flows south to the Gulf of California. One group, the Núuchi (Ute), used northeastern portions of the river and study area. Contemporary Native American communities face a host of common issues such as widespread poverty, health disparities, and housing shortages. For the Native American tribes discussed here, water shortages and the potential to impact agriculture is a significant concern. Brief ethnographic summaries of these tribes are provided in **Sections TA 13.1.1** through **TA 13.1.13**. These summaries focus on indigenous cultural connections to the Colorado River landscape and are derived primarily from the multivolume Class I cultural resources literature review conducted in support of this analysis (Tremblay et al. 2024a, 2024b; Eddy et al. 2024; Winslow et al. 2024; Eskenazi et al. 2024).

Several known or documented TCPs within or adjacent to the study area have been listed or are eligible for listing in the NRHP (**Table TA 13-1**). For example, Sugarloaf Mountain to the west of the lower Colorado River is identified as a TCP by the A:shiwi, Diné, Hopi, Hualapai, Nuwuvi, Pipa Aha Macav, and Yavapai. The Ripley Intaglios are considered sacred by all the Yuman Tribes. The Yuman Tribes consider their origin place, Avi Kwa Ame (Spirit Mountain), to be sacred; it is beyond the

project study area but within the newly created Avi Kwa Ame National Monument. Through ongoing consultation with tribes, the locations of several additional places that are considered sacred have been disclosed to Reclamation cultural resources staff. At the request of these tribes, descriptions and locations of those sacred places are confidential. Tribes discussed in this section revere the Colorado River. The Grand Canyon itself is an NRHP-eligible TCP for multiple tribes. Several important locations within the Grand Canyon TCP have been formally recorded in the canyon for the A:shiwi and Hopi and documented in ethnographic studies for the Diné and Hualapai.

Tribes consider places associated with origin stories, migrations, songs, and ceremonies to be sacred TCPs, as are ancestral sites, trails, cairns, rock writing, petroglyphs, pictographs, and geoglyphs. All water sources, especially those that come from belowground, are sacred. Plants, animals, and minerals are considered traditional cultural resources, often associated with specific locations. Reclamation is in ongoing consultation with tribes to identify specific locations and resources that are important to each tribe.

3.13.2 Environmental Consequences

Methodology

Of primary concern is how the alternatives might affect the integrity and sacredness of tribal resources. Because these resources attain significance through tribal cultural customs, and because many of these resources are sacred and their locations are confidential, the tribes are best situated to understand how the alternatives might affect them. Accordingly, the impact analysis is primarily qualitative and informed by ongoing tribal consultation.

There are many federally recognized tribes with entitlements to or contracts for Colorado River water or who may be affected or have interests in the alternatives. There are 30 federally recognized tribes within the geographic Basin. Reclamation consults regularly with these tribes regarding Colorado River issues. Additionally, the Ten Tribes Partnership is a coalition of 10 federally recognized tribes with rights and unresolved claims to Colorado River water. The partnership was created in 1992 and has an ongoing consultation relationship with Reclamation. Of the 22 federally recognized tribes in Arizona, 4 have quantified water rights, or partially quantified rights to water from the mainstream Colorado River through the Consolidated Decree. Another 10 tribes in Arizona have entered water rights settlements that include Central Arizona Project (CAP) water, one source of which is Priority 4 Arizona Colorado River water. Several more tribes hold CAP contracts. Reclamation consults not only with tribes who hold water rights or are located within the Basin's geographic boundary but also with a total of 43 tribes who may be affected or have interests in actions on the Colorado River. Consultation and coordination with these tribes are ongoing.

Impact Analysis Area

The study area for tribal resources is identical to that discussed in **TA 11**, Cultural Resources. It includes the Colorado River corridor from the upper limits of Lake Powell in Utah, through the Grand Canyon in Arizona and Lake Mead in Arizona, and from Hoover Dam to the SIB.

Assumptions

- Tribes will provide information regarding specific tribal resources and potential impacts on those resources during consultation.

Impact Indicators

- Qualitative assessment of potential impacts on TCPs informed by tribal consultation
- Qualitative assessment of potential impacts on culturally important resources informed by tribal consultation and by reference to relevant quantitative analysis sections of the EIS (for example, **TA 9**, Vegetation, and **TA 8**, Biological Resources – Fish and Aquatic Resources)

Issue 1: How would changes in dam operations affect TCPs?

TCPs are historic properties that are principally significant for their association with culturally significant events, as told through Indigenous oral history, or their association with individuals named by those traditions. Impacts on TCPs would consist primarily of changes to the natural environmental context resulting from continued active management of reservoir levels and water releases to downstream river segments. Impacts could also occur as reservoir elevations change and expose TCPs to increased erosion or visitation. Because TCPs are a specific category of historic property, adverse impacts on TCPs would be addressed through the project's programmatic agreement developed in compliance with Section 106 of the NHPA or through ongoing consultation with affected tribes.

Exposure of TCPs as lake levels fluctuate as a result of management actions described by the alternatives could facilitate access to these culturally important locations by tribal members; however, exposure would also increase access for non-Native visitation. End-of-year lake elevations for each alternative are explored in detail in **TA 3**, Hydrologic Resources, and are summarized here in the discussion of impacts on TCPs.

Across all alternatives and the CCS Comparative Baseline, Lake Powell's median WY elevations are generally similar under wet hydrologic conditions, except for the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), which shows lower median elevations. As conditions become drier, Lake Powell's elevations decrease and the differences among alternatives become more pronounced, with operations varying widely at lower water levels.

In the two driest flow categories, the Enhanced Coordination Alternative maintains the highest median reservoir elevations, followed by the Maximum Operational Flexibility Alternative. Both alternatives keep median reservoir elevations well above the critical threshold of 3,500 feet, even during dry periods; therefore, they would expose the fewest number of TCPs to increased erosion or visitation. In contrast, the No Action Alternative and the Basic Coordination Alternative have median elevations that fall below this critical threshold in dry hydrologic conditions, and these alternatives would facilitate the greatest access to TCPs and potentially expose them to wave erosion. Under the Representative Preferred Alternative, Lake Powell elevations remain relatively stable compared to other alternatives. In both the Dry Flow and Critically Dry Flow categories the Representative Preferred Alternative maintains median elevation above 3,500 feet. The Critically Dry Flow category shows greater variability in median elevations.

For Lake Mead, median EOCY elevations also decline as conditions become drier, but the relative performance of each alternative remains consistent. The Supply Driven Alternative (LB Pro Rata approach) consistently has the highest median reservoir elevations across all flow categories, followed by the Supply Driven Alternative (LB Priority approach); therefore, these would expose the fewest number of TCPs to increased erosion or visitation. The No Action Alternative consistently has the lowest median elevations, with the CCS Comparative Baseline having the second lowest; these

alternatives would facilitate the greatest access to TCPs and subsequent erosion. Most action alternatives show wide variability in Lake Mead's elevations, except for the Maximum Operational Flexibility Alternative, under which the elevation reliably remains above 975 feet. Under the Representative Preferred Alternative, Lake Mead elevations show moderate variability in dry conditions and somewhat lower variability in critically dry conditions staying above 975 feet in most years.

Issue 2: How would changes in dam operations affect lake elevations (primarily in Lake Powell and Lake Mead) and river flows downstream, which could impact sacred sites?

Sacred sites are specific locations that a tribe has identified as sacred because of the sites' traditional religious significance or because the sites are a discrete location for ceremonial use. Sacred sites often overlap significantly with TCPs and with Indigenous archaeological sites. Accordingly, impacts on sacred sites are qualitatively similar to impacts on archaeological sites. Of primary concern are direct impacts like wave action and wet-dry cycling that could occur from changes in lake levels or from changes to river flows caused by annual releases. Impacts on archaeological sites are analyzed in detail in **TA 11**, Cultural Resources, and that discussion is summarized here.

At Lake Powell and Lake Mead, continuous inundation of sacred sites or Indigenous archaeological sites helps preserve them better than cycles of flooding and exposure, which increase risks from wave action. The main concern is that dropping lake elevations could expose such sites that were previously underwater, making them vulnerable to wet-dry cycles and wave impacts. As water levels fall, more sites become exposed to these risks at lower elevations. Sites at higher elevations may be less affected by wet-dry cycling and wave action but could become more accessible, depending on their location.

Hydrologic models show that during wet hydrologic conditions, Lake Powell's water levels are projected to remain above 3,660 feet in all scenarios. As conditions get drier, the Enhanced Coordination and Maximum Operational Flexibility Alternatives maintain the highest median water levels during the Average Flow Category (12.0-14.0 maf), staying at or above 3,620 feet. These alternatives also perform best in the Critically Dry Flow Category (4.46-10.0 maf), but projected medians are still below 3,580 feet; this means sacred sites or archaeological sites—and any unknown sites—at these elevations would be exposed.

For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) maintains the highest water levels during both the Average and Critically Dry Flow Categories, followed by the Enhanced Coordination and Maximum Operational Flexibility Alternatives. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) has projected median elevations up to 1,150 feet in the Average Flow Category, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives have medians around 1,100 feet. In the Critically Dry Flow Category, all scenarios would expose sacred sites or archaeological sites and any unknown sites; however, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) could protect more sites, with upper interquartile ranges reaching about 1,120 feet. Under the Representative Preferred Alternative, Lake Powell and Lake Mead elevations are comparable to other alternatives though Lake Mead elevations show greater variability across alternatives for the driest flow categories.

This pattern is reflected in the Preservation Risk Model analysis. For Glen Canyon, the Enhanced Coordination Alternative is the most robust, and will impact the fewest sites, with 30 percent of

modeled futures in the initial modeling period staying below the preservation threshold, followed by the Maximum Operational Flexibility Alternative at 25 percent. Under the Representative Preferred Alternative the preservation threshold is met in 16 percent of modeled futures. For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust during the initial modeling period, with 5 percent of modeled futures meeting or staying below the threshold. The Maximum Flexibility Alternative and Representative Preferred Alternative both stay below the preservation threshold in 3 percent of modeled futures.

For the Colorado River stretches between Glen Canyon Dam and Lake Mead, and between Hoover Dam and Lake Mohave, water release volumes in the Wet (16.0-31.11 maf) and Average Flow Categories generally remain within the range of past annual releases. However, in the Critically Dry Flow Category, median annual release volumes drop below 7.0 maf below Glen Canyon Dam, with the Enhanced Coordination Alternative reaching as low as 5.1 maf. Below Hoover Dam, the median annual flows fall below 8.0 maf, with the Enhanced Coordination and Maximum Operational Flexibility Alternatives dropping to 6.5 maf. As a result, in critically dry hydrologic conditions, lower water levels increase the likelihood of sacred sites or archaeological sites near the riverbanks being exposed. The Representative Preferred Alternative has one of the narrowest interquartile range under critically dry hydrological conditions, with an upper limit around 6.0 maf, which is still below the bottom of the range of past flow volumes at 7.0 maf.

Below Davis Dam, impacts are expected to be minimal or nonexistent in any flow category. This is because the dams below Lake Mohave are managed to maintain lake elevations or meet targeted water deliveries, and many sections have channelized banks that further reduce exposure risks.

Issue 3: How would changes in dam operations impact natural resources important to Native Americans, including riparian vegetation and wildlife?

Indigenous worldviews do not differentiate between cultural and natural environments, as they do in Western science. Under many Indigenous perspectives, resources considered separately as cultural or natural are all interconnected and interdependent (Berkes 2018). Human interventions that disrupt these interconnections are considered adverse impacts. This EIS discusses many of these resources, such as water quality, air quality, terrestrial wildlife, and others. Although all resources are considered interconnected, Indigenous oral histories and ongoing consultation with Native American groups have identified riparian vegetation communities and aquatic wildlife as resource categories of particular concern along the Colorado River corridor. Accordingly, Reclamation considers riparian vegetation and aquatic wildlife (native and nonnative fish) below. Adverse impacts on these resources important to Native Americans would be addressed through ongoing consultation with the affected tribes.

TA 9, Vegetation, presents in detail the quantitative impacts on riparian vegetation communities and evaluations of which alternatives best support historical vegetation community conditions. Historical vegetation communities are those that prevailed in the decades prior to reservoir inundation and from Indigenous worldviews are the preferred condition. Those quantitative analyses are summarized here. Woody riparian vegetation is moderately tolerant of water fluctuations, but if variability increases over a 5-year period, these areas tend to decrease. Conversely, if water level variability decreases annually or over 5 years, woody riparian vegetation may expand.

For Lake Powell, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would maintain woody riparian vegetation most similar to historical conditions. For Lake Mead, the Maximum Operational Flexibility Alternative would best match historical vegetation patterns. However, in the stretch from Hoover Dam to the SIB, these two alternatives would cause vegetation to differ most from historical conditions, leading to greater changes in that area. The Basic Coordination Alternative would be least similar to historical conditions for Lake Powell but would be closest to historical vegetation patterns for Lake Mead and the Hoover Dam to SIB reach. The Representative Preferred Alternative would be least similar to historic conditions for Lake Powell and Lake Mead. This means no single alternative matches the historical vegetation conditions across all areas.

Most alternatives provide variability closer to historical conditions than the CCS Comparative Baseline in most reaches, except for Hoover Dam to the SIB, where only the Basic Coordination Alternative does so. This suggests that changing current management strategies would benefit much of the analysis area.

For the stretch between Glen Canyon Dam and Lake Mead, the alternative that best maintains historical vegetation depends on whether the starting hydrologic conditions are wet or dry. Under dry and critically dry hydrologic conditions, differences between the alternatives become more noticeable, especially in the lowest, median, and peak flows. However, across all alternatives, sub-reaches, and evaluation criteria (habitat area, native species richness, proportion of native species cover, and total annual vegetation cover), the interquartile ranges often overlap, making it hard to identify a clear best or worst alternative for preserving historical vegetation conditions.

Under all alternatives for Lake Powell, Lake Mead, and Hoover Dam to the SIB, the first decade is expected to have greater variability and reduced woody riparian habitats, compared with historical conditions. Conditions improve in the second and third decades, allowing vegetation to recover and be reestablished. If variability prevents woody riparian habitats from forming, the area may shift to another habitat type.

Quantitative impacts on aquatic wildlife are considered in detail in **TA 8**, Biological Resources – Fish and Other Aquatic Species, and those quantitative analyses are summarized here. Decreased water levels at Lake Powell affect lake and river habitats for culturally important native and nonnative fish. Among the alternatives, the No Action Alternative stands out because it increases the amount of exposed river habitat for endangered Colorado pikeminnow and razorback sucker, which is beneficial for these species. However, this also means less lake habitat for sportfish, which could negatively affect recreational fishing.

All alternatives except the Enhanced Coordination and Maximum Operational Flexibility Alternatives keep Lake Powell below critical elevation thresholds (3,598 feet for the Colorado River and 3,600 feet for the San Juan River), thereby increasing river habitat. The Enhanced Coordination and Maximum Operational Flexibility Alternatives are less effective in this regard, as they tend to flood critical habitats and reduce the value of riverine habitat.

No alternative is particularly successful at maintaining Piute Farms Waterfall as a barrier to prevent nonnative fish from moving upstream. On the other hand, all alternatives support native fish passage over the waterfall when it is inundated. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and the CCS Comparative Baseline are the most effective at maintaining the waterfall

as a barrier, while the Enhanced Coordination and Maximum Operational Flexibility Alternatives are more likely to allow inundation and fish passage.

For Lake Powell, the Representative Preferred Alternative provides moderate protection of riverine critical habitat but does not perform as well as the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches). Overall, it represents a moderate balance but is less robust than the best-performing alternatives for specific indicators.

For Lake Mead, the alternatives would affect tributary inflow habitats of culturally important fish populations. The No Action Alternative and CCS Comparative Baseline are the most effective at keeping Lake Mead below 1,090 feet for at least 90 percent of months. This helps restrict nonnative fish and maintain the current species composition in the Grand Canyon. However, these lower elevations also hinder native species—such as razorback sucker, flannelmouth sucker, and humpback chub—from moving upstream into Grand Canyon habitats.

The Basic Coordination Alternative performs moderately well in balancing these outcomes. In contrast, the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives are less effective, as they more often allow Lake Mead to rise above critical thresholds. This can make it easier for both native and nonnative fish to move upstream.

Among the alternatives, the Supply Driven Alternative (LB Pro Rata approach) is the most reliable for keeping Lake Mead above its historical minimum elevation, which supports greater habitat stability.

Summary Comparison of Alternatives

TCPs are historic properties significant to Indigenous communities, mainly due to their association with culturally important events or individuals, as described in oral traditions. The main impacts on TCPs come from changes in the natural environment caused by managing reservoir levels and water releases, as well as increased exposure, erosion, and visitation where water levels drop. Adverse impacts on TCPs are addressed through a programmatic agreement and ongoing consultation with tribes, in compliance with the National Historic Preservation Act.

As lake levels fluctuate, TCPs may become more accessible to both tribal members and non-Native visitors. Under wet hydrologic conditions, most alternatives keep Lake Powell's water levels high and exposure of TCPs low, except for the Supply Driven Alternative, which has lower elevations. In dry hydrologic conditions, the Enhanced Coordination and Maximum Operational Flexibility Alternatives maintain the highest water levels, limiting TCP exposure, while the No Action and Basic Coordination Alternatives result in lower elevations and greater access to TCPs. For Lake Mead, water levels also drop as conditions get drier. The Supply Driven Alternative (LB Pro Rata approach) keeps the highest water levels and limits TCP exposure, while the No Action Alternative and CCS Comparative Baseline have the lowest levels, increasing access to TCPs. Under the Representative Preferred Alternative, Lake Powell and Lake Mead elevations remain relatively stable compared to other alternatives with increasing variability in the driest flow categories.

Sacred sites are locations identified by tribes for their religious or ceremonial significance; these sites often overlap TCPs and Indigenous archaeological sites. Impacts on sacred sites are similar to those affecting archaeological sites, with the main concerns being damage from wave action and wet-dry

cycling caused by fluctuating lake and river levels. Continuous inundation helps preserve these sites, while exposure due to falling water levels increases risks.

During wet hydrologic conditions, Lake Powell's water levels are expected to remain high, minimizing exposure. As conditions become drier, the Enhanced Coordination and Maximum Operational Flexibility Alternatives maintain higher water levels than others but still fall below critical thresholds in extremely dry scenarios, exposing more sacred sites. For Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) maintains the highest water levels and protects more sites, especially in dry hydrologic conditions. For the river stretches between Glen Canyon Dam and Lake Mead, and between Hoover Dam and Lake Mohave, annual water releases in wet and average years generally match historical volumes. In critically dry years, releases drop significantly, increasing the risk of exposing sacred and archaeological sites near riverbanks. Below Davis Dam, impacts are minimal due to managed lake elevations and channelized banks.

Indigenous perspectives view cultural and natural resources as interconnected, so any disruption to these links is a potential impact. Along the Colorado River, riparian vegetation and aquatic wildlife are especially important to Native Americans. Woody riparian vegetation is moderately resilient to water fluctuations, but increased variability over several years can reduce these habitats. For Lake Powell, the Enhanced Coordination and Maximum Operational Flexibility Alternatives best maintain vegetation similar to historical conditions. For Lake Mead, the Maximum Operational Flexibility Alternative performs best, while the Basic Coordination Alternative is closest to historical conditions for Lake Mead and the Hoover Dam to SIB reach. No single alternative matches historical vegetation patterns across all areas, but most alternatives perform better than the CCS Comparative Baseline in most reaches. The Representative Preferred Alternative would be least similar to historic conditions for Lake Powell and Lake Mead.

Lower water levels at Lake Powell benefit endangered river species (Colorado pikeminnow and razorback sucker) by increasing their habitat, especially under the No Action Alternative; however, lower water levels reduce lake habitat for sportfish. Most alternatives (except the Enhanced Coordination and Maximum Operational Flexibility Alternatives) keep Lake Powell below critical thresholds, favoring river habitats. The Enhanced Coordination and Maximum Operational Flexibility Alternatives tend to flood critical habitats, reducing the river habitat value.

For Lake Mead, the No Action Alternative and CCS Comparative Baseline maintain lower water levels; this helps restrict nonnative fish but also limits upstream movement of native fish. The Basic Coordination Alternative offers a moderate balance. The Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives more often allow Lake Mead to rise above critical thresholds, which can facilitate movement for both native and nonnative fish. The Supply Driven Alternative (LB Pro Rata approach) is most reliable for maintaining Lake Mead above its historical minimum, supporting habitat stability. Overall, the Representative Preferred Alternative provides moderate protection of riverine critical habitat but does not perform as well as the Supply Driven Alternative (LB Pro Rata Approach).

3.14 Recreation

3.14.1 Affected Environment

This section describes existing recreational conditions along the Colorado River system from Lake Powell to the SIB. The analysis focuses on four primary recreational resources: shoreline public use, reservoir boating, river and whitewater boating, and sport fishing. For a more detailed description of these recreational resources, please refer to **Section TA 14.1**, Recreation, Affected Environment.

Geographic Reaches

Lake Powell and Glen Canyon National Recreation Area

Glen Canyon NRA receives approximately three to five million visitors annually (NPS 2025b). Lake Powell is the primary recreational feature within Glen Canyon NRA, and it supports swimming, power boating, houseboating, water skiing, fishing, personal watercraft use, nonmotorized boating, hiking, camping (developed and primitive), and viewing of cultural and geologic resources.

Recreational boating is the dominant activity on Lake Powell, with nearly two million visitors accessing the reservoir by private or rental boats (NPS 2025c). Operability of boat ramps and marinas is highly dependent on the lake's elevation. Several ramps and the Dangling Rope Marina have been closed in the last decade due to low water levels, requiring boaters to concentrate use at fewer facilities and increasing congestion at remaining ramps. The NPS is pursuing new ramps and facility modifications to maintain boating access at lower pool elevations (NPS 2025d).

Access to Rainbow Bridge National Monument has become more limited as lake levels have declined. At elevations below 3,544 feet, concession-operated boat tours can no longer reliably reach the area, and private boaters often must traverse mud, debris, and shallow water between the shoreline and the established trail (NPS 2021b). This has substantially reduced access for many visitors.

Additional shoreline issues at Lake Powell include the following:

- Harmful algal blooms: Increasingly frequent harmful algal bloom events can result in temporary closures of water-based recreation areas to protect public health (Deemer et al. 2023).
- Quagga mussels**:** Established populations of quagga mussels encrust canyon walls, shorelines, boats, and infrastructure. Accumulated shells along beaches can create hazards for visitors and pets and increase facility maintenance needs (NPS 2016).
- Newly exposed lands**:** Declining water levels have exposed approximately 100,000 acres of previously inundated Glen Canyon, revealing arches, side canyons, rock formations, and archaeological sites (Baker 2022; Kolbert 2021). These areas provide new hiking and sightseeing opportunities but are fragile and vulnerable to erosion and vandalism.

Glen Canyon Dam to Lake Mead (Colorado River Corridor)

The 15.5-mile reach downstream of Glen Canyon Dam to Lees Ferry is located within Glen Canyon NRA and is used extensively by anglers, campers, commercial float trips, and private boaters. Warmer water temperatures in recent years have increased use by paddle boarders, kayakers, and canoeists.

Downstream, GCNP begins at the confluence of the Colorado and Paria Rivers. GCNP, a United Nations Educational, Scientific and Cultural Organization World Heritage Site, receives approximately four to six million visitors annually and provides a range of backcountry and river-based experiences (NPS 2025e). Camping along the Colorado River corridor occurs on undeveloped sandbars. The number, size, and suitability of campsites vary over time due to the fluctuating size of sandbars, which are affected by dam operations, tributary floods, vegetation encroachment, and management closures. In general, campsites become fewer or harder to use between HFEs that build sandbars, as vegetation growth, erosion, tributary floods, and aeolian sand movement affect the beaches. The river corridor also borders tribal lands for approximately 108 miles, where the Navajo Nation, Hualapai Tribe, and other tribes manage additional shoreline recreation, such as guided rafting, camping, hunting, and hiking. Access to tribal lands requires permits from the respective tribes.

Lake Mead National Recreation Area

Lake Mead NRA encompasses Lake Mead, Lake Mohave, and the surrounding desert landscapes. Lake Mead NRA receives roughly five to eight million visitors annually (NPS 2025f). The primary recreational activities include boating, fishing, water sports, swimming, camping, hiking, and wildlife viewing. The Overton Wildlife Management Area and other shoreline sites provide additional opportunities for hunting, birdwatching, and photography.

Declining reservoir elevations at Lake Mead have exposed extensive mudflats in several shoreline areas. Visitors attempting to "chase the waterline" on foot or by vehicle for fishing and shoreline access have sometimes become stuck in wet, unstable sediment, necessitating rescues and increasing safety concerns. Multiple launch ramps and some marinas have closed because water levels dropped below critical elevations; these closures have concentrated use at the remaining facilities and contributed to crowding and operational challenges.

As lake temperatures, warm, recreation managers face increasing water quality concerns, including harmful blue-green algal blooms and rare but serious incidents involving *Naegleria fowleri,* which is known as the brain-eating amoeba (NPS 2022).

Lower Colorado River Reaches (Davis Dam to the SIB)

Downstream of Hoover Dam, recreation along the Colorado River is supported by a network of public recreation areas, national wildlife refuges, and state parks, including Davis Camp, Laughlin/Bullhead City, Havasu NWR, Lake Havasu State Park, Bill Williams River NWR, Cibola NWR, Imperial NWR, Martinez Lake, and various small shoreline facilities near Yuma.

Across these reaches, visitors engage in boating, houseboating, fishing, water skiing, swimming, paddling, hunting, hiking, wildlife viewing, and camping. Lake Havasu, in particular, is a high-use destination for motorized boating, angling, spring break, and family recreation. River segments adjacent to NWRs provide more natural settings valued for wildlife viewing, hunting, and low-density boating.

Flows below Hoover Dam are consistently low due to upstream diversions and delivery obligations. As a result, the range of operational changes evaluated across the alternatives is not expected to meaningfully alter flow conditions in a manner that would measurably affect recreation opportunities in this reach. Given the limited variability in flows and the constrained nature of water-based recreation downstream of Parker Dam, a detailed analysis was determined to be unwarranted.

Potential effects in this area would be negligible and would not differ substantially amongst the alternatives. Impacts on recreation below Hoover Dam are not further considered in this EIS.

Recreational Uses

Shoreline Public Use

Shoreline public use in the study area is supported by marinas, boat launch ramps, docks, campgrounds, and access points to major destinations. These facilities provide access for day use, extended boating trips, camping, hiking, and viewing of natural and cultural resources. Fluctuations in reservoir elevations influence the operability and safety of these facilities. Declining water levels can result in temporary or long-term closures of ramps and marinas, relocation or modification of facilities, congestion at remaining access points, and reduced or more difficult access to popular shoreline destinations.

Reservoir Boating

Reservoir boating throughout the system is directly affected by fluctuating water levels. As reservoir elevations decline, navigational hazards (for example, exposed rocks, sandbars, and constricted channels) increase, and safe boating capacities decrease. Management responses include the placement of buoys and markers, installation of warning signs, and formal closure of unsafe areas. Quagga mussel infestations further complicate reservoir boating operations by fouling boats, infrastructure, and shorelines.

In the upstream tributaries to Lake Mead, sediment deposition and receding water levels have created shallow, poorly defined channels. When lake elevations fall below approximately 1,170 feet, the upper end of Lake Mead becomes too shallow for most motorized boats to navigate upstream into the lower Grand Canyon. As Lake Mead has receded, the Colorado River has incised into deposited sediments near Pearce Ferry, forming a new high-hazard rapid (Pearce Ferry Rapid) that blocks upstream motorized navigation and has altered takeout operations.

Large changes in reservoir navigability are not anticipated under the proposed range of operations at Lake Mohave and Lake Havasu because these reservoirs are managed to meet relatively stable monthly target elevations. Lake Mohave and Lake Havasu are therefore not included in the environmental analysis.

River and Whitewater Boating

Whitewater boating is the primary recreational activity on the Colorado River between Lees Ferry and the downstream takeouts at Diamond Creek or Pearce Ferry. Trips may be commercial or private, use a variety of boat types, and range up to 25 days in length. GCNP staff manages river use under the Colorado River Management Plan, which establishes limits on daily launches, group size, trip length, and the timing of motorized and nonmotorized use (NPS 2006).

Navigability and the user experience are influenced by discharge levels, debris fan rapids, and changing channel conditions. Lower flows and increased side-canyon debris can make certain rapids more technically demanding.

Flow levels are a key determinant of whitewater trip quality and safety (Bishop et al. 1987; Shelby et al. 1992; Hall and Shelby 2000; Stewart et al. 2000; Neher et al. 2017). Studies and user surveys indicate that flows below about 10,000 cubic feet per second (cfs) and above about 45,000 cfs are generally

considered less than optimum, while flows between approximately 20,000 and 26,000 cfs are considered optimal for most whitewater users (Shelby et al. 1992; Bishop et al. 1987; Neher et al. 2017). Flows of 8,000–9,000 cfs are regarded as the minimum acceptable levels for safely running trips with passengers (Bishop et al. 1987; Shelby et al. 1992; Stewart et al. 2000).

Downstream of Hoover Dam, the proposed alternatives are not expected to substantially affect river or whitewater boating conditions between Hoover Dam and the SIB.

Sport Fishing

Sport fishing is an important recreational use across the study area. Although specific elevation thresholds for angler satisfaction are not well defined, fishing quality is closely linked to reservoir habitat, water temperature, access via ramps and marinas, and boat navigability.

Lake Powell supports warmwater fisheries, including for striped bass, smallmouth bass, largemouth bass, walleye, catfish, and panfish. Forage species, such as threadfin shad, are sensitive to temperature changes and influence predator populations.

The 15.5-mile tailwater reach below Glen Canyon Dam supports a Blue Ribbon[16] rainbow trout fishery at Lees Ferry. Historically, cold-water releases limited survival and reproduction of warmwater species entrained from Lake Powell. Recent warmer and lower-oxygen releases have increased the risk of establishment and recruitment of nonnative predators, such as smallmouth bass, which potentially reduces trout quality. Please refer to **TA 14**, Recreation, for more information on rainbow trout dynamics in this reach.

Lake Mead and Lake Mohave support diverse warmwater fisheries (for striped bass, largemouth bass, catfish, panfish, and stocked trout). Low reservoir levels have affected hatchery operations at Lake Mead, leading to facility modifications and water supply changes. Farther downstream, Lake Havasu and the lower river reaches support striped bass, largemouth and smallmouth bass, catfish, crappie, sunfish, and other species, with some areas subject to seasonal closures (for example, Cibola Lake) to protect wildlife.

Overall, sport fishing opportunities remain widespread throughout the system but are sensitive to changes in hydrology, water temperature, water quality, and access conditions associated with reservoir elevations and dam operations.

3.14.2 Environmental Consequences

Methodology

Consistent with Reclamation's 2007 Final EIS and 2024 Final SEIS, the analysis builds on traditional threshold-based evaluation methods by integrating DMDU concepts, including robustness heat maps and vulnerability bar plots. These tools highlight how each alternative performs across a wide range of plausible hydrologic futures with regard to shoreline public use facilities, reservoir boating and navigational hazards, whitewater boating, and sport fishing. Refer to **Section 3.2.6**, Decision Making

[16] A Blue Ribbon fishery designation indicates a high-quality recreational fishery that meets specific criteria, including water quality, natural reproduction capacity, and management strategies.

under Deep Uncertainty, for an overview of interpreting the DMDU robustness heat maps and vulnerability bar plots.

Method Used to Assess Shoreline Public Use Facilities

The evaluation of shoreline facilities relies on thresholds provided by the NPS that identify reservoir elevations at which specific marinas, docks, and launch ramps require modification, relocation, or closure. These thresholds serve as impact indicators for the loss or degradation of shoreline public use. Using the DMDU framework, the analysis examines the percentage of futures in which a given alternative maintains a minimum proportion of operable recreational sites throughout the summer high-use season (May 31–August 31). This period was selected because visitation is highest, and operational disruptions have the greatest impact on user experiences and local economies. Representative facilities were selected from Lake Powell and Lake Mead to align with the regional economic modeling (see **TA 16**, Socioeconomics). The analysis then analyzes the performance of alternatives in maintaining representative elevations important for reservoir boating access, including the minimum for safe navigation, a historic low, and the elevation at which all boat ramps and/or planned extensions would become inaccessible.

Method Used to Assess Reservoir Boating and Navigation Hazards

Reservoir boating impacts are analyzed using critical navigational thresholds identified in the 2007 Final EIS and continued in the 2024 Final SEIS. Threshold elevations indicate levels below which safe navigation becomes substantially impaired due to shallow channels, newly exposed hazards, or blocked passageways. DMDU outputs evaluate the frequency with which each alternative avoids falling below these elevations. This approach highlights the reliability of each alternative in maintaining safe boating conditions over multiple hydrologic futures.

Method Used to Assess Whitewater Boating

The evaluation of whitewater boating relies on minimum flow thresholds known to influence navigability, safety, and trip management. Prior studies (Shelby et al. 1992; Stewart et al. 2000) identify 8,000 cfs as the preferred minimum daytime flow for whitewater boating with passengers, 5,000 cfs as a low-flow threshold below which trip disruption and safety hazards increase, and 20,000–26,000 cfs as the preferred range for optimal whitewater boating experiences. DMDU heat maps assess the percentage of futures in which the alternatives maintain flows above the minimum thresholds during the daytime (7:00 a.m. to 7:00 p.m.) across the modeling period.

Methods Used to Assess Ferry and Taxi Boat Services

Thresholds provided by the Utah Department of Transportation (UDOT 2025) identify key elevations required for ferry operations, most notably 3,575 feet. The analysis evaluates whether reservoir elevations under each alternative would sustain these services or require extended closure.

Methods Used to Assess Sport Fishing

Reservoir sport fishing is influenced primarily by habitat availability, shoreline complexity, and thermal conditions. Because no discrete elevation thresholds exist for fishing suitability, DMDU is not used for reservoir sport fishing; instead, the analysis focuses on how general elevation trends under each alternative influence fish habitat.

A more detailed analysis (**TA 8**, Biological Resources – Fish and Other Aquatic Species) using DMDU information was conducted for the Lees Ferry rainbow trout fishery, where water temperature is directly linked to recreational quality and species viability.

Impact Analysis Area

The impact analysis area for recreation aligns with the general analysis area, which encompasses the Colorado River corridor from the full pool elevation of Lake Powell to the SIB. Given the limited flow variability and the constrained nature of water-based recreation downstream of Parker Dam, a detailed analysis below this area not warranted. Potential effects in this area would be negligible and would not differ substantially amongst the alternatives.

Assumptions

- The analysis assumes that the demand for recreational opportunities will either remain constant or increase over time. This assumption forms the basis for evaluating impacts on activities such as reservoir recreation, fishing, and whitewater boating.
- The analysis considers 5,000 cfs and 8,000 cfs as two levels at which commercial and private boaters may experience navigability challenges (Bishop et al. 1987; Stewart et al. 2000; Shelby et al. 1992).
- While HFEs are not directly incorporated into the recreation modeling, actual HFE frequency may differ from that assumed or predicted in other modeling efforts.
- Additional assumptions related to modeling are considered in the analysis, contributing to the accuracy and reliability of the hydrologic models used to anticipate impacts resulting from various actions.

Impact Indicators

- Threshold reservoir elevations
- Threshold river flows
- Water temperatures

Issue 1: How would the management of reservoir elevations affect recreation?

Lake Powell

Shoreline Recreational Facilities

Reservoir elevations exert a direct influence on the operability of Lake Powell's recreational infrastructure. Many of Lake Powell's primary launch ramps, marinas, and courtesy docks become inaccessible or require substantial modification when lake levels fall below the thresholds identified by the NPS (see **Table TA 14-3** in **TA 14**, Recreation). The DMDU results illustrate that in the Full Modeling Period and 2027-2039 subperiod, none of the alternatives would keep at least 60 percent of Lake Powell recreational sites open during the summer months (**Figure TA 14-1** in **TA 14**, Recreation). Based on the planned length of this decision, the Representative Preferred Alternative is unable to meet the preferred minimum performance across the Full Modeling Period and 2027-2039 subperiod, but does so in 30 percent of modeled futures in the 2040-2049 subperiod, and 22 percent of modeled futures in the 2050-2060 subperiod. Under all alternatives, periods of low water would be more likely, which could result in recurring closures of boat launch ramps, restricting marinas to limited operability,

and reducing shoreline access for day users, campers, and boaters. Visitors could experience longer wait times, congested remaining ramps, and reduced access to preferred boating destinations. Taken together, the projected reservoir conditions suggest that under most alternatives, the reliability of Lake Powell's shoreline public use facilities would decline from historical norms.

Boating Navigation

Safe boating access at Lake Powell depends strongly on maintaining reservoir elevations above the 3,620-foot threshold. Elevations below this level expose hazards and constrict navigation channels. The DMDU analysis shows that the Enhanced Coordination and Maximum Operational Flexibility Alternatives offer the greatest robustness at maintaining elevations above this threshold in at least 20 percent of months, doing so in roughly 80 percent of modeled futures. These alternatives would support safer boating conditions under a wider range of hydrologic conditions and preserve access to many of the canyon environments that are central to the Lake Powell recreational experience.

The other alternatives perform moderately to poorly in this regard. The Representative Preferred, No Action, and Basic Coordination Alternatives, achieve the threshold in approximately 60 percent of futures, while the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) maintains the threshold in approximately 40 percent of futures. Under these worse-performing alternatives, Lake Powell could experience prolonged periods during which safe passage through major navigation corridors is limited, reducing the quality and quantity of recreational boating opportunities across a wider range of hydrologic futures. All alternatives show poor performance in maintaining a Lake Powell elevation of 3,620 feet or above in 20 percent or more futures, indicating that the long-term return to historically common elevation levels is unlikely.

Sport Fishing

Sport fishing in Lake Powell is sensitive to changes in reservoir elevation because habitat complexity diminishes as water recedes. The Maximum Operational Flexibility and Enhanced Coordination Alternatives, which are more robust at achieving higher median elevations around 3,600 feet, would help preserve a more diverse array of shallow-water habitats favored by desirable warmwater sportfish, including largemouth bass, bluegill, and crappie. Conversely, the lower-elevation alternatives cluster around 3,560 feet and would result in diminished shallow-water habitat, promoting conditions that favor smallmouth bass and reducing the productivity of the fishery for many anglers. Thus, the alternatives that sustain higher average reservoir levels would provide more favorable sport fishing conditions throughout the year.

Ferry and Taxi Boat Services

Ferry and taxi boat services at Lake Powell require relatively high reservoir elevations to maintain safe docking and transit conditions. The ferry becomes inoperable at elevations below 3,575 feet. Because all alternatives frequently fall below this threshold across much of the modeled period, ferry service interruptions or full discontinuation would be a near-constant condition under all operational strategies. Only substantial engineering modifications or relocation efforts would restore reliable ferry service under extended drought conditions.

Lake Mead

Shoreline Recreational Facilities

Lake Mead recreational infrastructure is sensitive to threshold elevations. Many of the reservoir's launch ramps, marinas, and shoreline access points become impaired as water levels retreat, and steep, unstable slopes emerge. The DMDU analysis shows that all alternatives perform poorly at maintaining at least 80 percent of recreational facilities open during the summer season in the Full Modeling Period. The Supply Driven Alternative, particularly the Pro Rata approach, is the most effecting at maintaining this preferred minimum, but only succeeds in 14 percent of modeled futures. While this alternative preserves opportunities at Lake Mead, it also reflects trade-offs for Lake Powell. The Maximum Operational Flexibility Alternative performs moderately well, though not at the same level as the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches)

Under all alternatives, including the Representative Preferred Alternative, Lake Mead experiences low reliability in maintaining recreational sites. These deficiencies translate into recurring closures, reduced or eliminated launching opportunities, stranded infrastructure, and a substantial decline in the quality of recreational access. As reservoir conditions deteriorate under these alternatives, visitor safety concerns would increase, and more intensive management interventions would be needed to maintain even modest levels of access.

Boating Navigation

Maintaining Lake Mead above the 1,170-foot threshold is essential for preserving upstream navigation into the lower Grand Canyon. The analysis shows that only the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) provides a high likelihood of maintaining Lake Mead above this level for 10 percent or more of months, with success rates approaching 80 percent of futures. This alternative would help reduce navigation hazards, limit mudflat exposure, and sustain limited upstream boating opportunities.

The other alternatives show weaker performance, with the No Action Alternative and CCS Comparative Baseline exhibiting the poorest performance. Under all alternatives, including the Representative Preferred Alternative, it is likely that large areas of the reservoir would expose thick mudflats and shallow delta formations, making it dangerous or impossible for boaters to access several parts of the reservoir. These conditions would also exacerbate congestion at the limited number of remaining deep-water access points.

Issue 2: How would the management of releases from Glen Canyon Dam affect recreation, including from changes in water temperature?

Whitewater Boating

Whitewater boating conditions below Glen Canyon Dam depend heavily on reliable daytime flows that allow large commercial rafts to safely navigate rapids and manage trip logistics. The analysis shows that the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) performs the strongest in maintaining flows at or above the 8,000 cfs minimum threshold, providing favorable conditions in approximately 86 percent of futures. This alternative would make commercial and private boating groups less likely to face low-water hazards, allowing for safer, smoother navigation.

The Basic Coordination Alternative also performs well, while the CCS Comparative Baseline and the No Action, Maximum Operational Flexibility, Representative Preferred, and Enhanced Coordination Alternatives exhibit diminishing performance. The Enhanced Coordination Alternative, in particular, maintains the 8,000 cfs threshold in only 8 percent of futures, indicating substantial vulnerability to flows falling below the preferred safety conditions. As flows weaken, rafting parties could encounter more exposed rocks, shallower rapids, longer portaging distances, and increased risks of boating incidents. These hazards directly affect the quality, reliability, and safety of the Grand Canyon whitewater recreational experience.

When evaluating flows above the 5,000 cfs threshold, below which trip disruption and safety hazards increase, the analysis finds that the Enhanced Coordination, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives maintain this threshold in nearly 100 percent of futures. While these flows may not provide optimal conditions, they reduce the likelihood of severe navigational hazards. The other alternatives perform moderately to poorly, elevating risks for boaters and contributing to unpredictable trip conditions.

Overall, the alternatives that maintain higher flows offer substantially better protection of the whitewater recreational quality. Conversely, the alternatives that produce more frequent low-flow conditions increase safety risks, impede access to campsites, and alter trip durations.

Sport Fish Populations

Recreational fishing below Glen Canyon Dam, particularly at Lees Ferry, is highly sensitive to changes in water temperature. Rainbow trout experience thermal stress when temperatures exceed 20 °C (68 °F), while warmwater species, such as smallmouth bass, benefit from elevated temperatures and potentially expand their range.

The Enhanced Coordination Alternative offers the highest likelihood of maintaining cooler water temperatures, meeting the preferred temperature performance in 56 percent of futures. Under this alternative, conditions associated with maintaining the trout fishery would be most favorable. The Maximum Operational Flexibility Alternative also performs moderately well, while the Representative Preferred, Supply Driven (both LB Priority and LB Pro Rata approaches), and the No Action Alternatives perform poorly, allowing temperatures to exceed optimal thresholds in a large proportion of futures.

Under warmer and drier hydrologic futures, all alternatives become more vulnerable to undesirable temperature increases. Under such conditions, rainbow trout populations may decline, and warmwater species may proliferate, potentially altering recreational fishing patterns and diminishing the unique value of the Lees Ferry fishery. Without management interventions, such as cold-water bypass infrastructure, the ability to maintain high-quality trout fishing will remain constrained across all alternatives.

Summary Comparison of Alternatives

The alternatives vary considerably in their ability to sustain recreational resources over the full analysis period as well as all subperiods. The alternatives that favor higher Lake Powell elevations, such as the Enhanced Coordination and Maximum Operational Flexibility Alternatives, offer the greatest benefits for Lake Powell-based recreational resources. These alternatives help preserve access to boat ramps

and marinas, maintain more reliable boating corridors, and sustain more diverse sport fishing opportunities. By contrast, the alternatives that prioritize meeting compact delivery obligations through downstream releases, such as the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), perform more poorly for Lake Powell's recreational infrastructure.

At Lake Mead, the pattern is reversed. The alternatives that retain more water downstream, specifically the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), perform best at keeping facilities open and maintaining safe boating conditions. The Maximum Operational Flexibility and Enhanced Coordination Alternatives provide moderate benefits, while the No Action Alternative and the CCS Comparative Baseline offer the least reliable performance for Lake Mead–based recreation. The Representative Preferred Alternative generally performs in the middle of the range of alternatives for both Lake Powell and Lake Mead.

For whitewater boating in the Grand Canyon, the alternatives also yield varying results. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) maintains the highest likelihood of meeting the preferred 8,000 cfs flow threshold, supporting safer and higher-quality rafting opportunities. The Enhanced Coordination and Maximum Operational Flexibility Alternatives perform poorly in this regard, creating greater risks for boaters and reducing the reliability of commercial trip planning. The Representative Preferred Alternative generally performs in the middle of the range of alternatives for daytime flows.

In terms of water temperature and sport fishing below Glen Canyon Dam, the Enhanced Coordination Alternative performs most favorably, helping sustain the cold-water conditions that support the rainbow trout population. The Maximum Operational Flexibility Alternative also provides moderate support for cooler temperatures. The alternatives that prioritize downstream deliveries at the expense of upstream storage tend to worsen temperature conditions and increase the prevalence of warmwater predators. The Representative Preferred Alternative generally performs in the middle of the range of alternatives for water temperature for rainbow trout.

Overall, no alternative fully protects all recreational resources throughout the Basin under extended drought conditions. Instead, each alternative presents a unique set of trade-offs. Those alternatives that prioritize upstream reservoir elevations tend to support recreation at Lake Powell but reduce downstream releases needed for whitewater boating and temperature control; those that emphasize deliveries to the Lower Basin improve Lake Mead recreation but may worsen recreation conditions in Lake Powell and Lees Ferry. These trade-offs underscore the Basin-wide challenge of managing limited water supplies while simultaneously supporting diverse recreational resources that rely on adequate water levels and river flows.

3.15 Dams and Electrical Power Resources

3.15.1 Affected Environment

This section provides a summary of the infrastructure, spillway conditions, and hydropower capacity and generation of the four primary dams and reservoirs in the analysis area of the Colorado River corridor from the full pool elevation of Lake Powell to the SIB. These four dams and reservoirs are Glen Canyon Dam and Lake Powell, Hoover Dam and Lake Mead, Davis Dam and Lake Mohave, and

Parker Dam and Lake Havasu. For additional information and the full discussion of the affected environment and environmental consequences, please refer to **TA 15**, Dams and Electrical Power Resources.

This section addresses the interplay between reservoir elevations and dam releases, and how they influence dam spillway use, power generation, and capacity. It also provides the context necessary for evaluating the effects of the alternatives on dams and electrical power resources.

Hydropower output depends on how much water passes the turbines and the 'head' (the elevation difference between the reservoir surface and the turbine). The higher the reservoir elevation, the greater the head the water can exert as it passes through the turbines. Higher reservoir elevations allow greater power production, and conversely, if reservoirs drop below a specified elevation (the minimum power pool), power production is not possible.

Keeping the reservoir water level below the spillway crest reduces reliance on spillway infrastructure, preserves the water supply, and maintains flood storage capacity. Maintaining lower reservoir levels allows inflow to be routed through controlled outlets to respond to spring runoff. This section also provides the context for analyzing the effects of the alternatives on electricity rates. Reclamation operates and maintains the Glen Canyon, Hoover, Davis, and Parker Dams, while the Western Area Power Administration (WAPA) is responsible for marketing and transmitting the power generated at these facilities across the Upper and Lower Basins (Reclamation 2007a).

Glen Canyon Dam and Lake Powell

Glen Canyon Dam is located in Page, Arizona, and is a concrete arch dam rising 710 feet with a 35-foot-wide roadway connecting the dam's spillways. The dam's reservoir, Lake Powell, has a water storage capacity of 25.16 maf and a maximum reservoir elevation of 3,711 feet. The dam and reservoir are operated and maintained by Reclamation's Glen Canyon Field Division in Page, Arizona. Refer to **Figure TA 15-3** in **TA 15**, Dams and Electrical Power Resources.

Dam operations are managed to maintain the water surface elevation near or below 3,700 feet, which is the normal operating level. Operational preference is to maintain a water surface elevation below the top of active conservation, 3,700 feet, to minimize the occurrence of flood operations and the need for additional monitoring. Glen Canyon Dam is designed to safely accommodate the probable maximum flood including operating up to the maximum water surface elevation of 3,711 feet. Another important operational consideration is maintaining adequate vacant storage at or below an elevation of 3,684 feet on January 1, which provides the necessary capacity to preserve space for spring runoff inflows.

The Glen Canyon Dam powerplant has eight generators with a maximum combined capacity of 1,320 MW at a reservoir elevation of 3,700 feet (Reclamation 2016). At minimum power pool, the powerplant has an estimated physical capacity of 630 MW. The powerplant's physical capacity to generate power has recently been affected by decreases in Lake Powell reservoir elevations due to drought conditions. The decreases in elevation have led to lower head, which, combined with reduced annual releases, has reduced power generation since 1997. Refer to **Figure TA 15-4** and **Figure TA 15-5** in **TA 15**, Dams and Electrical Power Resources.

Hoover Dam and Lake Mead

Hoover Dam is located in Black Canyon on the Arizona–Nevada state line, approximately 35 miles southeast of Las Vegas, Nevada. The dam and its reservoir, Lake Mead, are operated and maintained by Reclamation's Lower Colorado Basin Dams Office. Hoover Dam is a concrete gravity-arch structure standing 726 feet high with a crest length of 1,244 feet. Lake Mead has a water storage capacity of 30.2 maf and a maximum reservoir elevation of 1,232 feet. Refer to **Figure TA 15-5** in **TA 15**, Dams and Electrical Power Resources.

Under normal conditions, nearly all Colorado River flow passes through the turbines, with the spillways and outlet works used only in exceptional circumstances. The maximum safe channel capacity is estimated to be 40,000 cfs. Current operations aim to keep Lake Mead below 1,219.6 feet as much as possible. While limited operations above this level have occurred historically, it is preferred to minimize time spent in the flood control space. The elevation of the bottom of the spillway drum gate is 1,205.4 feet. Operating below this elevation is desired because elevations above this point rely on mechanical gate function, where the risk of failure increases. The most critical elevation threshold is 1,226.9 feet. This elevation corresponds to a spillway discharge exceeding 40,000 cfs and represents an imminent emergency.

The Hoover Dam powerplant has 17 commercial generators with a maximum combined capacity of 2,074 MW. The powerplant requires a minimum Lake Mead elevation of 950 feet to produce power. At minimum power pool, the powerplant has an estimated capacity of 117 MW. The power-generating capacity of Hoover Dam has been affected by drought conditions. The drop in Lake Mead's elevation has reduced head, lowering electric power output. At Lake Mead elevation 1,035 feet, Hoover Dam's generating capacity decreases from 1,274 MW to 382 MW. Elevations above 1,035 feet in current market conditions, hydropower can be produced at or above market value. With current turbines, if the elevation drops below 1,035 feet, it is estimated that operating costs will exceed the value of the hydropower produced. Please reference **Figure TA 15-6** and **Figure TA 15-7** in **TA 15**, Dams and Electrical Power Resources.

Davis Dam and Lake Mohave & Parker Dam and Lake Havasu

Davis Dam is a 320-foot-tall, rock- and earth-fill gravity dam, rising 140 feet above the Colorado River. The dam spans the border of Arizona and Nevada in Pyramid Canyon and is 67 miles downstream from Hoover Dam. Its dam crest is 1,600 feet long and 50 feet wide. Its reservoir, Lake Mohave, has a water storage capacity of 1.8 maf and a maximum reservoir elevation of 647 feet. Davis Dam is operated and maintained by Reclamation's Davis Dam Field Division, which is part of the Lower Colorado Basin Dams Office.

Parker Dam, commonly known as the 'deepest dam in the world,' is a concrete arch structure with 73 percent of its height below the original stream bed elevation of the Colorado River. The dam is on the Arizona–California border and lies 88 miles downstream from Davis Dam. The dam has a crest length of 856 feet and a width of 39 feet. The dam's reservoir, Lake Havasu, has a storage capacity of 646,200 acre-feet and a maximum reservoir elevation of 450 feet. Parker Dam is operated and maintained by Reclamation's Parker Dam Field Division of the Lower Colorado Basin Dams Office.

Normal releases from Davis and Parker Dams are made through the powerplant turbines with the spillway and outlet works in the closed position. The safe downstream channel capacity on the river is 40,000 cfs.

The Davis Dam powerplant has four 51.75 MW generators and one 48 MW generator for a total capacity of 255 MW. The Parker Dam powerplant has four 30 MW generators, totaling 120 MW, with a discharge capacity of 22,000 cfs (Reclamation 2023c). Drought conditions have had less impact on the capacity at the Davis and Parker powerplants than at the Hoover and Glen Canyon powerplants because the elevations of Lake Mohave and Lake Havasu reservoirs have remained relatively constant. However, drought-induced reductions in river flow have resulted in a decline in electric power generation at these powerplants. Please refer to **Figure TA 15-8** in **TA 15**, Dams and Electrical Power Resources.

Hydroelectric Power Distribution

This section provides a high-level summary of hydroelectric power distribution. Please refer to **TA 15.1.4**, Hydroelectric Power Distribution, in **TA 15**, Dams and Electrical Power Resources, for a more in-depth discussion of the topic and a variety of associated topics, including: scheduling; load following, generation, and regulation; reliability standards; basin funds; emergencies and outages assistance; transmission system; power marketing; Tribal benefit crediting; and rates.

Hydroelectric power generation can be adjusted operationally through a coordinated effort between WAPA and Reclamation. This operational flexibility allows WAPA to quickly and efficiently increase or decrease generation in response to customer demand. WAPA markets long-term firm capacity and energy; short-term, firm capacity and energy; and non-firm energy. WAPA sets rates for Firm Electric Service from federal hydropower projects in its marketing territory, in accordance with Department of Energy regulations and applicable federal statutes. Customers pay rates that align specifically with the project from which they buy power.

WAPA sets rates through a public process (proposal, comment period, and final notice in the Federal Register). WAPA has various wholesale customers, including municipal utilities, federal and state public power facilities, rural electric cooperatives, and tribal entities. Power rates are set so that revenues are sufficient to cover all costs assigned to power within the required time periods. Retail rates are those paid by end users (residential, commercial, and industrial customers of WAPA's wholesale customers). The retail rates charged by not-for-profit entities are normally set to cover system operations and capital costs. As the costs of these individual components change, the retail rates are adjusted to ensure that enough revenue is collected to meet the utility's financial obligations.

3.15.2 Environmental Consequences

This section summarizes the analysis of the effects of the alternatives on the minimum power pool for Lake Powell and Lake Mead; the power capacity of the Glen Canyon Dam and Hoover Dam powerplants; the power generation of the Glen Canyon Dam, Hoover Dam, Davis Dam, and Parker Dam powerplants; the spillway use of Glen Canyon Dam and Hoover Dam; and electricity rates and the market value of the electricity.

Spillway use and hydropower capacity of the Davis Dam and Parker Dam are not analyzed because Lake Mohave and Lake Havasu reservoirs have historically remained relatively constant, and their

elevations are expected to remain so under all alternatives. Both Lake Mohave and Lake Havasu would continue to be operated under a rule curve that provides specific target elevations at the end of each month (refer to **Section TA 3.1.8**, Davis Dam to Lake Havasu, in **TA 3**, Hydrologic Resources).

For additional detail and the full analysis of effects, please refer to **Section TA 15.2**, Environmental Consequences, in **TA 15**, Dams and Electrical Power Resources.

Methodology

WAPA's CRSP Python-based (CRiSPPy) model and Reclamation's CRSS model analysis framework informs the basis for the effects analysis. For additional information on the methodology used, please refer to **Section 3.2.6**, Decision Making under Deep Uncertainty; **Appendix A**, CRSS Model Documentation; and **Section TA 15.2.1**, Methodology, in **TA 15**, Dams and Electrical Power Resources.

Impact Analysis Area

The analysis area for Issues 1–4 encompasses the four primary dams in the Colorado River corridor from the full pool elevation of Lake Powell to the SIB: Glen Canyon Dam and Lake Powell reservoir, Hoover Dam and Lake Mead reservoir, Davis Dam and Lake Mohave reservoir, and Parker Dam and Lake Havasu reservoir. The analysis area for Issue 5 consists of the retail electricity customers in Arizona, Colorado, Nevada, New Mexico, Nebraska, Utah, and Wyoming who receive power through local utilities and cooperatives supplied with Glen Canyon Dam power by WAPA. WAPA sells power at the wholesale level, while local utilities and cooperatives distribute that power directly to homes, businesses, and other customers.

Assumptions

All action alternatives except for the Basic Coordination Alternative incorporate mechanisms related to the storage and delivery of conserved water in Lake Powell, Lake Mead, or both (refer to Appendix S, Additional Description of Alternatives). Unless otherwise specified, impacts reflect modeling assumptions about voluntary conservation behavior.

The Lower Basin electrical generation and firm capacity modeling results are direct outputs from CRSS. Refer to **Appendix A**, CRSS Model Documentation, for more details related to model assumptions and documentation. The Glen Canyon Dam electrical generation and firm capacity modeling results are direct outputs from the CRiSPPy model. For additional information and modeling assumptions, please refer to *CRiSPPy: An Advanced Hydropower Scheduling Tool for the Colorado River Storage Project* (Ploussard et al. 2025). The Glen Canyon Dam rates analysis data was developed by Argonne National Laboratory. Information and modeling assumptions for the rates analysis can be found in *Post-2026 Environmental Impact Statement Rate Analysis for the Colorado River Storage Project* (Yu et al. 2025).

Impact Indicators

- Lake Powell and Lake Mead Reservoir elevations
- Firm capacity (MW)
- Energy generation (MWhs)
- Spillway releases

- Electricity rates
- The market value of electricity

Issue 1: How do the alternatives impact the frequency at which reservoir elevations drop below the minimum power pool at Lake Powell and Lake Mead?

Minimum power pool is the lowest reservoir elevation level at which a hydropower plant can produce power. The frequency at which reservoir elevations drop below minimum power pool for Glen Canyon Dam/Lake Powell and Hoover Dam/Lake Mead were measured by calculating the percent of futures in which the elevations of the reservoirs achieve the preferred minimum performance of maintaining elevations at or above 3,490 feet and 950 feet respectively (refer to **Figure TA 15-9** and **Figure TA 15-11**); and by using vulnerability figures that display conditions that could cause Lake Powell and Lake Mead to drop below these thresholds (3,490 feet and 950 feet respectively), representing undesirable performance when elevations fall below minimum power pool in one or more months (refer to **Figure TA 15-10** and **Figure TA 15-12**).

The Maximum Operational Flexibility Alternative would provide the greatest power pool robustness for both Lake Powell and Lake Mead. For Lake Powell, the Enhanced Coordination Alternative would provide the second-highest level of power pool, while the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would provide the lowest. Conversely, for Lake Mead, the Supply Driven Alternative (LB Pro Rata approach) would provide the second-highest level of power pool, followed by the Enhanced Coordination Alternative. For Lake Mead, the least robust alternative is the No Action Alternative.

Under the driest hydrologic conditions, the Maximum Operational Flexibility and Enhanced Coordination Alternatives would provide the most robust outcomes for maintaining Lake Powell elevations above the preferred threshold, whereas the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) and the No Action Alternative would provide the least. For Lake Mead, the Maximum Operational Flexibility Alternative, Supply Driven Alternative (LB Pro Rata approach), and Enhanced Coordination Alternative would provide the greatest robustness, while the No Action Alternative would provide the least.

For Lake Powell elevation power pool robustness, the Representative Preferred Alternative exhibits a better performance than the No Action, CCS Comparative Baseline, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) alternatives for the full modeling period. For Hoover Dam, the Representative Preferred Alternative is more robust than all alternatives except the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (LB Pro Rata approach) Alternatives in the 2027-2039 modeling period.

Issue 2: How would the alternatives impact the firm capacity of the Glen Canyon Dam and Hoover Dam powerplants?

Firm capacity is the reliable, guaranteed amount of power output from a powerplant that accounts for operational constraints such as water releases and ramp rates. Firm capacity is measured in MW. This section considers how the different alternatives affect the annual firm capacity of the hydropower plants at the Glen Canyon Dam and Hoover Dam for the month of August. The analysis uses boxplots to display August firm capacity at both dams across five categories of Lees Ferry natural flow conditions based on the preceding 3-year average Lees Ferry natural flow, as shown in **Figure TA 15-**

14 and **Figure TA 15-15** in **TA 15**, Dams and Electrical Power Resources. The boxplots illustrate firm capacity over a 3-year period for each flow category, allowing comparison of alternative performance across a range of hydrologic conditions.

For Glen Canyon Dam, the firm capacity would be highest in the Average Flow Category (12.0–14.0 maf) under the Enhanced Coordination Alternative, followed by the CCS Comparative Baseline, and would be lowest under the No Action Alternative. Under the other action alternatives, in the Average Flow Category there would be a similar capacity of between 675 and 725 MW. In the Critically Dry Flow Category (4.46–10.0 maf), the No Action Alternative, Basic Coordination Alternative, Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), and CCS Comparative Baseline would show a wide range of interquartile values, with all having the potential for capacity to drop to 0 MW. In the Critically Dry Flow Category, the capacity for every alternative and the CCS Comparative Baseline would be below 725 MW.

For Hoover Dam, in the Average Flow Category (12.0–14.0 maf), the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), Enhanced Coordination Alternative, and Maximum Operational Flexibility Alternative would yield the highest capacity, each exceeding 1,250 MW. The CCS Comparative Baseline, No Action Alternative, and Basic Coordination Alternative all would have wide interquartile ranges. The No Action Alternative would result in a lower capacity in the Average Flow Category. In the Dry Flow Category (10.0–12.0 maf), the Supply Driven Alternative (LB Pro Rata approach) would provide the highest capacity and the smallest interquartile range. All other action alternatives would have wide interquartile ranges and varying capacity in the Dry Flow Category. The No Action Alternative and the CCS Comparative Baseline would have lower capacity in the Dry Flow Category. In the Critically Dry Flow Category (4.46–10.0 maf), the Supply Driven Alternative (LB Pro Rata approach) would have the highest capacity but, like the other action alternatives, would have a wide interquartile range under the Critically Dry Flow Category. Under the Critically Dry Flow Category, the Supply Driven Alternative (LB Priority approach) and Basic Coordination Alternative would have the potential to drop to 0 MW. The CCS Comparative Baseline and the No Action Alternative would produce the lowest capacity in the Critically Dry Flow Category, and they both would have the potential to drop to 0 MW.

Issue 3: How would the alternatives impact the energy generation of the Glen Canyon Dam, Hoover Dam, Davis Dam, and Parker Dam powerplants?

Energy generation is the amount of energy created over a certain period, measured in MWh. Energy generation is dependent on reservoir head and water release volume. The model inputs used to develop the boxplot figures in this analysis simulated releases and lake reservoir elevations to calculate estimated energy generation for the Glen Canyon Dam, Hoover Dam, Davis Dam, and Parker Dam powerplants. The boxplots summarize results by five flow categories based on the preceding 3-year average Lees Ferry natural flow. Please refer to **Figure TA 15-17**, **Figure TA 15-18**, **Figure TA 15-19**, and **Figure TA 15-20** in **TA 15**, Dams and Electrical Power Resources.

At Glan Canyon Dam powerplant, under the Average Flow Category (12.0–14.0 maf; refer to **Figure TA 15-17** in **TA 15**, Dams and Electrical Power Resources), the Maximum Operational Flexibility and Enhanced Coordination Alternatives performed slightly above the historical average energy generation value. The median energy generation for the other alternatives remain near the historical average energy generation of approximately 3.4 million MWhs. In the Critically Dry Flow Category (4.46–10.0

maf), the Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives would have the highest median power generation (approximately 2 million MWhs) and the smallest interquartile ranges. The Basic Coordination and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), along with the CCS Comparative Baseline, would have larger interquartile ranges and lower levels of power generation.

For the Hoover Dam powerplant (as shown in **Figure TA 15-18** in **TA 15**, Dams and Electrical Power Resources), in the Average Flow Category, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) experience the highest median value that is comparable to the historic median value of 3.3 million MWhs. Most alternatives have interquartile ranges that fall within the historic median value. The No Action Alternative would have the greatest interquartile range and the lowest level of power generation of approximately 2 million MWhs. In the Critically Dry Flow Category, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would result in the highest median generation, followed by the Maximum Operational Flexibility, Representative Preferred, Enhanced Coordination, and the Basic Coordination Alternatives. In the Critically Dry Flow Category, the No Action Alternative would produce the least amount of power and, like the CCS Comparative Baseline and the Basic Coordination Alternative, have interquartile ranges that have potential to drop to 0.0 million MWh.

For the Davis Dam powerplant (as shown in **Figure TA 15-19** in **TA 15**, Dams and Electrical Power Resources), in the Average Flow Category, the No Action Alternative, and the CCS Comparative Baseline would result in the highest median generation, comparable to the historic median value of 1.1 million MWhs. The Enhanced Coordination Alternative experienced the lowest median value of approximately 0.95 million MWhs. In the Critically Dry Flow Category, the CCS Comparative Baseline, Basic Coordination Alternative, and Supply Driven Alternative (LB Priority approach) result in the highest median generation values. The alternatives with the lowest median generation value are Enhanced Coordination and Maximum Operational Flexibility. The No Action Alternative and CCS Comparative Baseline show the widest interquartile ranges, reflecting greater variability in annual energy generation under these flow conditions. Approximately 25 percent of the values fall at or below 0.75 million MWh.

For the Parker Dam powerplant (as shown in **Figure TA 15-20** in **TA 15**, Dams and Electrical Power Resources), in the Average Flow Category, the CCS Comparative Baseline, No Action, and Basic Coordination Alternatives performed comparability to the historical median generation value of 0.42 million MWhs. Enhanced Coordination Alternative and Supply Driven Alternative (LB Pro Rata approach) would have lowest median generation of approximately 0.37 and 0.38 million MWhs and wider interquartile ranges. In the Critically Dry Flow Category, the Basic Coordination Alternative and Supply Driven Alternative (LB Priority approach) would result in the highest median values of energy generation with the narrowest interquartile ranges. The Enhanced Coordination Alternative would experience the lowest median value for energy generation at approximately 0.32 million MWhs, followed by the Supply Driven Alternative (LB Pro Rata approach) at approximately 0.36 million MWhs.

Issue 4: How would the alternatives impact spillway use?

Spillway infrastructure is affected by the frequency of high reservoir elevations, which vary greatly between the alternatives. High reservoir elevations for extended durations pose a risk to spillway

infrastructure. This analysis compares the various action alternatives with the No Action Alternative and the CCS Comparative Baseline for the following metrics:

- Lake Powell pool elevations
- Lake Mead pool elevations

Keeping the reservoir below the spillway crest minimizes the infrastructure wear and tear and, preserves water supply and flood storage. Maintaining lower reservoir levels allows inflow to be routed through controlled outlets and respond to spring runoff. Maintaining Lake Powell elevation below 3,684 feet, the Representative Preferred Alternative is the most robust, meeting the preferred minimum in 86 percent of futures under the full modeling period. For the 2027-2039 model, the CCS Comparative Baseline is the highest performing alternative, meeting the preferred minimum in 91 percent of futures. The Enhanced Coordination, Maximum Operation Flexibility, and No Action Alternatives for the full modeling period and 2027-2039 model performed on average lower than any of the other alternatives (see **Figure TA 15-21** in **TA 15**, Dams and Electrical Power Resources). Maintaining Lake Powell elevation below 3,700 feet, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would be the most robust at meeting the preferred minimum in 66 percent of futures in the full modeling period. For the 2027-2039 model, the CCS Comparative Baseline and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) meet the preferred minimum in 82 percent of futures. The Enhanced Coordination and Maximum Operation Flexibility Alternatives for the full modeling period and 2027-2039 model performed on average lower than any of the other alternatives (see **Figure TA 15-23** in **TA 15**, Dams and Electrical Power Resources). Spillway release avoidance at Glen Canyon Dam for the full modeling period meets the preferred minimum in 78 percent of futures under the Representative Preferred and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives. For the 2027-2039 modeling period, the CCS Comparative Baseline meets the preferred minimum in 90 percent of futures, with Representative Preferred and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives following in 89 percent of futures (see **Figure TA 15-25** in **TA 15**, Dams and Electrical Power Resources).

For Hoover Dam/Lake Mead, maintaining elevation at 1,205.4 feet for spillway crest avoidance, the No Action Alternative and CCS Comparative Baseline, would be the most robust in meeting the preferred minimum under the full modeling period in 85 and 84 percent of futures, respectively. The worst performing alternative in the full modeling period was the Supply Driven Alternative (LB Pro Rata approach) at 43 percent of futures. For the 2027-2039 period, the No Action Alternative and CCS Comparative Baseline met the preferred minimum in 93 percent of futures. The lowest performing was the Supply Driven Alternative (LB Pro Rata approach) at 68 percent of futures (see **Figure TA 15-27** in **TA 15**, Dams and Electrical Power Resources). For Hoover Dam/Lake Mead to not exceed 1,219 feet in the full modeling period, the CCS Comparative Baseline and No Action and Basic Coordination Alternatives meet the preferred minimum in 99 percent of futures, followed by the Enhanced Coordination Alternative in 91 percent of futures. The least robust alternative for the full modeling period was the Supply Driven Alternative (LB Pro Rata approach) at 79 percent. In the 2027-2039 modeling period, the CCS Comparative Baseline, No Action, Basic Coordination, Enhanced Coordination, and Maximum Operational Flexibility Alternatives meet the preferred minimum in 93 percent or more of futures. The Supply Driven Alternative (LB Pro Rata approach) was the least robust at 84 percent of futures (see **Figure TA 15-29** in **TA 15**, Dams and Electrical Power Resources). For Hoover Dam/Lake Mead to not exceed 1,226.9 feet in the full modeling

period, the CCS Comparative Baseline and No Action Alternative meet the preferred minimum in 92 percent of futures and followed by Basic Coordination in 91 percent of futures. The least robust alternative for the full modeling period was the Supply Driven Alternative (LB Pro Rata approach) at 70 percent. In the 2027-2039 modeling period, the CCS Comparative Baseline and No Action Alternative meet the preferred minimum in 98 percent or more of futures. The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) was the least robust in 89 and 88 percent of futures (see **Figure TA 15-31** in **TA 15**, Dams and Electrical Power Resources).

Issue 5: How would changes in energy generation impact electricity rates and the market value of electricity?

Glen Canyon Dam

Argonne National Laboratories and WAPA's report, "Post-2026 Environmental Impact Statement Rate Analysis for the Colorado River Storage Project" (Yu et al. 2025), assessed the relative impacts of various Glen Canyon Dam hydrological scenarios on the CRSP's Firm Electric Service rates. This analysis utilized an advanced simulation tool to estimate future generation production along with a stepwise rate adjustment framework. This framework is consistent with CRSP's obligation to remain financially self-sustaining and deliver cost-based power services (DOE, 2025) and was used to evaluate the rate implications of simulated Glen Canyon Dam-only generation outcomes. It is important to note that CRSP's FES rates encompass hydropower generation resources beyond Glen Canyon Dam; therefore, the identified rate impacts are theoretical, representing uncertainty associated with future Glen Canyon Dam hydrological conditions. The report found that the Enhanced Coordination and Maximum Operational Flexibility Alternatives consistently yielded more favorable hydropower generation outcomes, associated with higher electricity production. These alternatives also indicated fewer rate adjustments, smaller average increases per adjustment, and substantially lower maximum rate increases when an increase was identified. Specifically, under wet or average hydrologic conditions, these alternatives led to results similar to or slightly better than other alternatives. Under dry hydrologic conditions, they resulted in substantially smaller rate increases and less frequent rate adjustments. Overall, the Enhanced Coordination and Maximum Operational Flexibility Alternatives are identified as entailing less adverse economic impact on U.S. electricity consumers and providing greater protection against extreme adverse outcomes compared to the other five alternatives. The modeling framework and key methodological choices supporting these findings, as documented in Yu et al. (2025), included comprehensive data on CRSP's plant characteristics, hydrological conditions, Argus forward prices, and CRSP's power purchase and sales transactions. Another important point to note is that the rate adjustment framework used in the study is a simplified version of actual rate-changing processes, as it is based solely on assumed revenue requirements and simulated electricity production. Consequently, it provides a directional analysis for comparing policy scenarios rather than forecasting actual consumer rates, requiring careful contextualization to avoid misinterpretation. Extreme hydrological conditions, potentially leading to very low or even zero simulated electricity production, can result in a non-trivial subset of degenerate results, projecting unrealistic rate increases or decreases. These extreme events, particularly zero electricity production from Glen Canyon Dam, are unprecedented and fall outside the scope of the current analysis framework, as they cannot be resolved through standard rate adjustments.

For the Glen Canyon Dam powerplant, changes in energy generation across the modeled flow categories directly influenced the market value of hydropower production. Under the Wet Flow

Category, the Representative Preferred Alternative achieves the highest median annual generation value (approximately $350 million), while the CCS Comparative Baseline and No Action Alternative have the lowest (approximately $260 million). Under the Average Flow Category, all alternatives perform similarly, although the Maximum Operational Flexibility Alternative produces the highest median value (approximately $230 million). Under Critically Dry Flow Conditions, the Enhanced Coordination and Maximum Operational Flexibility Alternatives perform best, maintaining the highest median values (approximately $125 million) and lowest variability, whereas the remaining alternatives exhibit greater variability and include outcomes with a 25 percent probability of annual generation values declining to $0 (see **Figure TA 15-34** in **TA 15,** Dams and Electrical Power Resources).

Hoover Dam

Hoover Dam provides federally marketed hydropower to Arizona, California, and Nevada through the Boulder Canyon Project, managed by WAPA. Funding for the project's operation, maintenance, and capital costs is entirely self-supported by these hydropower sales to contracted entities, requiring no taxpayer funding. Historically, cost-based rates kept Hoover power lower than regional wholesale market alternatives. Under this framework, customers pay a fixed annual base charge to cover these costs, allocated by contract share rather than actual generation. However, as declining water levels reduce generation output, the unit cost of the remaining power rises. This creates a financial swing: when generation drops sufficiently, Hoover's unit cost surpasses market rates, making the power uneconomical and potentially forcing contracted entities to abandon their long-term contracts.

Figure TA 15-35, in **TA 15,** Dams and Electrical Power Resources, shows the market value of hydropower at Hoover Dam. The analysis uses a dollar-per-MWh rate from the Lower Basin Dams Office (WY 2027 data), applied to modeled energy generation from CRSS. Market projections are based on the Preceding 3-Year Average Lees Ferry Natural Flow. Values depend on reservoir elevation with value increasing at elevations above 1,035 feet and lower below it. Under Average Flow conditions, most alternatives have median market values around $200 million. The Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives maintain higher medians with moderate variability. In contrast, the No Action and Basic Coordination Alternatives show lower medians and greater variability. Critically Dry conditions produce the lowest annual values. The Maximum Operational Flexibility, Basic Coordination, Representative Preferred, and Supply Driven (LB Pro Rata approach) Alternatives show the highest medians ($75–$150 million) and least variability, although the Basic Coordination Alternative has a wider spread. Other alternatives and the CCS Comparative Baseline show larger variability, with lower-end values dropping to $0.

Davis and Parker Dam

The Parker Davis Project is a federally operated system combining the Parker and Davis Dam hydroelectric facilities and transmission infrastructure on the Colorado River. Reclamation operates and maintains the dams and powerplants, while the WAPA markets and transmits the generated electricity to customers under long term contracts.

WAPA sets rates using a cost-recovery framework designed to recover annual project costs including operations, maintenance, replacements, and federal investment repayment. WAPA currently markets the project as a firm, fixed monthly delivery obligation, purchasing supplemental wholesale power to meet this commitment. Declining generation has increased the need for supplemental power, driving

significant rate increases due to market price volatility. Starting in October 2028, a new marketing plan will align APA's delivery obligations with hydropower availability. This change will potentially create a financial swing. If generation drops sufficiently, Parker-Davis Project rates could surpass market rates, making the power uneconomical and potentially forcing contracted entities to abandon their long-term contracts.

WAPA sets rates using a cost-recovery framework designed to recover annual project costs including operations, maintenance, replacements, and federal investment repayment. WAPA currently markets the project as a firm, fixed monthly delivery obligation, purchasing supplemental wholesale power to meet this commitment. Declining generation has increased the need for supplemental power, driving significant rate increases due to market price volatility. Starting in October 2028, a new marketing plan will align WAPA's delivery obligations with hydropower availability. This change will potentially create a financial swing. If generation drops sufficiently, Parker-Davis Project rates could surpass market rates, making the power uneconomical and potentially forcing contracted entities to abandon their long-term contracts.

Figure TA 15-36 in **TA 15**, Dams and Electrical Power Resources, shows the annual market value of hydropower at Davis Dam based on CRSS modeling of generation and an assumed dollar-per-MWhs rate to determine the financial value (in millions of dollars). The results are grouped by preceding 3-year average Lees Ferry natural flow to show how fiscal value is influenced by hydrology for each alternative. Differences in fiscal value are driven by differences in releases across the alternatives (see **Figure TA 3-26** for calendar year releases from Davis Dam). Under the Average Flow Category, the No Action Alternative and CCS Comparative Baseline show similarly high median market values of approximately $47 million and $46 million dollars annually, respectively. The Supply Driven (both LB Priority and LB Pro Rata approaches) and Enhanced Coordination Alternatives have the lowest median value at approximately $42 million. Under the Critically Dry Flow Category, the Maximum Operational Flexibility, Representative Preferred, and Enhanced Coordination Alternatives had the lowest median market values (approximately $35 million), while the Basic Coordination Alternative had the highest median market value at approximately $40 million.

Summary Comparison of Alternatives

No Action

For Glen Canyon Dam and Lake Powell, the No Action Alternative is among the least robust alternatives, with a relatively high likelihood of dropping below minimum power pool and experiencing losses in firm capacity and energy generation under dry conditions. Market values are generally lower and more variable across flow conditions.

For Hoover Dam and Lake Mead, the No Action Alternative is the least robust alternative for maintaining elevations above minimum power pool and for preserving high-head turbine operations. However, it performs favorably for avoiding high Lake Mead elevations and spillway-related risks.

At Davis and Parker Dams, the No Action Alternative generally performs well for energy generation and market value under moderately wet to dry conditions but experiences increased variability and reduced performance under critically dry conditions.

Basic Coordination

For Glen Canyon Dam, the Basic Coordination Alternative provides moderate performance for maintaining minimum power pool but remains more vulnerable to dry hydrologic conditions than the Enhanced Coordination and Maximum Operational Flexibility Alternatives. Firm capacity, energy generation, and market value are generally moderate but become increasingly variable under dry conditions.

For Hoover Dam, the Basic Coordination Alternative performs moderately well in maintaining elevations above minimum power pool protection. Firm capacity, energy generation, and market value remain moderate under wet and average flow conditions but become increasingly variable under dry and critically dry conditions, resulting in less consistent performance.

For Davis and Parker Dams, energy generation and market value remain generally consistent across most flow categories, with performance comparable to many of the other action alternatives. Because reservoir elevations at Lake Mohave and Lake Havasu remain relatively stable, differences among alternatives are modest, although generation and market value decline and become more variable under dry and critically dry conditions. In addition, the Basic Coordination Alternative performs favorably in limiting high reservoir elevations and spillway-related risks at both Lake Powell and Lake Mead, providing a balanced approach between hydropower performance and reservoir management objectives.

Enhanced Coordination

For Glen Canyon Dam, the Enhanced Coordination Alternative is one of the strongest-performing alternatives, maintaining minimum power pool in a high percentage of futures and consistently supporting relatively high firm capacity, energy generation, and market value across all flow categories. It is one of the few alternatives that avoids 0 firm capacity outcomes under critically dry conditions.

For Hoover Dam, Enhanced Coordination provides high robustness for maintaining elevations above minimum power pool and supports relatively stable generation and market value. Although total generation is sometimes lower than the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) under wet conditions, performance remains strong under dry and critically dry conditions.

For Davis and Parker Dams, energy generation and market value are generally comparable to other alternatives under wetter conditions, although performance may be somewhat lower than other alternatives under the driest flow categories. Overall, the Enhanced Coordination Alternative provides a strong balance of hydrologic robustness, generation performance, and market value while minimizing vulnerability to dry conditions.

Maximum Operational Flexibility

For Glen Canyon Dam, the Maximum Operational Flexibility Alternative provides the highest robustness for maintaining minimum power pool and consistently avoids 0 firm capacity conditions. It produces among the highest energy generation and market values under dry and critically dry conditions while maintaining low variability.

For Hoover Dam, this alternative provides some of the highest robustness for maintaining minimum power pool, strong firm capacity, and relatively stable energy generation and market values across

hydrologic conditions. While not always producing the highest generation during wet conditions, it consistently performs well as hydrologic conditions become drier.

For Davis and Parker Dams, energy generation and market values are generally moderate relative to other alternatives. Overall, Maximum Operational Flexibility is among the best-performing alternatives for reliability, generation stability, and market value across the system, particularly under adverse hydrologic conditions.

Supply Driven (both LB Priority and LB Pro Rata approaches) Alternative

For Glen Canyon Dam, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) generally provides high firm capacity and energy generation under wet and moderately wet conditions but are more vulnerable to low reservoir elevations than the Enhanced Coordination and Maximum Operational Flexibility Alternatives. Market values are high under favorable hydrology but become more variable as conditions dry.

For Hoover Dam, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) provides some of the highest firm capacity, energy generation, and market value outcomes across most flow categories. The Supply Driven Alternative (LB Pro Rata approach) performs particularly well at maintaining Lake Mead elevations above minimum power pool, although both approaches become more variable under dry conditions.

For Davis and Parker Dams, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) generally produces the highest energy generation and market values under wet conditions. Under drier conditions, performance becomes more comparable to other alternatives, with the Supply Driven Alternative (LB Pro Rata approach) sometimes produces among the lower generation outcomes. Spillway-related performance is strongest at Lake Powell but weakest at Lake Mead, where the alternatives result in more time at high reservoir elevations.

Overall, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) maximizes generation and market value, particularly at Hoover Dam, but involve tradeoffs related to reservoir elevation robustness and performance under increasingly dry conditions.

Representative Preferred Alternative

For Glen Canyon Dam, the Representative Preferred Alternative performs particularly well under wet conditions, producing the highest market values and strong firm capacity. Under dry and critically dry conditions, it continues to provide relatively high energy generation and market values, although performance is generally slightly below the Enhanced Coordination and Maximum Operational Flexibility Alternatives.

For Hoover Dam, the Representative Preferred Alternative provides strong minimum power pool performance, relatively stable generation, and competitive market values across most flow categories. While it does not consistently achieve the highest firm capacity or energy generation, it generally performs in the upper tier of alternatives.

For Davis and Parker Dams, performance is generally comparable to other action alternatives, with moderate-to-high energy generation and market values across hydrologic conditions. From a spillway

and reservoir-elevation perspective, it performs among the stronger alternatives at Lake Powell and in the middle range at Lake Mead.

Overall, the Representative Preferred Alternative provides a balanced combination of reservoir protection, power generation, market value, and infrastructure performance. This alternative performs well across all major measures and avoids many of the tradeoffs associated with alternatives focused on a single objective.

3.16 Socioeconomics

3.16.1 Affected Environment

This section briefly discusses key current conditions of economic indicators—such as employment, labor income, and unemployment rates—as well as social and nonmarket values. For additional details on these current conditions, refer to **Section TA 16.1**, Affected Environment, in **TA 16**, Socioeconomics. For overall demographic information, such as population and race and ethnicity data, refer to **Section TA 16.1.4**, Demographics, and **Section TA 17.1**, Affected Environment, in **TA 17**, Population and Land Use. For information on tribal populations and interests, refer to **TA 13**, Tribal Resources**.**

The socioeconomic analysis area includes counties in Arizona, California, Nevada, and Utah (see **Map TA 16-1**). The Arizona analysis area consists of Apache, Coconino, Gila, Graham, La Paz, Maricopa, Mohave, Navajo, Pima, Pinal, Yavapai, and Yuma Counties. The California analysis area consists of Imperial, Los Angeles, Orange, Riverside, San Bernardino, and San Diego Counties. The Nevada analysis area consists solely of Clark County. The Utah analysis area consists of Garfield, Kane, and San Juan Counties. These analysis areas include the following:

- Counties that are directly adjacent to Lake Powell, Lake Mead, or the mainstream Colorado River
- Counties that receive water from the Colorado River and in which impacts from Colorado River shortages would likely occur
- Counties that have ties to recreation-related economic activity on the Colorado River
- Counties where tribal reservations affected by Colorado River shortages are located
- Counties where tribal reservations that have ties to tribal water rights settlements involving CAP water and non-CAP Colorado River water delivered through the CAP are located.

The analysis of impacts on economic and social conditions due to changes in agricultural production includes Arizona, California, and Nevada. The analysis of economic impacts from changes in recreation use includes Arizona, California, Nevada, and Utah. The impact analysis on ecosystem services and nonmarket values includes Arizona, California, Nevada, and Utah.

Baseline Economic Conditions

The following section provides an overview of county-level data for baseline economic conditions, including data on employment, labor income, unemployment rates, poverty, and the market value of agricultural production in the analysis areas. The county-level data do not distinguish between the

water sources that were used in support of the economic conditions presented, which may include a combination of the mainstream Colorado River, CAP, and other water sources.

Arizona

In 2022, total employment in the analysis area counties (about 4.2 million jobs) represented approximately 98.1 percent of total employment in Arizona. Farm employment in the 12 counties totaled almost 26,000 jobs in 2022 (about 0.6 percent of total analysis area employment). While total employment in the analysis area increased from 2010 employment levels by about 36 percent, farm employment decreased during the same time period by about 2 percent (see **Table TA 16-1** and **Table TA 16-2**). Employment in the arts, entertainment, and recreation sector totaled approximately 84,000 jobs (or 2.0 percent of the total employment in the analysis area) in 2022, which was an increase of about 27 percent from the number of jobs in 2010.

In 2022, the total market value of agricultural products sold in the Arizona analysis area contributed $4.8 billion to Arizona's economy, which was about 91 percent of the market value of agricultural products sold in the state. Across Maricopa, Pima, and Pinal Counties, the market value of crops sold in 2022 ranged from about $87.1 million in Pima County to about $742.6 million in Maricopa County (USDA 2024; see **Table TA 16-5**). In 2022, the Maricopa, Pima, and Pinal Counties accounted for approximately 55 percent of Arizona's harvested acres of hay and haylage crops, 65 percent of the state's harvested acreage of cotton, and 44 percent of the harvested wheat acreage. The three western Arizona counties that are located along the Colorado River—Mohave, La Paz, and Yuma Counties—accounted for approximately 33 percent of the statewide harvested hay and haylage acreage, 78 percent of the harvested acres of vegetable crops, and 53 percent of the harvested wheat acres in 2022. Yuma County alone accounted for 77 percent of the state's total harvested acres of vegetable crops (USDA 2024). Additional information on irrigated agricultural acreage within the analysis area is provided in **TA 17**, Population and Land Use.

California

In 2022, total employment in the analysis area counties (about 13.9 million jobs) represented approximately 55 percent of total employment in California. Farm employment in the six counties totaled almost 31,000 jobs in 2022 (about 0.2 percent of the total analysis area employment). Farm employment made up a larger percentage of total employment in Imperial County than the rest of the counties in the analysis area, with 4.7 percent of total employment coming from the farm sector in Imperial County (BEA 2024). While total employment in the analysis area increased from 2010 employment levels by about 30 percent, farm employment decreased by about 9 percent during the same time period (see **Table TA 16-7** and **Table TA 16-8**).

In 2022, the total market value of agricultural products sold in the California analysis area contributed $6.1 billion to California's economy. The market value of crops sold in the analysis area was about $4.7 billion, ranging from about $69.5 million in Orange County to about $2.2 billion in Imperial County (USDA 2024; see **Table TA 16-11**). In 2022, the California analysis area counties accounted for approximately 30 percent of California's harvested acres of hay and haylage crops, 16 percent of the state's harvested acreage of vegetables, and 35 percent of the harvested wheat acreage (USDA 2024).

Nevada

In 2022, total employment in Clark County (about 1.5 million jobs) represented approximately 74 percent of the total employment in Nevada. In 2022, employment in the arts, entertainment, and recreation sector totaled almost 47,000 jobs, or 3.1 percent of the total employment in the county. Farm employment represented less than 0.1 percent of total employment, with a little more than 400 jobs (see **Table TA 16-13**).

Approximately 8.4 percent of Nevada's land area in 2022 was used for agricultural purposes (on cropland, pastureland, woodland, or other; USDA 2024). In 2022, the market value of agricultural products sold in Nevada contributed nearly $1 billion to the statewide economy.

Utah

In 2022, total employment in the analysis area counties (about 17,000) represented approximately 1.0 percent of the total employment in Utah. In 2022, employment in the arts, entertainment, and recreation sector totaled approximately 400 jobs (or 2.4 percent of the total employment in the analysis area) and represented 6.0 percent of employment in Kane County (see **Table TA 16-16**).

Economic Contributions from Recreational Use

Total economic output for lake-based recreation in the analysis area was $358 million from Lake Mead NRA and $670 million from Glen Canyon NRA, and the total economic output for river-based recreation was $1,022 million in Grand Canyon National Park (GCNP; see **Table TA 16-19** and **Table TA 16-20**).[17] These amounts reflect total economic output from visitor spending made by local and nonlocal visitors. Spending by nonlocal visitors represents an influx of dollars from outside the local economy. In addition, nonlocal visitors typically have higher levels of spending on food, lodging, and other activities on a per-trip basis. Over 88 percent of recreation spending in Glen Canyon NRA, Lake Mead NRA, and GCNP came from nonlocal visitors (Flyr and Koontz 2024). In 2023, Glen Canyon NRA recreation spending supported 6,300 jobs, Lake Mead NRA recreation supported 3,131 jobs, and GCNP recreation supported 10,064 jobs (Flyr and Koontz 2024; see **Table TA 16-21** and **Table TA 16-22**).

In addition to general recreation sector contributions, visitor use supports concessionaires, including those associated with water-based recreation, such as commercial river trips. In GCNP, commercial river trips hosted about 17,000 passengers in 2023 (a slight decrease from about 20,000 passengers in 2022 and 21,000 passengers in 2021). From these river trips, river concessionaires contributed $63.6 million in 2023 in gross revenue (a decrease from $66.4 million in 2021, in 2023 dollars), representing 29 percent of the total concessionaire revenue at GCNP. River concessionaire franchise fees paid to the NPS in 2023 totaled $6.25 million, of which 80 percent stays at GCNP.[18]

NWRs also support economic contributions through expenditures from recreational visitors, such as entrance fees, lodging near the refuges, and purchases from local businesses for items to pursue their

[17] Economic output for recreation is the total estimated value of the production of goods and services supported by visitors' spending, including the direct, indirect, and induced impacts. Direct impacts occur when businesses sell goods and services to area visitors. Indirect impacts are economic activity supported when businesses purchase supplies and services from other local businesses. Induced impacts occur when employees use their income to purchase goods and services in the local economy.

[18] Laurie Dyer, NPS supervisory concessions management specialist in the Commercial Services Division at GCNP, personal communication provided on September 27, 2024.

recreational experience. In 2017, the Imperial NWR supported about $11.1 million in total economic output (see **Table TA 16-23**).

For additional information on recreation and levels of use in the analysis area, refer to **TA 14**, Recreation.

Social and Nonmarket Values

Nonmarket values refer to resource benefits that are not captured in market transactions or traditional economic measures. Along the Colorado River, these values include the enjoyment of natural scenery, opportunities for recreation and solitude, preservation of landscapes, and the symbolic and ecological importance of the river itself. Such values are important for understanding how river operations affect people's experiences, sense of place, and well-being, even when no direct economic exchange is involved. Place-based communities—such as gateway communities—and non-place-based communities—such as individuals who may never visit but who value the river—derive nonmarket values from the Colorado River, including cultural identity, recreation quality, aesthetics, and existence values. These values often differ by type of community as well as an individual's beliefs. Understanding these values provides important context for assessing potential changes in access and the quality of nonmarket and social values under the post-2026 operational alternatives. For additional details on these social and nonmarket values, refer to **Section TA 16.1**, Affected Environment.

3.16.2 Environmental Consequences

Methodology

Agriculture

Below is a brief summary of the methodology used to analyze economic conditions from changes in agricultural production as a result of a reduction of irrigation water. For additional details on the methodology, refer to **Section TA 16.2.1**, Methodology.

Based on the SAMs and ADMs (see **Appendix C**, Shortage Allocation Model and the Alternative Distribution Model Documentation), Reclamation modeled the change in agricultural revenue from fallowed crops for each priority group by county and state in the impact analysis area due to water shortages at a variety of shortage levels across each alternative and the comparative baseline.

Forgone agricultural revenue from fallowed crops was estimated by multiplying the county-level revenue per acre by the number of acres reduced (or fallowed) for each crop. The county-level revenue was calculated based on the most recent available data on yields and prices. The number of acres reduced for each crop was modeled using an assumed fallowing order based on the crops' profitability and water use, the level of shortages and available water for each priority group by county and state, and the most recent available data on acres harvested. For data that were not available for specific crops grown in the county, estimated data were used based on statewide averages, data from nearby counties, or averages from nearby states or regions for the same or similar crops.

Irrigated crops in the analysis area that were analyzed include field crops, vegetables, and fruit and nut trees and vines, separated out into eight agricultural crop group types that would be affected by the Colorado River shortages and that made up at least approximately 1 percent of a county's harvested

acres. The eight crop groups were alfalfa, cotton, crucifer vegetables, field grains, fruit and tree nuts and vines, other hay and haylage, small grains, and small vegetables.

Impacts on economic conditions, such as jobs and income, from changes in agricultural production were analyzed using the IMPLAN input-output economic model. IMPLAN is a regional economic model that estimates how a change in one sector affects jobs, income, and spending in other parts of the economy. For example, the IMPLAN model provides annual average estimates of how a direct change in economic spending (such as through reduced agricultural revenues) would ripple through the broader economy and other industries. Prior to running the model, cost data were converted to a consistent dollar year (2025). Unless stated otherwise, monetary values are reported in the year 2025 dollars.

Recreation

This analysis evaluates how changes in reservoir elevations and river flows may affect recreational use and related economic contributions. The approach integrates visitor use data, spending information, and economic modeling tools to characterize potential changes in both the recreational experience and the regional economy.

For lake-based recreation, the analysis uses visitor statistics from the NPS and Reclamation to estimate changes in visitation levels under different hydrologic conditions. Visitor days are categorized by visitor type, including local and nonlocal trips. Each visit type is linked to an established spending profile that reflects patterns in lodging, food, transportation, recreational services, and other trip-related expenditures. Total spending estimates are then used in IMPLAN to assess potential changes in jobs, labor income, value added, and overall economic output resulting from changes in recreational use.

For river-based recreation, the analysis also evaluates net economic value, which is the value of the benefits that recreationists receive beyond what they spend directly on a trip. Consistent with the approach used in the 2024 LTEMP Final SEIS, past survey research, including that by Gaston et al. (2015), informs models that relate the willingness to pay for boating and angling experiences to the river's flow conditions. These models estimate how changes in hydrologic patterns may affect the value of specific recreational experiences in Glen Canyon and Grand Canyon.

For the action alternatives, potential changes to recreation's contributions are discussed qualitatively, based on the DMDU modeling output and conclusions related to Lake Powell and Lake Mead access to recreation and river-based recreation, as determined by river flow levels and fluctuations, as discussed in **TA 14**, Recreation.

Together, these components provide a qualitative and quantitative framework for assessing how operational changes influence recreational access, the quality of the experience, and economic contributions. Additional methodological detail, including data sources, assumptions, and model parameters, is provided in **TA 16**, Socioeconomics.

Ecosystem Services and Nonmarket Values

The analysis of ecosystem services and nonmarket values uses a qualitative framework to evaluate how changes in Colorado River operations may affect benefits that are not reflected in market transactions but that contribute to community well-being, cultural identity, and the recreational experience. These include values such as scenic quality, sense of place, ecological integrity, and cultural connections to the

river corridor. The analysis draws on scoping input, existing literature, and information from other resource sections to understand how various groups interact with and derive value from the Colorado River system. Additional details on information sources, assumptions, and community context are provided in **TA 16**, Socioeconomics.

Impact Analysis Area

Agriculture

The quantitative impact analysis was conducted for the following counties: La Paz, Maricopa, Mohave, Pima, Pinal, and Yuma Counties in Arizona; Imperial, Riverside, and San Bernardino Counties in California; and Clark County in Nevada. The impact analysis area for the qualitative discussions extends to the surrounding communities and tribal reservations.

Recreation

The analysis area is consistent with the general socioeconomic study area defined in **Section 3.1**, Introduction. This includes major recreation hubs, gateway communities, and rural areas where economies rely heavily on river- and reservoir-based recreation. Specifically, the recreation impact analysis area encompasses three primary NPS units: Lake Mead NRA, Glen Canyon NRA, and GCNP.

Ecosystem Services and Nonmarket Values

The analysis area for social and nonmarket values is the Colorado River corridor from Lake Powell to the SIB, consistent with the overall socioeconomic study area. The analysis focuses on communities within the river corridor, but it also includes communities outside of the area for whom the river holds symbolic, ecological, or recreational importance.

Assumptions

Modeling Representative Preferred Alternative Shortage Distributions

Under the Representative Preferred Alternative, two different approaches to distributing shortages are modeled, where (1) 2027-2028 modeling assumes shortage volumes up to 1.5 maf are distributed using the approach developed by the Lower Division States, and shortage volumes from 1.5 maf to 3.6 maf are distributed using the priority system, and (2) from 2029 through 2060, modeled shortage volumes are distributed using the priority system. Refer to **Section 2.4** for additional information. Some impacts are influenced by how the Representative Preferred Alternative distributes Lower Basin shortages in 2027-2028 vs. 2029-2060, and some impacts are either minimally sensitive or not sensitive to this distinction. Impacts discussion will include references to different time periods where relevant.

Agriculture

Below is a list of the key assumptions used in the analysis. For additional details on assumptions, refer to **Section TA 16.2.1**, Methodology.

- Farmers would fallow irrigated crops in response to water shortages rather than using other water sources or switching to more profitable or less water-intensive crops. The assumption that farmers would fallow rather than switch crops is based on the investments and institutional knowledge that have been made in plants, supply chains/relationships, and/or machinery that create barriers for changing crops. Reclamation understands that there could be farmers who are able to switch crops, rather than fallow; however, for the purpose of this analysis, this assumption provides a conservative estimate; if some farmers switch crops or

water sources instead, impacts would likely be less severe than discussed below. Impacts on economic conditions due to the use of groundwater to replace the estimated water shortage are discussed qualitatively.

- As discussed above, the analysis assumes that the least profitable crop would be fallowed first, analyzed for each county separately, and crops were assumed to have constant profitability per acre of land and per acre-foot of water.
- Estimated shortages in the agricultural sector are based on the SAMs and ADMs (**Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation). Shortages to individual entitlement holders are measured in terms of consumptive use for a common basis of comparison with state apportionments and volumes of total shortage. Impacts on future opportunities to expand water use due to shortages for irrigation entitlement holders who currently use less than their entitlement are discussed qualitatively.
- In most cases, the contractor, subcontractor, or entitlement holder of an allocation is shown as the entity bearing shortage. In some cases, water allocated to an entitlement holder (for example, a tribal CAP contractor) may lease its allocation to other users (for example, to a non-Indian municipality). The SAMs and ADMs do not attempt to replicate those arrangements, and they only provide approximate estimates at the level of the entitlement holder, contractor, or subcontractor. The entitlement holder, contractor, or subcontractor involved in a leasing arrangement would make specific decisions during Shortage Conditions to administer those arrangements that Reclamation cannot predict with sufficient certainty to analyze in this EIS.

Recreation

- Lake-based recreational spending per visitor trip is based on the most recent NPS Visitor Spending Profiles.
- IMPLAN results represent regional impacts, including direct, indirect, and induced economic activity associated with lake-based recreation.
- Recreational spending per trip for anglers and whitewater rafting (adjusted for inflation) would follow results from willingness-to-pay surveys (Gaston et al. 2015) with variation based on river flows.

Ecosystem Services and Nonmarket Values

- Nonmarket values are not directly quantifiable through market-based indicators; however, they can be described qualitatively based on existing studies, stakeholder input, and related resource analyses.
- Changes in nonmarket values are assumed to be closely linked to conditions evaluated in other technical appendices, such as those for recreation, population and land use, cultural resources, and visual resources.
- Changing hydrology may influence how these values are perceived, particularly where access, scenic character, or ecological conditions are affected.

Impact Indicators

Agriculture

- Change in acres of fallowed cropland
- Change in production value or revenue associated with fallowed cropland
- Change in jobs and income associated with agriculture
- Change in nonmarket values and social conditions associated with changes in agriculture

Recreation

- Changes in direct recreational visitor spending across the affected NPS units and recreation sites
- Changes in regional employment, labor income, value added, and total economic output from lake-based recreation-related activities
- Impacts on the recreational value associated with river-based boating and angling
- Impacts on commercial outfitters, concessionaires, and permittees, especially in areas dependent on rafting, boating, and guided recreation

Ecosystem Services and Nonmarket Values

- Changes in the availability or quality of recreational opportunities not captured by direct spending
- Changes in the river's existence and symbolic values due to shifts in the scenic character or ecological conditions

Issue 1: How would the anticipated water shortages affect the economic contributions and social conditions from agriculture?

Under all alternatives and the CCS Comparative Baseline, anticipated shortages would result in increases in acres of fallowed cropland and agricultural production loss, and the modeled agricultural production loss would result in impacts on the associated jobs, income, and total economic output. Additionally, under the alternatives and the CCS Comparative Baseline, water shortages would likely lead to changes in the quality and access to nonmarket values and social conditions associated with changes in agriculture (Curtis et al. 2023). These values that could be affected by water shortages include the way of life of individuals throughout the surrounding communities, how individuals perceive their sense of place, food and other resources supported by the Colorado River, access to affordable health care, and access to cultural, traditional, and spiritual practices. The magnitude of impacts on economic, nonmarket, and social conditions varies by region, irrigation and tribal entitlement holder, priority group, and the alternatives and the CCS Comparative Baseline. The discussion below provides a summary of impacts on economic, nonmarket, and social conditions across the alternatives and the CCS Comparative Baseline by state and irrigation and tribal entitlement holder. For additional details and the figures with modeling results, including results separated by priority group, refer to **Section TA 16.2.2**, Environmental Consequences, Issue 1.

On average, for non-tribal agriculture entitlement holders in Arizona, the greatest impacts on economic and social conditions from increases in fallowed lands and reductions in the market value of crops, during a maximum shortage, would occur under the Maximum Operational Flexibility Alternative (during a shortage of 4.0 maf), with an annual estimated reduction of about 1,000 jobs,

$56.5 million in labor income, and $237.7 million in total economic output. The lowest impacts on economic conditions from increases in fallowed lands and reductions in the market value of crops, during a maximum shortage, would occur under the No Action Alternative (during a shortage of 0.6 maf), for non-tribal agriculture entitlement holders in Arizona; under this alternative, there would be an annual estimated reduction of about 13 jobs, $0.6 million in labor income, and $2.8 million in total economic output. Under the Representative Preferred (2027-2028) Alternative, during a shortage of 1.5 maf, there would be a reduction of about 40 jobs, $2.0 million in labor income, and $8.9 million in total economic output[19]. Under the Representative Preferred (2029-2060) Alternative, during a maximum shortage of 3.6 maf, there would be a reduction of about 900 jobs, $50.5 million in labor income, and $210.7 million in total economic output.

For non-tribal agriculture entitlement holders in California, on average, the largest impacts on social conditions from increases in fallowed lands and reductions in the market value of crops, during a maximum shortage, would occur under the Enhanced Coordination Alternative (during a shortage of 3.0 maf). However, the biggest impacts on jobs, labor income, and economic output during a maximum shortage would occur under the Maximum Operational Flexibility Alternative, with an annual estimated reduction of about 11,000 jobs and $824.7 million in labor income, and $1.8 billion in economic output. For non-tribal agriculture entitlement holders in California, there would be no impacts on fallowed lands, the market value of crops, and economic conditions during a maximum shortage under the No Action Alternative (during a shortage of 0.6 maf) and the Basic Coordination Alternative (during a shortage of 1.5 maf). Under the Representative Preferred (2027-2028) Alternative, during a shortage of 1.5 maf, there would be a reduction of about 140 jobs, $8.5 million in labor income, and $36.9 million in total economic output. Under the Representative Preferred (2029-2060) Alternative, during a maximum shortage of 3.6 maf, there would be a reduction of about 9,000 jobs, $718.1 million in labor income, and $1.3 billion in total economic output.

For tribal agriculture entitlement holders in Arizona, during a maximum shortage, the highest level of impacts on economic and social conditions from increases in fallowed lands and reductions in the market value of crops would occur under the Maximum Operational Flexibility Alternative (during a shortage of 4.0 maf), with an annual estimated reduction of about 1,000 jobs, about $64.7 million in labor income, and $222.6 million in total economic output. The lowest impacts on economic and social conditions during a maximum shortage would occur under the No Action Alternative (during a shortage of 0.6 maf), for tribal agriculture entitlement holders in Arizona, with an annual estimated reduction of about 140 jobs, $10.7 million in labor income, and $34.8 million in total economic output. Under the Representative Preferred (2027-2028) Alternative, during a shortage of 1.5 maf, there would be a reduction of about 400 jobs, $25.2 million in labor income, and $83.3 million in total economic output. Under the Representative Preferred (2029-2060) Alternative, during a maximum shortage of 3.6 maf, there would be a reduction of about 1,000 jobs, $64.0 million in labor income, and $220.0 million in total economic output.

For California and Nevada tribal entitlement holders, the only impacts on fallowed lands, the market value of crops, and economic conditions are expected to occur under the Enhanced Coordination

[19] While the Representative Preferred (2027-2028) Alternative models shortages above 1.5 maf in 2028, consistent with the sideboards, under the Preferred Alternative, Reclamation would consult with stakeholders if Lake Mead elevation is projected below 1,000 feet. (See **Chapter 2** for more details on the sideboards under the Preferred Alternative).

Alternative and Supply Driven Alternative (LB Pro Rata approach). The greatest impacts on economic and social conditions from increases in fallowed lands and reductions in the market value of crops, during a maximum shortage, would occur under the Enhanced Coordination Alternative (during a shortage of 3.0 maf), with an annual estimated reduction of about 63 jobs, $3.9 million in labor income, and $15.9 million in total economic output for tribal entitlement holders in California; for Nevada, there would be an estimated reduction of about 13 jobs, $0.1 million in labor income, and $0.9 million in total economic output for tribal entitlement holders. There are no expected impacts on fallowed lands, the market value of crops, and economic conditions under all other alternatives and the CCS Comparative Baseline for California and Nevada tribal entitlement holders, including under the Representative Preferred Alternative.

Long-term, severe shortages could further affect entitlement holders that have unused water entitlement above their current consumptive use. Irrigation entitlement holders who currently use less than their entitlement (measured in terms of diversion, consumptive use, or both) might not immediately experience impacts on economic contributions from water shortages; however, long-term, continued shortages would limit future opportunities to expand the irrigation entitlement holders' water use, which would result in impacts on economic contributions through reduced opportunities for future developments, expansion of crop production, or additional opportunities to lease water.

If farmers and agricultural producers decide to use irrigation water from other sources—such as other surface water or groundwater sources—instead of fallowing agricultural acreages, the impacts on the economic and social conditions, discussed above, are likely to be lessened in the short term. However, in the event of long-term shortages, if the sustained demand for groundwater results in a reduction in supply from the aquifers, there would likely be increased impacts on economic and social conditions. Additionally, the reliance on more pumped groundwater to offset delivery shortages can lead to substantial additional pumping costs, particularly for electricity, which can affect economic conditions. These impacts on economic and social conditions would affect tribal and non-tribal entitlement holders in Arizona, California, and Nevada, as well as farmers and tribes who rely solely on groundwater for irrigation and domestic needs.

Issue 2: How would operational changes affect economic contributions and the value associated with lake-based and river-based recreation?

Recreation along the Colorado River is a key part of several local economies, supporting thousands of jobs and generating revenue through visitor spending. Lake-based recreation at Glen Canyon NRA and Lake Mead NRA, combined with river-based activities in GCNP, currently contribute approximately 19,000 jobs and $2.1 billion in annual economic output (Flyr and Koontz 2024). These benefits extend beyond direct spending on lodging, food, and equipment and include indirect and induced impacts throughout gateway communities. Stable reservoir elevations and predictable river flows are essential for maintaining these contributions.

Operational changes under the proposed alternatives would influence these conditions in different ways. The alternatives that maintain higher and more consistent water levels would preserve boating access, marina operations, and shoreline recreational opportunities. This stability would support continued visitation and minimize disruptions to businesses dependent on tourism. Conversely, the alternatives that result in greater variability in lake elevations and river flows would affect recreational quality and access and related levels of contributions.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) poses the greatest risk to recreation-based economies relying on economic contributions from reservoir-based recreation in Lake Powell, while the CCS Comparative Baseline and the No Action Alternative have the least robust modeled performance for supporting recreational opportunities and spending associated with Lake Mead recreation. In contrast, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would result in more consistent reservoir levels at Lake Powell to support recreation, and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would support the greatest level of contributions from recreation in Lake Mead.

However, under all alternatives, limited launch access and safe navigation routes at Lake Powell, along with navigation challenges in Lake Mead would continue to affect lake-based recreational opportunities and the associated spending. As a result, outfitters and concessionaires operating in these areas would face increased uncertainty, affecting employment and revenue streams under all alternatives. Research indicates that declines in lake elevation can reduce visitation by more than 25 percent, amplifying economic losses for local communities (Johnson et al. 2016). Lake Mead would experience similar constraints, with boating access severely limited during extended drought periods.

River-based recreation is also vulnerable to operational changes. Activities such as angling in Glen Canyon and whitewater rafting in Grand Canyon depend on stable flows to ensure safety and trip quality. Reduced flows shorten rafting seasons and diminish the overall experience, leading to lower recreational value and reduced demand for outfitter services and the associated hospitality sectors. The Basic Coordination Alternative would provide the most support for continued or increased economic value associated with boating and angling and the related economic contributions (see **Figure 16-13** and **Figure 16-14** in **Section TA 16.2.3**). The Enhanced Coordination Alternative would be the least robust at maintaining or exceeding the minimum desired daytime flows to support boating in Grand Canyon; it also would result in the greatest potential for a reduction in the recreational value for whitewater rafting and angling, as well as the regional economic contributions associated with these uses. Impacts would be most pronounced under dry conditions.

Economic impacts extend beyond direct visitor spending. Gateway communities, often small and rural, rely heavily on tourism-related income to sustain local businesses and municipal services. When lake levels drop or river flows decline, these communities experience cascading impacts, including reduced tax revenues and job losses in sectors such as lodging, food service, and transportation. The magnitude of these impacts would depend on the frequency and duration of low-elevation conditions, which would vary significantly across the alternatives.

Maintaining reservoir elevations and river flows within ranges that support recreation is critical for protecting the economic contributions and community well-being. For detailed analysis, including supporting data and tables, see the technical appendix sections for socioeconomics and recreation.

Issue 3: How would anticipated water shortages and changes in water levels in reservoirs and river segments affect access and the quality of nonmarket values?

Nonmarket values, such as scenic quality, opportunities for solitude, and cultural connections, are central to the Colorado River system and its surrounding landscapes. These values are not reflected in direct economic measures but are essential to visitor experiences and the cultural identity of tribes and gateway communities. Stable reservoir elevations and predictable river flows help maintain visual

integrity, access to culturally significant sites, and the immersive qualities that define national parks and recreation areas (Flyr and Koontz 2024).

The alternatives that maintain relatively stable reservoir levels and minimize flow variability provide stronger protection for these intangible benefits. Under these scenarios, boating and rafting experiences retain their quality, the scenic character remains intact, and opportunities for solitude and reflection are disrupted less. These conditions also support traditional practices for tribes, which often depend on predictable water levels and access points for cultural and spiritual activities. There may be exceptions to this generalization; for example, alternatives which provide better support for river-based recreation and associated values may result in less preferable outcomes for reservoir-based recreation and vice-versa.

During wet hydrologic conditions, the range of alternatives would generally produce conditions where lake levels and flows along the Colorado River would result in minimal impacts on nonmarket values, although this varies by resource. For example, nonmarket values such as scenic integrity, solitude, and cultural connections to the river corridor would be maintained at a level similar to current conditions. Similarly, ecological services, including riparian habitat and wildlife viewing opportunities, remain similar to current conditions and cultural landscapes would retain the factors which are associated with nonmarket values. Recreational experiences for boating, angling, and rafting, however, may be impacted under all alternatives in their quality and support for sense of place for gateway communities and visitor, as modeling indicates that periods of reservoir elevations below thresholds for recreation facility access and navigation would be more likely than that under historic conditions.

As conditions become drier, the No Action Alternative and CCS Comparative Baseline would result in the most modeled futures where impacts could occur to resources with nonmarket values. For example, nonmarket values for recreation and ecosystem services could be reduced in instances of prolonged drought, which could reduce shoreline aesthetics and diminish the opportunities for solitude at Lake Powell and Lake Mead over time. Extended low-flow periods could also impact river-based experiences in Grand Canyon due to changes in setting which could impact perceived naturalness. Cultural and spiritual values tied to iconic landscapes and cultural artifacts could also be affected in low-hydrologic flow periods. Ecological services such as riparian habitat stability may decline, influencing nonuse values related to wildlife and vegetation communities.

Under drier conditions, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would be more robust in terms of the support for nonmarket values; particularly for values associated with Lake Powell. Reservoir levels which are maintained at thresholds that support access for boating and camping in more modeled futures, support experiential benefits and cultural connections (see **TA 11**, Cultural Resources). The quality of river-based recreation is expected to remain high, due to increased stability with flow-dependent activities (see **TA 14**, Recreation); however, a lower average flow may impact some values. However, the Maximum Operational Flexibility, Enhanced Coordination, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives include the largest potential shortages to minimize the number of future conditions where dead pool could be reached based on DMDU modeling as described in **TA 4**, Water Deliveries.

More frequent low-elevation conditions would be introduced in the Basic Coordination Alternative, which could noticeably affect the nonmarket values tied to lake-based recreation and scenic quality (see **TA 14**, Recreation) although at a reduced level compared with the No Action Alternative and the CCS Comparative Baseline. Reduced reservoir levels may expose previously submerged areas, altering visual character and diminishing the opportunities for solitude. River-based recreation could experience flow variability that affects trip quality and angling success (see **TA 3**, Hydrologic Resources); however, higher average flows may support some river-based values.

Outcomes produced by the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) vary depending on the hydrology and location. In wet years, the nonmarket values supported would remain similar to those under the CCS Comparative Baseline; however, in dry sequences, reduced reservoir elevations and altered flow regimes would diminish the scenic quality and access for boating and angling at Lake Powell (see **TA 14**, Recreation). At Lake Mead, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) is the most robust at maintaining reservoir levels that support nonmarket values. River-based recreation would experience moderate variability in trip quality, while ecosystem services and the associated nonuse values would fluctuate with water availability (see **TA 8**, Biological Resources – Fish and Other Aquatic Species). Similar to the Basic Coordination Alternative, however, higher average flows may support some river-based values.

Under the Representative Preferred Alternative, as under all alternatives, non-market values associated with recreation would continue to be impacted, by reduced access to recreation facilities and navigation challenges in Lake Powell and Lake Mead. Modeled results show reduced low-elevation outcomes compared to more vulnerable alternatives, but vulnerability remains under drier future hydrologic conditions (see **TA 3,** Hydrologic Resources). The Representative Preferred Alternative generally performs in the middle of the range of alternatives for both Lake Powell and Lake Mead elevations as well as river flow, showing moderate robustness in terms of overall support for recreation associated benefits (**TA 14**, Recreation). Overall, this alternative would provide moderate protection for riverine habitat to support cultural values (see **TA 13**, Tribal Resources).

Summary Comparison of Alternatives

The lowest impacts on economic and social conditions from reductions in agricultural production and increases in fallowed lands due to shortages in irrigation water, across all alternatives, states, and tribal and non-tribal irrigation entitlement holders, would occur under the No Action Alternative due to the low maximum shortage of 0.6 maf; however, across the action alternatives, impacts on economic and social conditions from changes in agriculture would vary across irrigation entitlement groups, based on the maximum shortage levels and water shortage distribution methods. For all irrigation entitlement holders except Arizona tribal, impacts on the economic and social conditions from agricultural activity would tend to be lower under the alternatives with a low maximum shortage level and priority-based shortage distribution methods, and impacts would tend to be higher under the alternatives with a high maximum shortage level or pro rata-based shortage distribution methods, compared with other action alternatives.

However, for Arizona tribal entitlement holders, lower impacts on economic and social conditions due to reductions in agricultural production would occur under alternatives with pro rata shortage distribution methods, and higher impacts occur under the alternatives with priority shortage distribution methods, compared with other action alternatives. Overall, the alternatives demonstrate a

trade-off between shortage distributions across irrigation entitlement holders, flexibility in the maximum allowable shortage implementation, and the ability to support stable agricultural production and social well-being.

Operational changes under the proposed alternatives would influence these conditions in different ways. The alternatives that maintain more consistent reservoir levels would preserve boating access, marina operations, and shoreline recreational opportunities. This stability would support continued visitation and minimize disruptions to businesses dependent on tourism. Conversely, the alternatives that result in greater variability in lake elevations and river flows would affect the recreational quality and access and the related levels of contributions. Similarly, the alternatives that maintain consistent and adequate river flow below Glen Canyon Dam would offer continued support for recreational experiences with high value for whitewater boating and angling, and for the related spending in gateway communities and the regional economy.

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) poses the greatest risk to recreation-based economies relying on economic contributions from reservoir-based recreation in Lake Powell, while the CCS Comparative Baseline and the No Action Alternative have the least robust modeled performance for supporting recreational opportunities and spending associated with Lake Mead recreation. In contrast, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would result in more consistent reservoir levels at Lake Powell to support recreation, and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would support the greatest level of contributions from recreation in Lake Mead. However, under all alternatives, access to launch facilities and safe navigation routes for Lake Powell and navigational challenges in Lake Mead would continue to impact lake-based recreational opportunities and the associated spending.

River-based recreation is also vulnerable to operational changes. Activities such as angling in Glen Canyon and whitewater rafting in Grand Canyon depend on stable flows to ensure safety and trip quality. Reduced flows shorten rafting seasons and diminish the overall experience, leading to lower demand for outfitter services and the associated hospitality sectors. While the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would offer more consistent flows than the other alternatives, it would not fully mitigate risks. The Enhanced Coordination Alternative would be the least robust at maintaining or exceeding the minimum desired daytime flows to support boating in Grand Canyon; it would also result in the greatest potential for a reduction in the recreational value for whitewater rafting and the associated regional economic contributions associated with these uses.

Nonmarket values, such as scenic quality, opportunities for solitude, and cultural connections, are central to the Colorado River system and its surrounding landscapes. In general, stable reservoir elevations and predictable river flows support these factors and the value for locals and visitors. As a result, the alternatives that maintain relatively stable reservoir levels and minimize flow variability would provide stronger protection for these intangible benefits. During wet hydrologic conditions, the range of alternatives would generally produce conditions where lake levels and flows along the Colorado River would result in minimal impacts on nonmarket values. As conditions become drier, however, the No Action Alternative and CCS Comparative Baseline would result in greater variability in reservoir elevations and river flows. This would result in the potential to expose barren drawdown zones, alter shoreline appearance, and reduce the aesthetic values tied to natural landscapes. Variability in flows can also affect the timing and accessibility of cultural practices, creating challenges for

maintaining traditional uses. Visitors seeking a consistent wilderness experience may perceive degraded conditions when confronted with stark elevation changes or shortened seasons, which can influence perceptions of resource stewardship and long-term visitation patterns.

Under drier conditions, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would generally be more robust at maintaining key reservoir and river flow thresholds that support the resources with associated nonmarket values. On the other hand, the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would result in the most robust preservation of Lake Mead's reservoir levels at thresholds to support resources with nonmarket values.

3.17 Population and Land Use

3.17.1 Affected Environment

This section explores the baseline conditions and potential impacts from different Colorado River operational strategies on analysis area population dynamics and land use changes, with a focus on potential changes in developed lands and lands used for irrigated agriculture.

The full detailed analysis of population and land use can be reviewed in **TA 17**, Population and Land Use. **Sections TA 17.1.1**, **17.1.4**, and **17.1.6** provide comprehensive baseline information to characterize the existing setting and trends related to population, general landownership and management, and developed land patterns. Information is also provided for municipal water, which supports developed land use. Data are provided related to historical agricultural land use to support the discussion of irrigated agriculture.

Due to the influence of municipal water availability on developed lands, the impacts analysis examines changes to water availability for municipal supply and the related impacts on population and land use changes. **Sections TA 17.1.2** and **17.1.3** provide detailed information on industrial and municipal water uses and study area municipalities.

Due to the influence of irrigation water availability on agricultural land use, the impacts analysis examines changes to irrigation water availability and related impacts on acres of lands in agriculture. **Section TA 17.1.5** provides detailed information on agricultural land use within the study area, including irrigated acres of harvested cropland and the percentage of irrigated water from surface water resources.

The analysis area for the population and land-use section is separated by state and is described in **Section 3.17.2**. For a detailed description of the analysis area and rationale for selecting the Arizona, California, Nevada and Utah Counties, refer to **TA 17.1.** A high-level overview of key trends for population and land use is provided below.

Population

Population is one driver of demand for consumptive water use, particularly for municipal water. Communities throughout much of the western U.S. have followed trends of increasing populations over the past decade. In the analysis areas, the population growth rate has generally been positive or

stable. **Section TA 17.1.1** provides the historical and projected population for the Arizona, California, Nevada, and Utah analysis area counties.

Population trends varied across the analysis areas over the past decade. Arizona experienced population growth, particularly in urban and suburban settings, due in part to relatively affordable housing and expanding job opportunities in emerging sectors. In Nevada, population growth was concentrated in Clark County and the Las Vegas metropolitan area, where tourism, hospitality, and related services continue to support population growth. California experienced more varied population trends, with urban centers experiencing steady growth while certain rural areas experienced slower growth or population declines.

In Arizona, population growth in some counties has reached over 30 percent, and Nevada's urban centers have seen substantial increases that exacerbate water demand and place stress on existing resource systems. California, with its large and diverse population, faces the challenge of balancing high urban density with water conservation measures, ensuring that residential and industrial growth complies with sustainable water use practices. Projections across the three states indicate continued growth that will necessitate further investments in water infrastructure and resources to meet municipal demands. More detailed information is provided in **Section TA 17.1.1**.

Population growth can increase the demand for water for domestic, agricultural, and industrial use and increase pressure on existing water sources. Studies have shown that population growth can be a dominant driver of long-term municipal water demand (Liu et al. 2025). Insufficient water supply can constrain population growth and development by limiting an area's capacity to support residents.

Industrial and Municipal (Domestic) Water Uses and Trends

The Colorado River is an important water source serving municipalities, industries, and agricultural operations in Arizona, Nevada, and California. **Section TA 17.1.2** provides a detailed overview of industrial and municipal (domestic)[20] water supply, demand, and use trends within the U.S. and the Lower Basin. **Section TA 17.1.3** provides information on the municipalities within Arizona, California, and Nevada with the potential to be affected by changes in domestic water availability. Municipal water systems in these regions face growing pressures from population growth, climate trends, and uncertainties in future water availability, demand, and technological or policy adoption (Liu et al. 2025). Water management strategies—including conservation measures, demand-side management, and technology upgrades—have been implemented to mitigate these pressures and maintain system reliability.

Although existing and ongoing municipal water management strategies do not change domestic water entitlement amounts, they illustrate how municipal systems have adapted—and may continue to adapt—to evolving water supply and demand conditions. This context is important for understanding how communities in the region would respond to variability in water availability under different future conditions. Across the analysis areas, municipal providers employ a range of adaptation measures to manage supply variability and shortages. In Arizona, measures commonly include demand management and conservation; increased reliance on groundwater and stored supplies, including recharge and banking, where available; reclaimed water for non-potable demands; and system

[20] Domestic water use includes the use of water for "household, stock, municipal, mining, milling, industrial, and other like purposes" (1922 Colorado River Compact, section II(h)).

interconnections or operational changes. In California, measures commonly include conservation; recycled water expansion; stormwater capture and local recharge; groundwater management; interties and transfers, where available; and targeted supply or treatment improvements. In Nevada (Clark County), measures commonly include incentives to reduce outdoor water use, extensive reuse and return-flow management, and storage and exchange arrangements coupled with operational and infrastructure modifications to improve drought resilience. Many measures involve substantial capital costs and multiyear implementation timelines and may be constrained by legal or contractual availability, physical system capacity, water quality and treatment requirements, permitting, energy demands, and environmental considerations, which can limit feasibility or timing for some communities.

The availability of and access to domestic water can influence population dynamics and land use patterns in the region (**Section TA 17.1.2**). Peer-reviewed studies have documented the relationships between population growth, land use patterns, and domestic water delivery. Urban sprawl, characterized by low-density development and increased impervious surfaces, has been shown to elevate per capita water demand through higher outdoor water use (Heidari et al. 2021). In contrast, high-density development often reduces water use per capita and can lessen the frequency and severity of water shortages. Rapid urbanization and population growth can also increase pressure on existing water infrastructure, creating challenges in maintaining consistent domestic water delivery.

Municipal water demand within the analysis area depends on more than population or economic growth and can reflect long-term trends in conservation, efficiency, reuse, land-use patterns, climate, and provider policies. Many municipal providers in the Lower Basin have implemented demand management programs and operational practices that have reduced per-capita use over time, such that total municipal demand may remain stable or grow more slowly than population in some communities. Conversely, the magnitude of realized conservation and the remaining potential for additional cost-effective savings vary by provider due to differences in existing program maturity, customer mix, climate, built environment, system losses, regulatory constraints, and local supply portfolios.

Municipal planning and development within the Lower Basin counties in the analysis area rely on assumptions about the reliability, timing, and quality of water supplies used to serve existing and future demands. Within the analysis area counties, local governments and water providers typically integrate water-supply expectations into general plans, zoning and subdivision decisions, capital improvement programs, and long-range utility master planning. These assumptions inform the sizing and sequencing of major infrastructure (e.g., treatment, conveyance, storage, and pressure zones), operational and drought contingency planning, and the ability to maintain service standards under variable hydrologic conditions. Many providers in these counties manage portfolio supplies that may include Colorado River–derived deliveries alongside local surface water, groundwater, conservation, reuse, and interconnections. Because of this, domestic water reliability depends not only on annual volume but also operational availability during peak demand, drought response triggers, and constraints associated with treatment and regulatory compliance. Accordingly, changes in the reliability of Colorado River supplies can be relevant to municipal planning baselines and the context for evaluating potential effects related to domestic water shortages discussed in **Section 3.17.2** (**Section TA 17.2.2** for more information).

Water supply has influenced land use and development within the analysis area. Arizona Department of Water Resources' (ADWR) Assured and Adequate Water Supply programs provide a concrete example of how water availability can constrain development. While not directly tied only to Colorado River water, The ADWR's Assured and Adequate Water Supply programs require developers to demonstrate assured or adequate water supplies before proceeding with new projects. This context provides one example of how planning assumptions for water supply relate to residential and commercial development and helps frame how communities might respond to changes in water availability under future conditions.

Domestic water supply reliability also supports baseline employment and community functions across the socioeconomic analysis area. **TA 16**, Socioeconomics, **Section TA 16.1.2** provides baseline employment by sector for the Arizona, California, Nevada, and Utah counties included in the socioeconomic analysis area for 2010 and 2022 (see **Tables TA 16-1, 16-2, 16-6, 16-7, 16-11**, and **16-14**). These tables provide context for the composition of employment in the analysis area, including sectors that typically rely on continuous municipal water service to support day-to-day operations and public services. Examples of these sectors include but are not limited to information; healthcare and social assistance; retail trade; real estate; arts, entertainment, and recreation; construction; finance and insurance; manufacturing; professional, scientific and technical services; state and local government; and accommodation and food services. While county-level employment data do not distinguish among the water sources supporting certain sectors and associated economic activity and public services, the sector employment helps frame domestic water supply, demand, and use trends in the counties included in the analysis area.

In models of projected water yield and demand in the western U.S. to 2070, data indicate that demands for municipal water are increasing across the socioeconomic analysis area, while projected water availability is decreasing (see, for example, Warziniack and Brown 2019). While this trend is seen throughout the western U.S., the Colorado River region has the largest percentage increases in projected domestic water use and the greatest percentage decreases in projected water yield from all sources, including Colorado River water (Warziniack and Brown 2019).

Study Area Municipalities

The analysis area is informed by the SAMs and includes the counties represented in the SAMs. Further, the Arizona, California, and Nevada municipalities with potential to be affected by the alternatives are described in detail in **Section TA 17.1.3**. and include those represented in the SAMs.

Land Use

This section describes existing land use conditions along the mainstream Colorado River from Glen Canyon Dam to the U.S.–Mexico border. Land use includes recreation, agriculture, tribal land use, conservation and habitat management, residential and urban development, and utility and infrastructure corridors.

Landownership along the Colorado River is highly variable and includes federal (NPS, BLM, FWS, and Reclamation), tribal, state, and private lands. Federal agencies manage much of the land in the upper and middle portions of the river corridor, particularly in areas surrounding Glen Canyon NRA, GCNP, Lake Mead NRA, and multiple NWRs. Tribal lands are prominent in both Arizona and

California. State and private lands are more common in the Lower Basin, especially in urban areas like Bullhead City and Yuma and along agricultural corridors in Arizona and California.

Developed land uses occur in concentrated areas where communities and infrastructure directly rely on the Colorado River. These include recreation sites, marinas, campgrounds, roadways, water delivery systems, hydropower infrastructure, and municipal areas. While most of the corridor remains undeveloped, developed areas have expanded since the early 2000s in several locations due to population growth, recreational demand, and infrastructure upgrades. Agricultural lands are also a major land use along the river's lower reaches, particularly in western Arizona and southeastern California, where irrigated farming depends heavily on surface water deliveries.

Reservoir elevations and river flow conditions strongly influence how land near the river is used and managed. Declining water levels at Lake Powell and Lake Mead have resulted in increased shoreline exposure, changes in recreational access points, and new management needs for erosion control, sediment exposure, and public safety. These hydrologic shifts also affect agricultural land use by altering water availability for irrigation, which can contribute to fallowing or shifts to less water-intensive crops in some areas.

Agricultural Land Use

Agriculture is a major land use along the lower Colorado River, particularly in western Arizona and southeastern California, where irrigated farming relies heavily on surface water deliveries. Key agricultural areas include Yuma, La Paz, and Mohave Counties in Arizona and Imperial and Riverside Counties in California. These regions support extensive production of food, feed, and fiber crops and represent some of the most productive irrigated farmland in the country. Western Arizona counties such as Pinal, Maricopa, and Pima also contain irrigated agricultural lands, although these areas have experienced reductions in irrigated acreage over time due to water availability constraints. Trends in county-level cropland data show shifts in harvested and irrigated acreage across the region, reflecting long-term drought, changes in water deliveries, and adaptation by agricultural producers (Dieter et al. 2018; Presson and Eden 2023; USDA NASS 2024). More detailed information on the location and extent of irrigated agricultural lands is provided in the technical appendix.

3.17.2 Environmental Consequences

Methodology

The analysis of population and land use impacts evaluates a) how operational changes and changes to domestic water delivery could affect overall population and land use patterns, including developed lands for residential and commercial uses, and b) how operational changes and changes to irrigation water could affect lands used for irrigated agriculture.

To analyze how operational changes may affect population and land use patterns (Issue 1), the DMDU analysis was used. The DMDU analysis of domestic water impacts used modeled shortages to domestic users provided by the SAMs and ADMs[21] and proceeded in two main steps. First, domestic priorities were grouped: Arizona CAP non-Indian agriculture [NIA]-A and NIA-B (Group 1), Arizona

[21] There are three unique SAMs and five ADMs to capture the nuances of the alternatives and sensitivity analyses; these are further explained in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation.

CAP M&I and Priority 4(i) (Group 2), Arizona Priorities 2 and 3 (Group 4), Arizona PPR (Group 5), California Priority 4 (Group 6), California PPR (Group 7), Nevada Priority 8 (Group 8), Nevada Priorities 1–7 (Group 9) to capture variation in modeled shortage by priority across the SAMs. Second, the modeled domestic shortage was analyzed for each priority group to determine the shortage levels at which the group's average percentage shortage equaled approximately 20, 40, 60, 70, 80, or 100 percent of its total entitlement. These thresholds were applied within the DMDU framework to develop **Figures TA-17-2** through **TA-17-9**, which depict the percentage of modeled futures where each priority group maintains the specified fraction of normal water deliveries in 90 percent of years across the action alternatives. For the purpose of this analysis, "normal delivery" is defined as a full Colorado River or CAP entitlement supply. The figures provide a direct comparison of domestic water impacts across priority groups and the alternatives. Additional information on the DMDU robustness and vulnerability concepts used to interpret these results is provided in **Appendix E** (DMDU Overview and Approach). Modeling assumptions and shortage allocation frameworks that inform domestic delivery outcomes are documented in **TA 4**, Water Deliveries. While this section focuses on domestic shortage impacts on priority groups, domestic shortage impacts for each entitlement can be found in **Appendix C**.

To analyze how operational changes may affect agricultural land use (Issue 2), this analysis relied on modeled shortages to irrigation users at the state level, produced by the SAMs. For more detailed information on the SAMs and consumptive impacts on irrigation users, see **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation. For more information on water deliveries and shortage impacts, including those for irrigation, refer to **TA 4**, Water Deliveries.

Impact Analysis Area

The analysis area for the population and land use section is separated by state and is the same for both population and land use issues. The impact analysis area is defined by those counties that may be affected by management direction that could result in water shortages to domestic and irrigation users. As described above, both issue statements rely on the SAMs. As a result, the analysis area is informed by the SAMs and includes the counties represented in the SAMs. The Arizona analysis area consists of Apache, Coconino, Gila, La Paz, Maricopa, Mohave, Navajo, Pima, Pinal, and Yuma Counties. These include counties that are directly adjacent to Lake Powell, Lake Mead, or the Colorado River and counties in which shortages would likely occur. The California analysis area consists of Imperial, Los Angeles, Orange, Riverside, San Bernardino, and San Diego Counties. These counties were selected because they are either directly adjacent to the lower Colorado River, or they are within the MWD service area. Although Ventura County is also in the MWD service area, it does not receive any water from the Colorado River; therefore, it is not included in the analysis area. The Nevada analysis area consists of Clark County. The Nevada analysis area was limited to Clark County because Clark County is adjacent to Lake Mead and encompasses SNWA's service area and other individual water providers. Shortages in Nevada would be limited to SNWA's service area.

Across the states, these counties were selected for inclusion in the analysis area because they represent the counties in which there is potential for direct impacts from shortages, based on modeled domestic (municipal) delivery outcomes and the service areas of major municipal providers. Secondary impacts could also occur in adjacent counties, across states as a whole, in adjacent states, and/or at the national scale (e.g., through economic linkages and supply chains). However, due to analytical constraints and

the focus of this analysis on a DMDU-informed assessment of modeled domestic shortage outcomes for selected municipal providers, the population and land use analysis focuses on direct impacts within the counties that correspond to municipal service areas and areas where delivery reductions could most directly influence land-use-related conditions.

This approach is consistent with the socioeconomic framing (**TA 16**, Socioeconomics), which defines analysis areas using counties adjacent to reservoirs and the Colorado River and counties containing major municipal service areas that receive water from the Colorado River (e.g., in California, counties within the MWD of Southern California service area that receive Colorado River water).

Assumptions

- Colorado River operations do not directly control population change, but they may indirectly influence migration patterns.
- Local socioeconomic conditions and demographic trends may also be influenced by factors outside river operations, such as housing costs, infrastructure investment, local attitudes towards water conservation, and regional employment patterns.
- In most cases, the contractor, subcontractor, or entitlement holder of an allocation is shown as the entity bearing shortage. In some cases, water allocated to an entitlement holder (for example, a tribal CAP contractor) may lease its allocation to other users (for example, to a non-Indian municipality). The SAMs and ADMs do not attempt to replicate those arrangements, and they only provide approximate estimates at the level of the entitlement holder, contractor, or subcontractor. The entitlement holder, contractor, or subcontractor to the leasing arrangements would have specific decisions to make during Shortage Conditions to administer those arrangements that Reclamation cannot predict with sufficient certainty to analyze in this EIS.
- Under the Representative Preferred Alternative, two different approaches to distributing shortages are modeled, where (1) 2027-2028 modeling assumes shortage volumes up to 1.5 maf are distributed using the approach developed by the Lower Division States, and shortage volumes from 1.5 maf to 3.6 maf are distributed using the priority system, and (2) from 2029 through 2060, modeled shortage volumes are distributed using the priority system. Refer to **Section 2.4** for additional information. Some impacts are influenced by how the Representative Preferred Alternative distributes Lower Basin shortages in 2027-2028 vs. 2029-2060, and some impacts are either minimally sensitive or not sensitive to this distinction. Impacts discussion will include references to different time periods where relevant.
- Impacts under the Preferred Alternative may be different from what is shown for the Representative Preferred Alternative, as this alternative provides a framework that allows for shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**. As a result, the potential for fallowing, crop switching, and other associated long-term land-use patterns in any given area may vary and impacts may be mitigated in part by specific operating guidelines.

Impact Indicators

- Shortage to domestic water users
- Acres of developed land within the analysis areas and the potential for changes based on municipal water availability
- Acres of irrigated agricultural land within the analysis areas and the potential for changes based on agricultural water availability

Issue 1: How would operational changes affect population and developed land use patterns?

This issue examines how modeled changes in domestic (municipal) delivery reliability may influence population and developed land use patterns in communities that rely on Colorado River water for municipal uses. While Colorado River operations do not directly determine population movement or developed land use patterns, long-term changes in water availability and recreational access may influence migration patterns and developed land patterns. This issue statement is analyzed by first synthesizing the DMDU results presented in **TA 17**, Population and Land Use, and then by assessing how domestic water delivery impacts would impact population and developed land use patterns. Modeled domestic (municipal) delivery outcomes are used to understand how reduced reliability may constrain population- and land-use-related conditions, including residential and commercial development, existing communities, and essential services. The DMDU results are interpreted as indicators of potential exposure to domestic shortage and associated impacts, not as direct forecasts of county-level population change, local economic output, or sector-specific impacts. Additional detail on the modeling assumptions and domestic delivery results is provided in **TA 17,** Population and Land Use, **TA 4,** Water Deliveries, **Appendix C, and Appendix E.**

Population is not treated as a direct proxy for consumptive use because conservation, reuse, and local policy can affect per-capita water use. Similarly, municipal-scale economic impacts are discussed qualitatively because comparable economic, utility finance, and sector-specific data are not uniformly available across municipal providers and service areas. **TA 16**, Socioeconomics, provides baseline socioeconomic context, including employment by sector, and **TA 17**, Population and Land Use, uses that context to discuss qualitative pathways by which reduced domestic delivery reliability may affect communities and developed land use.

Figure TA 17-2 through **Figure TA 17-9** in **TA 17**, Population and Land Use, display potential impacts on domestic water deliveries by presenting the percentage of normal domestic water deliveries that can be achieved across a range of modeled futures. Each figure illustrates the percentage of normal domestic water deliveries achieved in 90 percent of years over a 34-year modeling period, representing varying percentages of potential future scenarios for each priority group. The metric of 90 percent of years was selected for this analysis, rather than 100 percent of years, because it better displays variation between the alternatives. For each figure, the rows represent different performance thresholds, as percentages of normal delivery. Higher rows indicate a higher volume of delivery (closer to normal conditions) and are therefore challenging to achieve across a large percentage of potential futures, while lower rows represent lower levels of delivery that are easier to achieve because they allow for more frequent modeled shortages to domestic water delivery. For this analysis, greater than 80 percent of normal delivery in 90 percent of years was selected as the preferred minimum performance level. This row was highlighted because it represents the performance level closest to

normal domestic water delivery of the thresholds displayed in the figures, while also representing the earliest point at which differences among alternatives begin to emerge in the DMDU results. In other words, the greater than 80 percent row reflects the least amount of modeled shortage to domestic water users displayed in the figures and is the first row where shortages begin to manifest across alternatives.

In addition, each figure includes a bottom row that shows futures with dead pool–related reductions. These occur when Lake Mead lacks sufficient water to meet downstream demands or when Hoover Dam infrastructure limitations force releases below the required volume, typically when the lake approaches dead pool (895 feet) or even earlier (up to 950 feet). Although this analysis does not address the allocation of reductions related to dead pool, displaying these figures provides important context on the robustness of the alternatives.

Figure TA 17-2 through **Figure TA 17-9** in **TA 17**, Population and Land Use, do not capture individual years within the modeling period, however, they are modeled. The modeling assumptions for the Representative Preferred Alternative in the first two years (2027–2028) are described in **Chapter 2** and the shortages are distributed via LB priority. Therefore, up to 1.5 maf of shortage, in the first two years, impacts to Arizona CAP NIA-A and NIA-B; CAP Indian, M&I, and 4(i); and Priorities 2 and 3; California Priority 4 entitlements; and Nevada Priority 8 (including Balance and Surplus) entitlements, would be more similar to the Supply Driven Alternative (LB Priority Approach). Refer to **Appendix C**, **Table C-28** for domestic shortage impacts for each entitlement holder under the LB Priority distribution (up to 1.5 maf shortage). The results for the Representative Preferred Alternative in 2029–2036, in which Priority distribution is applied, would result in more shortage impacts on Arizona junior entitlements.

The alternatives with greater robustness would likely result in fewer potential indirect impacts on population growth and developed land. Greater robustness corresponds to a higher percentage of futures in which domestic water delivery remains consistent with normal conditions and shortages occur less frequently. In contrast, less robust alternatives are more susceptible to reductions in domestic water availability because modeled shortages occur more frequently or the volume of shortage is higher. These shortages could manifest as reduced water deliveries, delivery restrictions, or the need for additional conservation measures, which could in turn limit the capacity to meet domestic water demand. A more robust alternative would therefore help ensure that domestic water supplies remain reliable to support existing populations and accommodate anticipated future growth, thereby minimizing potential secondary impacts on development patterns and land use. More detailed information on the nature and type of impacts associated with reductions in municipal delivery reliability is provided in **TA 17.2.2** and **TA 17.2.3**. The SAMs used to inform the DMDU analysis do not incorporate water management measures, such as conservation programs, or demand-reduction strategies. These measures do not change entitlement amounts or shortages; however, as noted in the affected environment section, conservation programs and other management strategies can influence domestic water demand and help mitigate the operational pressures associated with shortages, uncertain supply, and population growth. The potential impacts on domestic water supply for the Lower Division States would also depend in part on existing and future management strategies and conservation measures implemented by the states, local water providers, and individual users. Potential impacts would also depend on other external factors such as environmental and economic conditions.

Communities and municipal providers may respond to shortages through a range of adaptation measures, which could include increased conservation and demand management, use of existing storage or water banking arrangements where available, investments in infrastructure (e.g., treatment upgrades, reuse, interconnections), operational changes, or pursuit of alternative supplies and agreements. The feasibility, timing, and effectiveness of these measures would vary by location and provider, and may be constrained by physical and geographic availability of replacement water, jurisdictional and legal limitations (including state-law and contractual considerations), the time required for planning, permitting, financing, and construction, and constraints related to existing infrastructure configurations and prior investments. Adaptation measures may also involve direct and indirect economic costs to providers and ratepayers, and may require tradeoffs among objectives under different future conditions. Because the DMDU framework tests many uncertain futures, these uncertainties and constraints should be considered when interpreting robustness results and evaluating the extent to which an alternative can reduce both direct delivery impacts and potential secondary effects on development patterns and land use.

Table ES-7, Summary of Potential Effects, Population and Lands, in the **Executive Summary** provides an overview of impacts on population, lands, and domestic water by alternative based on the DMDU figures discussed in detail in **TA 17**, Population and Land Use. The table demonstrates how the different alternatives perform in terms of the percentage of normal delivery in potential futures. The table with a summary of effects on the population and lands includes two performance indicators: greater than 80 percent of normal delivery and greater than 60 percent of normal delivery in 90 percent of modeled futures, across the full modeling period. The table displays how each alternative performs for these two performance indicators, by priority group. The performance indicators illustrate how each alternative performs in maintaining domestic water deliveries under a wide range of uncertain future conditions. The alternatives that would achieve greater than 80 percent of normal delivery in 90 percent of years demonstrate strong robustness, indicating that domestic deliveries would remain near normal levels across most modeled futures. These alternatives would result in fewer and less severe shortages, which would provide greater reliability for domestic water users. This performance indicator is difficult to achieve under many alternatives.

To show further variation across the alternatives, **Table ES-7**, Summary of Potential Effects, Population and Lands, in the **Executive Summary** includes greater than 60 percent of normal delivery in 90 percent of years. The alternatives that only meet the greater-than-60-percent-of-normal-delivery-in-90-percent-of-years threshold demonstrate lower robustness. Under these conditions, more frequent domestic delivery reductions or shortages could occur in modeled futures, particularly for junior priority groups. Such outcomes could increase the likelihood of secondary socioeconomic impacts, including constraints on growth or secondary changes in land development patterns.

As described in **Section TA 17.1**, Affected Environment, and **Section 3.1**, Introduction, above, peer-reviewed studies document that domestic water availability significantly influences population dynamics and land use. **Section TA 17.2.3**, DMDU Analysis Summary, provides a detailed overview of potential impacts on domestic water and the associated impacts on population and land use patterns for Arizona, Nevada, and California. Key summaries are also provided below.

Arizona: Across the first decade of the modeling period, the CCS Comparative Baseline and No Action, Basic Coordination, and Supply Driven (LB Priority Approach) Alternatives would result in

similar impacts on domestic water supply for Arizona PPR and Arizona Priorities 2 and 3, with greater than 80 percent of normal delivery in 100 percent of potential futures. In other words, there would be no domestic shortage impacts for Arizona PPR and Priorities 2 and 3 under these alternatives. However, potential impacts do vary under the other action alternative for these two priority groups. Under the Maximum Operational Flexibility and Representative Preferred Alternatives, over 80 percent of normal delivery to Arizona Priorities 2 and 3, occurs in 26 percent and 57 percent of potential futures across the first decade of the modeling period, respectively.

In contrast, for Arizona CAP NIA-A, CAP NIA-B, CAP Indian, M&I, and 4i priorities, no alternative achieves the preferred minimum performance level of over 80 percent of normal delivery in 90 percent of years across the first decade of the modeling period. Further, under the Basic Coordination, Enhanced Coordination, and Representative Preferred Alternatives, there are no potential futures in which Arizona CAP NIA-A, CAP NIA-B, CAP Indian, M&I, and 4(i)) priority groups receive any percentage of normal domestic water delivery. Under these less robust alternatives, there is a higher frequency of shortage and no potential futures in which normal domestic delivery to these priorities occurs. A higher frequency of shortages and fewer potential futures with normal domestic delivery to these junior priorities could result in potential impacts on municipalities and communities that rely on domestic water delivery under these entitlements. Should shortages result in a reduction or elimination of legal access to municipal water, widespread impacts on social and economic conditions may also be possible. Further, the shortage distributions applied under these alternatives could result in the complete loss of domestic water for these users. However, the Enhanced Coordination and Supply Driven (LB Pro Rata Approach) Alternatives allow for over 60 percent of normal delivery in 100 percent of modeled futures for these priority groups, demonstrating its robustness compared with the other alternatives.

When considering all Arizona priority groups, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives generally demonstrate the most robust performance for domestic water entitlements, based on maintaining greater than 60 percent of normal delivery in at least 90 percent of years across the full modeling period, for the greatest number of users. Compared with the CCS Comparative Baseline and No Action Alternative, under these alternatives 60 percent or more of normal domestic water delivery occurs across the largest percentage of potential futures and for the greatest number of priority groups. While this approach maximizes delivery reliability for more users overall, it involves a trade-off: Some senior entitlements would experience delivery reductions that would not occur under priority distribution, whereas more junior entitlements may continue to receive near-normal deliveries, across the modeled futures. This allocation reflects a balance between broad delivery coverage and the reallocation of shortage risk across the priority groups.

California: For California PPR, all alternatives, excluding the Enhanced Coordination Alternative, achieve the preferred minimum performance level of over 80 percent of normal delivery in 90 percent of years, across the first decade of the modeling period. Therefore, under all alternatives, excluding the Enhanced Coordination Alternative, there would be no shortage to California PPR across modeled futures. For California Priority 4, the No Action, Basic Coordination, and Supply Driven (LB Pro Rata approach) Alternatives achieve the preferred minimum performance of over 80 percent of normal delivery in 90 percent of years, across the first decade of the modeling period. The Maximum Operational Flexibility and the Representative Preferred Alternatives demonstrate the most robust performance for California PPR compared with other alternatives. However, for California Priority 4,

deliveries greater than 80 percent of normal delivery occurs in no potential futures under the Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives. Therefore, under these alternatives modeled delivery reductions could result in impacts on existing residents, economic sectors, and essential services reliant on domestic deliveries. Communities could experience increased constraints on existing and new residential and commercial development, need for additional adaptation measures, and greater pressure to accelerate development of replacement supplies.

When evaluating both California priority groups together, the Supply Driven Alternative (LB Pro Rata approach) is the most robust, compared with the No Action Alternative and all other action alternatives. It provides 100 percent of normal delivery to California PPR and California Priority 4 in 90 percent of years across 100 percent of potential futures. Additionally, considering the dead pool–related reductions, which could affect these users, the Supply Driven Alternative (LB Pro Rata approach) has the third lowest percentage of futures with constrained releases (12 percent), compared with all other alternatives. Reliable domestic water deliveries under the Supply Driven Alternative (LB Pro Rata approach) would support continued population growth and land development in areas served by California PPR and Priority 4.

Maintaining near-normal deliveries reduces the likelihood of constraints on planned and new development, housing availability, and municipal services that rely on water supply. In contrast, the alternatives with lower reliability or greater exposure to dead pool–related reductions could limit opportunities for residential and commercial growth, particularly in high-demand areas, and could influence land use patterns or delay new construction. Ensuring robust water delivery across multiple futures is therefore directly tied to supporting existing communities, sustainable population growth, and land use planning in California.

Nevada: Similar to Arizona PPR, for Nevada Priorities 1–7, all alternatives, excluding the Enhanced Coordination and Supply Driven (LB Pro Rata Approach) Alternatives, achieve the preferred minimum performance level of over 80 percent of normal delivery in 90 percent of years, across the first decade of the modeling period. In contrast, for Nevada Priority 8, the No Action Alternative is the only alternative that meets the preferred minimum performance. For Nevada Priorities 1–7 specifically, the Maximum Operational Flexibility Alternative is the most robust, followed by the Representative Preferred Alternative, compared with the No Action Alternative and the other action alternatives. In contrast, for Nevada Priority 8, these same alternatives are some of the least robust, with deliveries greater than 80 percent of normal occurring in only 1 percent of potential futures (Maximum Operational Flexibility Alternative) and no potential futures (Representative Preferred Alternative).

When considering both Nevada priority groups together, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, provide the most robust performance. These alternatives deliver greater than 60 percent of normal domestic water across the largest percentage of potential futures and for the greatest number of priority groups. Robust domestic water deliveries are critical to supporting existing communities and population growth and land development in Nevada. The alternatives that maintain more reliable deliveries for both priority groups reduce the risk of constraints on existing and new housing, commercial development, and essential municipal services that depend on water supply. Conversely, the alternatives with lower reliability, particularly for Nevada

Priority 8, could result in impacts on the capacity to support existing residents, economic sectors, and essential services reliant on domestic deliveries. Communities could experience increased constraints on existing and new residential and commercial development, impacts on the capacity of communities to expand, and effects on land-use patterns or delays to new construction projects. Modeled delivery reductions could result in the need for additional adaptation measures, and greater pressure to accelerate development of replacement supplies. By sustaining domestic water availability across a broad range of potential futures, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives may help support existing residents, economies, and essential services; stable population growth and more predictable land use planning across the state, where modeled deliveries remain reliable.

Issue 2: How would operational changes affect irrigated agricultural land use patterns?

Irrigated agriculture in Arizona and California remains sensitive to changes in Colorado River operations. Across all modeled alternatives, reductions in irrigation deliveries occur as reservoir elevations decline and system shortage volumes increase. Differences among the alternatives primarily reflect how shortages are distributed, either according to priority systems or through coordinated or pro rata sharing, and whether conservation and flexibility mechanisms are available to offset impacts.

Arizona experiences the greatest exposure to shortages under most alternatives because many irrigation users in Yuma, La Paz, and Mohave Counites hold junior priority rights. Under conditions without new conservation or shortage-sharing mechanisms, such as the No Action and Basic Coordination Alternatives, Arizona irrigation users face frequent and severe reductions. Literature indicates that these reductions can accelerate fallowing, crop switching, and farmland retirement in western Arizona counties (USGS 2019b; Arizona Extension 2024; Presson and Eden 2023). Even under the CCS Comparative Baseline, modeled shortages still affect Arizona at low to mid-levels of system stress, reflecting ongoing vulnerability despite existing conservation programs.

California agriculture, particularly in senior-rights districts, such as the Imperial Valley, is less affected under priority-based alternatives; however, it faces greater reductions under coordinated or pro rata frameworks. The Enhanced Coordination and Supply Driven (Pro Rata approach) Alternatives distribute shortages more evenly across Lower Basin water users, reducing concentrated impacts in Arizona but increasing exposure for California. Studies show that even modest reductions can influence land use in California's irrigation districts through shifts toward drought-tolerant crops or partial land retirement (Prakash 2023; Lee et al. 2020).

The alternatives that incorporate operational flexibility or large conservation reserves, such as the Maximum Operational Flexibility Alternative and portions of the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), may lessen the severity of shortages during milder hydrologic periods, though long-term reliability still depends heavily on conservation participation and system conditions. Research indicates that agriculture increasingly relies on adaptive practices, such as deficit irrigation and crop switching, to maintain productivity under prolonged water scarcity (USDA ERS 2021).

Up to 1.5 maf of shortage, the Representative Preferred Alternative for 2027-2028 would result in shortages similar to that under the Maximum Flexibility Alternative and the Supply Driven Alternative (LB Priority approach), with impacts concentrated on junior users. In the longer term (2029-2060)

modeled outcomes for the Representative Preferred Alternative follow the priority approach for distribution, and indicate potential for fallowing of land as noted under the Basic Coordination Alternative, with impacts concentrated on junior users.

The analysis shows that operational changes to the Colorado River system would continue to influence land use in irrigation-dependent regions. Concentrated shortages under priority-based operations are most likely to drive localized land fallowing and economic disruption in central Arizona, while pro rata or coordinated approaches lead to broader, more evenly distributed impacts in Arizona and California. More detailed modeling results and county-level outcomes are provided in the technical appendix.

Summary Comparison of Alternatives

Population and Developed Land Use: The alternatives vary in how they distribute domestic shortages and in their potential to impact domestic water deliveries and, in turn, indirectly impact population dynamics and land use within the analysis area.

As shown in **Table TA 17-17**, for the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives, which apply a priority-based distribution of shortage, under most modeled futures, water users with senior entitlements would likely continue to experience relatively consistent domestic water deliveries. This is because these entitlements are contractually prioritized during periods of reduced supply. However, junior entitlements could face greater reductions in water deliveries during Shortage Conditions. Consequently, while senior entitlement holders may maintain service levels closer to normal, junior entitlement holders could experience more frequent or severe delivery constraints.

Under the No Action, Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives, greater than 80 percent of normal domestic delivery to most senior entitlements occurs in all potential futures. The specific Arizona, California, and Nevada senior entitlements vary by alternative (see **Table TA 17-17**). Because these alternatives have greater robustness for senior priority groups, there could be fewer potential indirect impacts on existing communities as well as population growth, and land development. A higher percentage of potential futures with greater than 80 percent of normal delivery could support existing populations, future population growth, water demand, and development in areas serviced by these priority groups.

Under the Basic Coordination, Maximum Operational Flexibility, Supply Driven (LB Priority approach), and Representative Preferred Alternatives, for junior entitlements there are fewer potential futures, and in some cases no potential futures, in which there is any percentage of normal delivery across the first decade of the modeling period. The specific Arizona, California, and Nevada junior entitlements vary by alternative (see **Table TA 17-17**). Under the Enhanced Coordination, Maximum Operational Flexibility and Representative Preferred Alternatives, greater than 80 percent of normal domestic delivery to all junior entitlements occurs in no potential futures, across the first decade of the modeling period. Domestic shortages could manifest as reduced water allocations, delivery restrictions, or the need for additional adaptation and conservation measures, which could in turn limit the capacity to meet domestic water demand. Reduced capacity to meet domestic water demand could impact existing residents and essential services, constrain planned and future development, and create conveyance or treatment system challenges. The extent of these effects would vary by community

based on local water portfolios, infrastructure, regulatory context, conservation achievements, financing capacity, hydrologic conditions, and adaptation feasibility. Further, the shortage distributions applied under these alternatives could result in the complete loss of domestic water for these users. Should shortages result in a reduction or elimination of legal access to municipal water, widespread impacts on social and economic conditions could also be possible. For example, in some scenarios, municipalities could even find the need to pursue alternative water sources or hauled water, if available, as an alternative to support continued services. However, adaptation measures (for example, new supplies, infrastructure, treatment, interconnections, and related financing) can require substantial time and resources and may not be available on the same schedule for all communities. While these specific local project decisions would occur outside the scope of this Final EIS, it is important to note the potential for impacts. In addition, indirect social costs could occur as a result of a reduction in ecosystem services; also, indirect social costs could occur from a reduction of benefits to people provided by the environment. For example, trees in urban areas have been shown to provide high levels of benefits to people in the form of shade, which mitigates urban heat impacts (that is, heat-related illness), local air quality improvements, and enhancement of the visual setting. Should a reduction in domestic water supply result in die-offs of urban and suburban area trees, this could represent a loss of value that would take decades to recapture, due to the growth time required for trees (see, for example, Bloome et al. 2016).

As shown in **Table TA 17-17**, the Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives, which apply pro rata distribution of shortage under most modeled futures, would generally allow a larger number of priority groups to receive domestic water deliveries closer to normal conditions. While a pro rata approach would change the distribution of water across all users during shortages, this section solely focuses on the distribution of water to domestic users. This approach would deviate from the priority-based distribution, resulting in some modeled reductions to domestic deliveries for some senior entitlement holders who would otherwise maintain normal domestic delivery under the existing priority system. In contrast, more domestic junior priority water entitlement holders would continue to receive some level of water supply under this approach. In general, the pro rata method would result in more existing users receiving moderate water deliveries during shortages through a redistribution of water from senior entitlements.

Agricultural Land Use: The alternatives vary in how they distribute irrigation shortages and in their potential to influence long-term land use patterns. The No Action and Basic Coordination Alternatives rely on priority-based distribution and result in concentrated impacts on junior priority users in Arizona (primarily in Yuma, La Paz and Mohave Counites, with limited mitigation tools. These conditions increase the likelihood of fallowing, crop switching, and economic stress in affected communities.

The Enhanced Coordination and Supply Driven (LB Pro Rata approach) Alternatives distribute shortages more broadly across the states and users, reducing concentrated impacts on junior priority holders but introducing greater reductions in California, which could lead to more widespread land use changes. The Maximum Operational Flexibility and Supply Driven (LB Priority approach) Alternatives incorporate adaptive tools and conservation reserves, offering potential buffers against extreme shortages; however, their effectiveness depends on stakeholder participation and hydrologic conditions.

Up to 1.5 maf of shortage, the Representative Preferred Alternative for 2027-2028 would result in shortages similar to those under the Maximum Operational Flexibility Alternative and the Supply Driven (LB Priority Approach), with impacts concentrated on junior users. In the longer term (2029-2060) modeled outcomes indicate potential for the greatest level of shortage to junior priority users of any alternative. However, the distribution of shortage under any specific operating guidelines adopted under the Preferred Alternative decision framework may differ from the priority distribution method reflected here for the Representative Preferred Alternative, as a result, the potential for fallowing, crop switching, and other associated long term land -use patterns in any given area may vary and impacts may be mitigated in part by specific operational guidelines.

3.18 Indian Trust Assets

3.18.1 Affected Environment

The U.S. has a trust responsibility to tribes as defined by statutes, court decrees, treaties, or other applicable law.[22] ITAs are legal interests in assets held in trust by the federal government for the benefit of federally recognized Native American tribes or individual Native Americans (Reclamation 1994). ITAs can be located on or off established reservation lands and can consist of land, water entitlements;[23] natural resources; monies, such as trust funds; mineral rights; hunting, fishing, trapping, and gathering rights; and others. Beneficiaries of the Indian trust relationship are tribes and individual Native Americans; the U.S. is the trustee. ITAs are generally restricted against alienation (that is, they cannot be sold, transferred, abandoned, or lost without approval from the Secretary of the Interior). With federal authority and approval, ITAs may be leased to generate income for tribes or individual Native Americans (Department 2025).

It is the general policy of the Department to carry out activities in a manner that protects ITAs and avoids adverse effects whenever possible (Reclamation 1993). In accordance with Reclamation ITA policy and guidance (Reclamation 1994), tribal consultation addressing trust assets should be initiated with appropriate tribal groups and the Bureau of Indian Affairs (BIA), and the presence or absence of ITAs should be addressed explicitly in all NEPA documents. Reclamation has consulted with tribes regarding the proposed Post-2026 Operational Guidelines and Strategies for Lake Powell and Lake Mead Environmental Impact Statement.

The following sections summarize the affected environment for different types of ITAs. See **TA 18**, Indian Trust Assets, for additional detail.

Trust Lands

Indian trust lands are lands that the U.S. holds in trust for the benefit of a tribe (tribal trust land) or for an individual Native American (individual trust land). Trust lands may be located on or off a reservation. While reservations are not always synonymous with trust lands, the exterior boundaries of reservations are used to define the trust land assets for purposes of this NEPA analysis, to be

[22] Nothing in this technical appendix is intended to modify, abrogate, or create ITAs. Any particular ITA remains defined by and subject to applicable authority.

[23] Rights and entitlements may be used interchangeably in this technical appendix for simplicity, and no legal change to any ITA is intended.

inclusive. There are 30 federally recognized tribes in the Colorado River Basin; 29 of these have established reservations. Tribal land uses include, but are not limited to, communal and spiritual uses, domestic use, and agriculture and economic development.

Water Entitlements, Water Deliveries, and Storage and Conservation Options

The management and operation of the Colorado River and delivery of its waters to various users is governed by a complex set of treaties, statutes, Supreme Court decrees, and other settlements and agreements collectively known as the "Law of the River". In general terms, the Law of the River establishes a priority system for the distribution of available water. Higher priority (senior) water entitlements are filled first, and lower priority (junior) entitlements are filled next. Some tribal water entitlements have higher priorities and others are lower priorities. **Appendix C,** Shortage Allocation Model and Alternative Distribution Model Documentation, provides more detail on the priority of each tribal water entitlement in the Lower Basin.

TA 4, Water Deliveries, provides more detail on the Law of the River. **TA 18**, Indian Trust Assets, includes a discussion of tribal mainstream Colorado River water entitlements and CAP contracts.[24] The entitlements included in this analysis are consistent with those in the SAMs and ADMs (see **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation) and other sections of the EIS.[25]

Other Indian Trust Assets

ITAs can also include hunting, fishing, trapping, and gathering rights; mineral rights; and cultural, biological, and other resources. Whether specific rights or resources legally qualify as an ITA is complicated and depends on multiple factors, such as land status (Reclamation 1994). Reclamation consulted with tribes and the BIA to identify ITAs. To date, potential changes in water deliveries and activities affected by potential changes in water deliveries (for example, irrigated agriculture) have been the primary concerns related to ITAs.

Reclamation acknowledges that the 30 Basin Tribes depend on the Colorado River and its tributaries for a variety of purposes, including cultural and spiritual activities, wildlife, instream flows, recreation, and other purposes. See **TA 13**, Tribal Resources, and **TA 11**, Cultural Resources, for analysis of tribal and cultural resources, respectively. In general, those analyses apply to tribal and cultural resources that qualify as ITAs.

Although income derived from ITAs is not an ITA in and of itself, income derived from ITAs, such as agricultural products, water leases, and fees charged for outdoor recreation on tribal land, can be an important source of income for tribes.

3.18.2 Environmental Consequences

Following Reclamation ITA policy (Reclamation 1994), the following analysis discusses actions that affect the value, use, or enjoyment of ITAs.

[24] While some entitlements are not ITAs, they are included for reference in **TA 18**, Indian Trust Assets.
[25] Tribes may have other sources of water, including groundwater and other surface water, which are not part of this analysis.

Methodology

The methodology varies for each type of ITA. Quantitative metrics are analyzed where possible; otherwise, a qualitative discussion is provided. Refer to **Section TA 18.2.1**, Methodology, for more information on the methodology used. As described in **Section 3.4.1**, the geographic scope of this EIS does not extend above Lake Powell and accordingly does not include an analysis of the impact on Upper Basin water users.

Impact Analysis Area

The impact analysis area includes land within the boundaries of reservations and off-reservation trust land within the Colorado River Basin (29 reservations are listed in **Section TA 18.1**).[26]

Assumptions

- Trust land includes land within the borders of established reservations and off-reservation trust land.
- For the water deliveries analysis, the assumptions of the CRSS modeling (**Appendix A**, CRSS Model Documentation) and SAM modeling (**Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation) apply.
- For potential impacts on agricultural land, the assumptions of the agricultural modeling apply (see **TA 16**, Socioeconomics, for more details).

Impact Indicators

- Percentage of normal water entitlement delivered to Upper and Lower Basin Tribes
- Changes in acres of irrigated tribal agricultural land in the Lower Basin

Issue 1: How would changes in dam operations affect tribal water rights, water deliveries, and water storage and conservation options?

With respect to potential tribal water deliveries, the alternatives can be distinguished based on the following characteristics:

- The maximum shortage, which affects the relative frequency and severity of Lower Basin water shortages, including potential dead pool–related reductions (that is, releases reduced by low Lake Mead levels or outlet limits).
- The approach used to distribute Lower Basin water under shortages.
- Options for tribes and other water users to conserve and store water in Lake Powell or Lake Mead.

Figure TA 18-2 and **Table TA 18-5** in **TA 18**, Indian Trust Assets, summarize the alternatives based on these characteristics. The following sections summarize the anticipated effects of the alternatives on water deliveries and the storage and conservation options.

[26] As discussed in **Section 3.18.1**, one of the 30 Basin Tribes does not have an established reservation; therefore, there are 29 reservations.

Upper Basin

Water Entitlements and Deliveries

No alternative would affect Upper Basin tribal water entitlements or deliveries.

Storage and Conservation Options

The No Action and Basic Coordination Alternatives have no new water storage mechanisms and would not affect water storage and conservation by Upper Basin Tribes. The other four alternatives, including the Preferred Alternative, do have new storage and conservation mechanisms. See **Chapter 2**, Description of Alternatives, and **Appendix S**, Additional Description of Alternatives, for a full description of these mechanisms and how they would operate. Note that in all cases, stored water would be available for water transactions with other Upper Basin water users, both within and across Upper Division States.

Lower Basin

Water Entitlements

The approaches to distributing Lower Basin shortages incorporated in all alternatives are designed to explore a wide range of potential concepts and impacts; they do not reflect an intention by Reclamation to alter apportionments or water entitlements. However, because the concepts would affect a range of users, impacts on deliveries to different entities are analyzed, and addressed in **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation.

Water Deliveries

In this analysis, three main factors combine to determine the potential Lower Basin tribal water deliveries in any given year:[27] (1) the magnitude of potential shortages, (2) the distribution method used to allocate water under shortages, and (3) the frequency of dead pool–related reductions.[28] This analysis focuses on the first two factors. The third factor, dead pool–related reductions, is not a focus of this analysis.

Figure TA 18-3 in **TA 18**, Indian Trust Assets, illustrates how the percentage of normal water delivery changes as shortages become more severe under different distribution methods. For the purposes of this analysis, tribes are aggregated into the following four groups based on entitlement priorities:[29]

- The "AZ CAP NIA" group has the most junior entitlements and includes tribes with Arizona CAP NIA-A and NIA-B priorities. This group consists of four tribes with contracts totaling approximately 177,000 afy.
- The "AZ CAP Indian, CAP M&I, and AZ 4i" group includes tribes with Arizona CAP Indian, CAP M&I, and Arizona 4i priorities. This group consists of 13 tribes and 16 individual entitlements (including mainstream water reserved for future settlement and unallocated), totaling approximately 374,000 afy.

[27] The phrase "potential water deliveries" is intended to recognize that some tribal water entitlements are not fully developed or utilized. For simplicity, this analysis assumes that water deliveries and water entitlements refer to the same quantities of water.
[28] Discussion of dead pool–related reductions can be found in **TA 4**, Water Deliveries.
[29] The number of tribes, water entitlements, and amounts listed below come from the SAM (see **Appendix C**, Shortage Allocation Model and Alternative Distribution Model Documentation, for modeling assumptions and descriptions of priority nomenclature).

- The "AZ 3" includes one tribe with Arizona third priority, totaling 50,000 afy.
- The PPR group is the most senior entitlements; this group includes five tribes in all three Lower Division States. This group of five tribes includes 15 discretely quantified entitlements totaling approximately 503,000 afy.

The DMDU analysis integrates information on the percentage of futures in which different amounts of shortages are estimated to occur under the different alternatives. For tribal water deliveries, deliveries of 20, 40, 60, and 80 percent of normal deliveries are modeled. The results show the percentage of futures in which these thresholds are met in 90 percent or more of the years within each modeled future.

The DMDU figures are presented in **Figure TA 18-4** through **Figure TA 18-12** in **TA 18**, Indian Trust Assets. Solely for the purposes of considering vulnerability within the DMDU modeling framework, a "preferred minimum performance" outcome is defined as a future trace in which at least 80 percent of normal water deliveries are estimated to be delivered in at least 90 percent of the years in a modeled future. In contrast, an "undesirable performance" future means that the preferred minimum performance criteria are not met. The 80 percent threshold was chosen as the preferred minimum performance because it is the model outcome with the largest quantity of water delivered.[30]

Key findings differentiating the alternatives based on the full-period DMDU modeling are listed below. See **Section TA 18.2.2** for additional details, including key findings by priority group.

- There is no alternative that is the most robust across the priority groups in terms of maximizing water deliveries to all tribes. The alternatives perform differently for the priority groups. For some priority groups, the performance depends on the importance placed on results, considering only shortages relative to the frequency of futures with dead pool–related reductions.
- Considering shortages only (that is, not considering dead pool–related reductions), the No Action Alternative is estimated to meet the preferred minimum performance criteria in 100 percent of normal water deliveries to all priority groups except the AZ CAP NIA group. This result is likely due to a lower maximum shortage compared with the other alternatives. However, the No Action Alternative has the highest potential for dead pool–related reductions of any alternative, with 70 percent of futures estimated to have dead pool–related reductions. Therefore, water delivery would be unlikely under the No Action Alternative.
- The CCS Comparative Baseline is similar to the No Action Alternative, except 22 percent of futures meet the preferred minimum performance criteria for the CAP Indian, CAP M&I, and AZ 4i priority group, and 6 percent of futures meet the preferred minimum performance criteria for the CAP NIA group. Dead pool–related reductions are estimated to occur in 50 percent of modeled futures, which is less frequent compared with the No Action Alternative.
- The Representative Preferred Alternative is the second-best performer for the PPR priority group. It is not among the most robust alternatives for any other priority group. Impacts under the Preferred Alternative may be different from what is shown in the DMDU figures for the Representative Preferred Alternative, as this alternative provides a framework that allows for

[30] In this context, "preferred minimum performance" and "undesirable performance" are terms selected to understand a modeling analysis, and they do not imply any policy, legal conclusion, or other conclusions about the analysis or ITAs.

shortages to be distributed based on agreements among states that may arise, consistent with sideboards described in **Chapter 2**.

- The Basic Coordination Alternative is not among the most robust alternatives for any priority group.
- The Enhanced Coordination Alternative has a more complicated pattern of robustness. Twenty-one percent of futures meet the preferred minimum performance criteria for all priority groups; this is less than some other alternatives. This is likely because shortages start relatively early compared with the other alternatives, and there is a high maximum shortage (see **Figure TA 18-2** and **Table TA 18-5** in **TA 18**, Indian Trust Assets). However, this alternative performs well in terms of delivering at least 60 percent of normal water, as it does so in 91–100 percent of modeled futures for all priority groups. This result is likely due, in part, to its use of the pro rata distribution method. Finally, this alternative has 16 percent of futures with dead pool–related reductions, which is among the fewest of the options modeled.
- Considering only shortages, the Maximum Operational Flexibility Alternative is more robust than the Enhanced Coordination Alternative for the two more senior water entitlements groups (PPR and AZ 3) and is less robust than the Enhanced Coordination Alternative for the two less senior water entitlements groups (AZ CAP Indian, M&I, and 4i; CAP NIA). It has the lowest percentage of futures with dead pool–related reductions (9 percent) of all the options modeled.
- The Supply Driven Alternative (LB Priority approach) generally is similar or less robust than the Maximum Operational Flexibility Alternative with respect to shortages for three of the four priority groups and has a higher percentage of futures with dead pool–related reductions (24 percent).
- The Supply Driven Alternative (LB Pro Rata approach) is closest to the Enhanced Coordination Alternative but does not meet the preferred minimum performance criteria as often; therefore, it is less robust.
- It is important to consider the first decadal subperiod, as the Preferred Alternative is a 10-year decision framework. The conclusions above all hold for the first decadal subperiod with the one exception: for the Arizona Priority 3 group, a case could be made that either the Maximum Operational Flexibility, Supply Driven (LB Priority approach), or Representative Preferred Alternatives are the best performing.[31] These three alternatives have various trade-offs between water deliveries considering only shortages and the percentage of futures with a dead pool-related reduction.

Storage and Conservation Options

The No Action and Basic Coordination Alternatives have no water storage mechanisms that would affect Lower Basin Tribes or the quantities of water available to them. Under both alternatives, water conserved under previous mechanisms that remains in Lake Mead in 2027 would be delivered in accordance with existing agreements. The other four alternatives do contain new water storage and conservation mechanisms. See **Chapter 2**, Description of Alternatives, for a full description of these mechanisms and how they would operate. Note that in all cases, stored water would be available for

[31] In the full period results, the Maximum Operational Flexibility Alternative performs better than the Representative Preferred Alternative.

water transactions with other Lower Basin water users, both within and across the Lower Division States. The Enhanced Coordination Alternative is unique in that it explicitly allows for compensating tribes for water used to contribute to a federally managed conservation pool in Lake Mead. See **Section TA 18.2.2** for additional details.

Issue 2: How would changes in dam operations affect Indian trust lands?

Changes in dam operations under the different alternatives would not affect the borders of established reservations or the definitions of any trust lands. Trust land will remain trust land. Future potential acquisitions of land into trust are not limited by the operations. Further, in addition to (uncontrollable) drought conditions in any given year, the different alternatives of various distributions of the available water could add an incremental impact on the use of trust lands. An important aspect of the use of trust lands involves agricultural land, as fluctuations in water levels are estimated to result in some tribal agricultural lands being fallowed. Other changes in the use of tribal land and resources are discussed in **TA 13**, Tribal Resources. The considerations therein generally apply to Trust and non-Trust resources.

Agricultural Land

The potential impacts of changes in dam operations on agricultural land are assumed to be inversely dependent on water deliveries, meaning agricultural impacts are estimated to increase as water deliveries decrease.

Upper Basin

As noted in the Upper Basin water deliveries section above, none of the alternatives, including the Representative Preferred Alternative, would directly or indirectly affect water deliveries to Upper Basin Tribes. However, changes in storage and conservation options under some alternatives could provide opportunities for tribal participation. All else equal, the new mechanisms for conserving and storing water for Upper Basin Tribes (contained in the Preferred, Enhanced Cooperation, Maximum Operational Flexibility, and Supply Driven [both LB Priority and LB Pro Rata approaches] Alternatives) would provide additional options for tribes in the Upper Basin.

Lower Basin

TA 16, Socioeconomics, discusses the potential impacts of changes in dam operations and resulting changes in water deliveries on tribal and non-tribal agricultural economies in the Lower Basin. Estimates are presented for several socioeconomic metrics: acres of fallowed agricultural land, direct market value, jobs, and economic output. Results are presented at the state level and by priority groups for Arizona, California, and Nevada. See **TA 16**, Socioeconomics, for a full discussion of the modeling and results. This section focuses on the acres of fallowed land as an indicator of potential impacts **to** Trust land.

Table TA 18-6 summarizes the modeling results for estimated changes in fallowed tribal agricultural land. Some key findings include the following:

- As indicated in the Lower Basin water deliveries analysis above, the seniority of water entitlements combined with the distribution method makes a large difference in the results.
- Tribal agriculture in Arizona is estimated to experience the largest impacts in terms of the absolute changes in acres of fallowed land. This is likely because the majority of the

reservation land is in Arizona (see **Figure TA 18-1** in **TA 18**, Indian Trust Assets). The Representative Preferred Alternative is would fallow the second-least number of acres in Arizona, relative to the other alternatives.

- No alternative is clearly the most robust for Arizona. The different alternatives and the CCS Comparative Baseline have varying trade-offs between fallowed acreage under shortages and the percentage of futures with dead pool–related reductions.
- In California and Nevada, impacts are only associated with the alternatives that use the pro rata distribution (the Enhanced Coordination and Supply Driven [LB Pro Rata approach] Alternatives). All the other alternatives, including the Representative Preferred Alternative, and the CCS Comparative Baseline use some variation of the priority system and estimate no reductions in water deliveries; therefore, there would be no fallowed agricultural land in these states.
- The Maximum Operational Flexibility Alternative performs the best for California and Nevada; this is because there are zero fallowed acres and the percentage of futures with dead pool–related reductions are minimized. This would be true for PPRs in Arizona as well.

Issue 3: How would changes in dam operations affect other ITAs?

Changes in dam operations would not directly affect the status and corpus of other ITAs. Trust assets will remain trust assets. Future potential acquisitions of assets into trust are not limited by the operations. Further, in addition to (uncontrollable) drought conditions in any given year, changes in dam operations could incrementally affect water levels, vegetation, fish, and wildlife, and therefore could indirectly affect the use of ITAs. General changes in vegetation, fish, and wildlife are discussed in their respective sections of this Final EIS.

Summary Comparison of Alternatives

How the alternatives affect ITAs depends on the type of ITA and other factors. For both irrigated agriculture and water deliveries in the Lower Basin, the most robust alternative depends on the interactions between the priority of water entitlements, the maximum shortages, and the percentage of futures with dead pool–related reductions. See **Section TA 18.2.8**, Summary Comparison of Alternatives, for more detailed summary comparisons of the alternatives by the type of ITA, basin, and priority group.

In general, the action alternatives are more robust than the No Action Alternative for water deliveries and irrigated agricultural land. All else equal, the action alternatives that use a variation of the priority distribution method (the Representative Preferred, Basic Coordination, Maximum Operational Flexibility, and Supply Driven [LB Priority approach] Alternatives) are more robust for more senior water entitlements; the action alternatives that use a variation of the pro rata distribution method (the Enhanced Coordination and Supply Driven [LB Pro Rata approach] Alternatives) are more robust for more junior water entitlements.

3.19 Visual Resources

3.19.1 Affected Environment

Visual resources are the physical features that make up the visible landscape, including land, water, vegetation, topography, and human-made features such as buildings, roads, utilities, and structures. They also include the response of viewers to those features.

Visual resources are important both to visitors to GCNP, Glen Canyon NRA, and Lake Mead NRA and to the Basin Tribes who use these lands for subsistence or ceremony uses. The Grand Canyon Protection Act of 1992 specifically calls for the conservation of visual resources, which are also a key component of federal management of these areas. GCNP, Glen Canyon NRA, and Lake Mead NRA are managed under their general plans which identify management direction for visual resources as part of their general management plan, which is described in **TA 19.1**, Affected Environment, in **TA 19**, Visual Resources.

Lake Powell and Glen Canyon Dam

Landscape Character

The landscapes of the Lake Powell and Glen Canyon area are characterized by sweeping vistas of red rock towers, buttes, and mesas typical of the Colorado Plateau (Fenneman 1931). Navajo Sandstone and desert varnish dominate the existing landscape character with Lake Powell framing these natural features. Lake Powell has deposits of calcium carbonate, which become visible as reservoir levels decrease. At lower lake elevations, the colorful sandstone canyon walls show a light-toned band of calcium carbonate deposit between the full reservoir elevation and the lower reservoir elevation; these deposits contrast with the natural, red-colored sandstone (see **Figure TA 19-1**, in **TA 19**, Visual Resources). Additionally, sediment deltas have formed near the inflow areas of Lake Powell as a result of sediments carried by the Colorado River and the San Juan, Dirty Devil, and Escalante Rivers, resulting in downstream-progressing deltas. These appear as expansive, deep, and eroding mud flats cut by river channels. For more information on existing landscape character, refer to **TA 19.1**, Affected Environment, in **TA 19**, Visual Resources.

Attraction Features

The analysis focuses on Cathedral in the Desert and Glen Canyon Dam, consistent with the 2007 Final EIS and 2024 Final SEIS. These were selected to focus on visibility of specific geologic features and large-scale built structures associated with each reservoir. Note that the discussion of potential impacts on recreation sites and other viewing locations is described under Issue Statement 2. For more information on these attraction features, see **TA 19.1**, Affected Environment, in **TA 19**, Visual Resources.

Lake Mead to Hoover Dam

Landscape Character

The landscapes of the Lake Mead and Hoover Dam area are similar to those described for the Lake Powell area, except the adjacent landscapes are more typical of the Basin and Range region, characterized by parallel, north–south-oriented mountain ranges surrounded by nearly level, typically undrained basins (Fenneman 1931). Similar to Lake Powell, Lake Mead has deposits of calcium

carbonate that contrast with the natural rock colors. For more information on existing landscape character, refer to **TA 19.1**, Affected Environment, in **TA 19**, Visual Resources.

Attraction Features

The analysis will focus on Hoover Dam, consistent with the 2007 Final EIS and 2024 Final SEIS. For more information on this attraction feature, see **TA 19.1**, Affected Environment, in **TA 19**, Visual Resources.

Hoover Dam to SIB

The landscapes from the Hoover Dam area to the SIB are characterized by arid mountain ranges and intervening desert plains associated with the Basin and Range region (Fenneman 1931). The availability of Colorado River water has resulted in large areas of irrigated landscapes, including agricultural lands in Arizona, California, and Nevada (Lower Division States), which have altered the natural landscapes. This increased water availability has introduced vivid greens associated with crops and ornamental plantings into these landscapes and has expanded the influence of the Colorado River into adjacent arid lands beyond the narrow, natural riparian corridor.

3.19.2 Environmental Consequences

Methodology

Reclamation used methods similar to those in the 2007 Final EIS and 2024 Final SEIS to analyze potential impacts on visual resources. This analysis assesses the potential effects on attraction features, the extent of the visible calcium carbonate ring, and exposure of sediment deltas at reservoir inflow areas, while incorporating the DMDU framework for this EIS. Additionally, this analysis considers the effects of expanded shoreline exposure on the area's landscape character.

Using modeling and DMDU concepts, the analysis first focuses on the percent of time during the planning window that Lake Powell would decrease below elevation 3,550 feet. At that elevation, Cathedral in the Desert and other geological attraction features—including Gregory Bridge, La Gorce Arch, and other features inundated by Lake Powell—would become visible and accessible. Based on historical averages, Lake Powell was below 3,550 feet approximately 9.9 percent of months between October 2007 and May 2025. The alternatives comparison focuses on maintaining this lake elevation for at least 10 percent of the months during the planning window. Conversely, this analysis also identifies the percentage of preferred minimum performance futures in which Lake Powell would be above 3,550 feet, resulting in less of the upstream side of Glen Canyon Dam being visible, as higher reservoir levels obscure the structure.

The potential height of the calcium carbonate ring was calculated by comparing differing reservoir elevations with the full pool elevations of Lake Powell (3,700 feet) and Lake Mead (1,229 feet) under DMDU concepts. The assessment of effects from sediment deltas and shoreline exposure considers these differing reservoir elevations and references the analysis conducted in the 2007 Final EIS.

Reclamation added two new analysis items, similar to the 2024 Final SEIS, to assess impacts on the Colorado River's landscape character and broader landscape character in the Lower Division States. This assessment is based on changes in modeled hydrologic conditions under the No Action Alternative and CCS Comparative Baseline, as well as management direction associated with the action

alternatives. To assess potential changes to the landscape character along the Colorado River (between Glen Canyon Dam and Lake Mead), this analysis includes a qualitative assessment of effects associated with lower flow rates and the potential inability to conduct HFEs from Glen Canyon Dam. For more information on historic flow rates along the Colorado River, refer to **Section TA 19.2.1**, Methodology, in **TA 19**, Visual Resources, and **Section 3.3**, Hydrologic Resources**.**

The assessment of potential impacts on the broader landscape character in the Lower Division States considered changes in annual Colorado River water supplies available to these states. This assessment identifies the extent of large-scale changes in visual character in irrigated landscapes, including changes associated with agricultural production through shortages and the potential for Lake Mead to reach dead pool–related reductions, as described in **Section 3.4**, Water Deliveries. This analysis considers and references assessment items contained in **Section 3.16**, Socioeconomics, including the effect of each alternative's proposed distribution of water on agricultural operations and the effect of increased dust generation from aridification of exposed lands, as described in **Section 3.7**, Air Quality, potentially impacting visibility and views within GCNP and other visually sensitive landscapes.

Impact Analysis Area

The visual resources impact analysis area was defined as the area within 5 miles of the Colorado River from Lake Powell to the SIB, including the full pool elevations of Lake Powell and Lake Mead. Visual effects beyond this geographic area were considered where appropriate, including the potential effects on the broader landscape character associated with potential decreased water availability for the Lower Division States. For more details on the impact analysis area, refer to **Section TA 19.2.1**, Methodology, in **TA 19**, Visual Resources.

Assumptions

- The analysis methods are consistent with the 2007 Final EIS and 2024 Final SEIS. Attraction features analyzed include Cathedral in the Desert, Glen Canyon Dam, and Hoover Dam.
- Decreasing flow rates along the Colorado River, and the potential inability to conduct HFEs from Glen Canyon Dam, would modify the river corridor's natural, visual character by limiting natural flooding processes.
- This EIS references the analysis from the 2007 Final EIS and 2024 Final SEIS regarding impacts associated with expanding sediment deltas.
- Decreasing water availability for the Lower Division States would result in large-scale changes to the visual character of irrigated landscapes, including those associated with agricultural production.

Impact Indicators

- Attraction features: Qualitative assessment describing effects on visibility and access to Cathedral in the Desert and effects from increased visibility of the upstream sides of Glen Canyon Dam and Hoover Dam, informed by the CRSS and DMDU analyses. Quantitative analysis showing the percentage of futures that meet the preferred minimum performance level where Lake Powell is below 3,550 feet (and thus Cathedral in the Desert would be visible and accessible) in at least 10 percent of months under each alternative. Conversely, this analysis

identifies the percentage of futures that meet the preferred minimum performance level in which Lake Powell is above 3,550 feet, reducing visibility of the dam's upstream face.

- Calcium carbonate rings: Comparison of modeled ring height (feet) at Lake Powell and Lake Mead under each alternative, considering the CRSS and DMDU analyses.
- Exposed shoreline and sediment deltas: Qualitative assessment referenced from the 2007 Final EIS and 2024 Final SEIS, considering differing reservoir elevations under each alternative, to assess receding shorelines and formation of sediment deltas resulting from lower reservoir elevations.
- Colorado River landscape character: Qualitative description of the effect associated with proposed flow rates and the potential to conduct HFEs from Glen Canyon Dam under each alternative, considering modeling presented in **Section 3.9**, Vegetation Including Special Status Species; **Section 3.5**, Geomorphology and Sediment; **Section 3.14**, Recreation; and **Section 3.7**, Air Quality.
- Broader landscape character: Qualitative description of the effects associated with potential decreases in water availability for the Lower Division States on the broader landscape character. This includes considering modeling associated with potential changes to crop production resulting from proposed distribution of water, as described in **Section 3.16**, Socioeconomics, as well as the potential for Lake Mead to reach dead pool–related reductions as described in **Section 3.4**, Water Deliveries.

Issue 1: How would management of reservoir elevations affect visibility of attraction features?

The assessment of impacts on landscape character associated with the elevations of Lake Powell considers two concepts. The assessment notes that some visitors view visibility and access to Cathedral in the Desert and other attraction features inundated by Lake Powell (below 3,550 feet) as a benefit, while others prefer higher water levels. For more information on the first portion of this issue, refer to **Section TA 19.2.2**, Visibility of Attraction Features, in **TA 19**, Visual Resources.

The second part of the analysis focuses on keeping the Lake Powell water levels high, which reduces the visibility of Glen Canyon Dam, specifically when above 3,550 feet. As reservoir levels drop and more of the dam is exposed, its visual prominence increases and can dominate the surrounding landscape. As shown in **Figure TA 19-3** in **TA 19**, Visual Resources, the Enhanced Coordination and Maximum Operational Flexibility Alternatives would result in more preferred minimum performance futures where less of the upstream side of Glen Canyon Dam is visible because higher water levels obscure the structure. Lower flows could keep Lake Powell at higher elevations under the Enhanced Coordination and Maximum Operational Flexibility Alternatives compared with the CCS Comparative Baseline, No Action Alternative, Basic Coordination Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches). Considering the first 10 years (modeled 2027-2039), the CCS Comparative Baseline, No Action Alternative, and all action alternatives would have similar results as during the full modeling period except the Enhanced Coordination Alternative, which would have a smaller percentage of preferable futures over the first 10 years compared to the full modeling period. The Representative Preferred Alternative exhibits a similar performance as the No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives

for the first 10 years (modeled 2027-2039 period) with the results being within the range analyzed associated with these alterantives.

As shown in **Figure TA 19-4** in **TA 19**, Visual Resources, comparing DMDU modeling with the driest historic 10-year average flows, the CCS Comparative Baseline, No Action Alternative, Basic Coordination Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would require higher flows to maintain similar elevations, which makes those alternatives more vulnerable to missing the preferred minimum performance level. Specifically, those alternatives would be more vulnerable than the Enhanced Coordination and Maximum Operational Flexibility Alternatives, with over 75 percent of traces in the reference hydrology exhibiting conditions resulting in the potential for Lake Powell to decrease below 3,550 feet for 10 percent or more of months during the planning period. Based on updated modeling, approximately 50 percent of traces in the reference hydrology under the Enhanced Coordination Alternative and Maximum Operational Flexibility Alternatives exhibit conditions that are expected to result in Lake Powell falling below 3,550 feet for 10 percent or more of the planning period. The Representative Preferred Alternative exhibits a similar performance as the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) with the results being within the range analyzed associated with these alternatives.

Modeling of lake levels within Lake Powell and Lake Mead indicates that, under the CCS Comparative Baseline and the No Action, Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives, Hoover Dam visibility follows the same pattern described for Glen Canyon Dam. Under the Basic Coordination Alternative and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), based on managing higher reservoir levels in Lake Mead than in Lake Powell, less of the upstream side of Hoover Dam would be visible, with comparatively more of the upstream side of Glen Canyon Dam being visible, as described above. Therefore, as Lake Mead reservoir levels decrease, exposing more of the dam's concrete structure, its effect on the area's landscape character would increase and further dominate the landscape character.

Issue 2: How would management of reservoir elevations affect landscape character, including visibility of calcium carbonate rings, exposed shoreline, and sediment deltas?

The assessment compares how often modeled futures fall into reservoir elevation ranges relative to full pool, and relates those ranges to changes in landscape character. This difference in reservoir elevations creates a light-toned band of calcium carbonate deposit as well as generating larger sediment deltas and exposing more shoreline. The lower the lake levels become, the impacts on landscape character increase including effects from calcium carbonate rings, exposed shoreline with trash and other debris, and sediment deltas. To compare alternatives, the assessment focused on whether calcium carbonate rings would exceed historic maximums at any time during the planning period.

For Lake Powell, the tallest calcium carbonate ring, which occurred in February 2023, was 179 feet tall. As shown in **Figure TA 19-5**, **Figure TA 19-6**, and **Figure TA 19-7** in **TA 19**, Visual Resources, based on updated modeling, all alternatives would exceed the historical maximum during the modeling period. In looking at a higher threshold of 200 feet tall, the CCS Comparative Baseline and the No Action Alternative, Basic Coordination Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would result in more futures where the calcium carbonate rings would exceed the 200-foot maximum during the modeling period. Only 5 percent, 4 percent, 13 percent, and 18 percent of futures under these alternatives, respectively, would result in calcium carbonate rings

being less than 200 feet tall for all the months of modeling. Considering the first 10 years (modeled 2027-2039), the CCS Comparative Baseline, No Action Alternative, and all action alternatives would have similar results as the full modeling period except all the action alternatives would result in slightly higher percentage of preferable futures over the first 10 years compared to the full modeling period. The Representative Preferred Alternative would potentially exceed the 200-foot maximum height, with 45 percent of futures resulting in calcium carbonate rings being less than 200 feet for all months of modeling for the first 10 years (modeled 2027-2039 period) and 24 percent of futures during the full modeling period, with these results within the range analyzed associated with these alterantives.

For Lake Mead, the tallest calcium carbonate ring, which occurred in July 2022, was 180 feet. As shown in **Figure TA 19-8**, **Figure TA 19-9**, and **Figure TA 19-10** in **TA 19**, Visual Resources, based on updated modeling, all alternatives would exceed the historical maximum during the modeling period except for the Supply Driven Alternative (LB Pro Rata approach) which would have a 1 percent of futures where this threshold is not exceeded. In looking at a higher threshold of 200 feet tall, the CCS Comparative Baseline and the No Action Alternative would result in more futures where calcium carbonate rings would exceed the 200-foot maximum during the modeling period, with only 13 percent and 6 percent of futures under these respective alternatives resulting in calcium carbonate rings being less than 200 feet tall for all the months of modeling. Under the Basic Coordination Alternative, Enhanced Coordination Alternative, Maximum Operational Flexibility Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), these percentages would increase to 16 percent, 14 percent, 20 percent, and 40 percent, respectively. Considering the first 10 years (modeled 2027-2039), the CCS Comparative Baseline, No Action Alternative, and all action alternatives would have similar results as the full modeling period with all alternatives, including the No Action Alternative, resulting in slightly higher percentage of preferable futures over the first 10 years compared to the full modeling period. The Representative Preferred Alternative would likely exceed the 200-foot maximum height, with 23 percent of futures resulting in calcium carbonate rings being less than 200 feet for all months of modeling for the first 10 years (modeled 2027-2039) and 17 percent of futures during the full modeling period, with these results within the range analyzed associated with these alterantives.

As described in the 2007 Final EIS, sediment deltas would continue to build up over time and would be visible as the reservoir elevations decrease, including under the No Action Alternative. The expanding sediment deltas would become populated by vegetation, including tamarisk, which would introduce into the landscape bright greens that would contrast with the arid landscapes adjacent to Lake Powell and Lake Mead. Additionally, the receding shorelines would expose trash and other debris, which would diminish the area's landscape character. The lower the lake levels become, impacts on landscape character associated with calcium carbonate rings, exposed shoreline with trash and other debris, and sediment deltas would increase. Additionally, lower lake levels would facilitate re-emergence of side canyons including public access for recreation (see **Section 3.14**, Recreation). The calcium carbonate ring, exposed shoreline with trash and other debris, and sediment deltas would modify the landscape character along the edge of Lake Powell. These modifications would be visible for motorists on Utah State Route 95, boaters on Lake Powell, recreationists at developed and undeveloped recreation areas, and hikers on trails adjacent to Lake Powell. Similarly, the calcium carbonate ring, exposed shoreline with trash and other debris, and sediment deltas would modify the landscape character along the edge of Lake Mead; these modifications would be visible for motorists on US

Highway 93 (between Boulder City, Nevada, and the Hoover Dam), boaters on Lake Mead (including visitors to Overton Beach and Pearce Ferry), and hikers on trails adjacent to Lake Mead.

Issue 3: How would management of releases from Glen Canyon Dam affect landscape character along the Colorado River?

The No Action Alternative and the CCS Comparative Baseline would include lowering releases from Glen Canyon Dam as Lake Powell elevations decrease; this would result in releases as low as 7.0 maf when elevations drop below 3,525 feet. Since neither the No Action Alternative nor the CCS Comparative Baseline would reduce releases from Glen Canyon Dam under 7.0 maf, including if Lake Powell drops below power pool but remains above dead pool, there would be minor, incremental impacts on the landscape character along the Colorado River, including through the Grand Canyon. The current trend of increasing bank armoring associated with expanding riparian vegetation areas (including tamarisk) would continue under the No Action Alternative and CCS Comparative Baseline. If the elevation of Lake Powell were to drop below dead pool, flows from Glen Canyon Dam could dramatically decrease, resulting in more extensive impacts on the landscape character, including the appearance of river features not visible under current conditions. Additionally, the positive influence of the moving, turbulent Colorado River adds to the existing landscape character, which would be degraded if releases from Glen Canyon Dam were dramatically reduced. The No Action Alternative would result in relatively short and few HFE releases, providing fewer opportunities for sand bar volumes to increase compared with the CCS Comparative Baseline, which would result in longer and more frequent HFE releases with more opportunities for increased sand bar volumes.

The Basic Coordination Alternative would result in impacts similar to those under the No Action Alternative and CCS Comparative Baseline, since it includes a similar range of releases from Glen Canyon Dam, but would include an increased number of futures where HFEs are conducted. The Enhanced Coordination Alternative, Maximum Operational Flexibility Alternative, and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) would include lower releases—as low as 4.7 maf, which is lower than historical minimum flows. Lower releases from Glen Canyon Dam would result in less water flowing along the Colorado River (and through the Grand Canyon), which could increase existing trends of bank armoring associated with more extensive riparian vegetation, including tamarisk. The Representative Preferred Alternative would also include lower releases, as low as 6.0 maf, which would result in similar impacts along the Colorado River as the other action alternatives but since these releases would result in more water flowing along Colorado River, the trends described above would be tempered. Lower releases also could limit the number of times an HFE could be triggered from Glen Canyon Dam; a trigger would only occur when the HFE furthers maintenance of target reservoir elevations.

The Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives would result in the greatest number of futures where HFEs are conducted. These lower flows may also result in the appearance of river features not visible under current conditions and less movement of the river's natural sandbars. If yearly elevations facilitate releases of 7.0 maf or more under the Enhanced Coordination, Maximum Operational Flexibility, Supply Driven (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternatives, the impacts under these alternatives would be similar to those described under the No Action Alternative and CCS Comparative Baseline as the lower releases from Glen Canyon Dam would be avoided. If the elevation

of Lake Powell were to drop below dead pool, flows from Glen Canyon Dam could dramatically decrease, resulting in impacts similar to those described under the No Action Alternative and CCS Comparative Baseline. For more information on the impacts on riparian vegetation, refer to **Section 3.9**, Vegetation Including Special Status Species; for impacts associated with sand bars, including their volume, refer to **Section 3.5**, Geomorphology and Sediment; and for impacts on recreation, including the visibility of river features, refer to **Section 3.14**, Recreation.

Issue 4: How would management of water availability for the Lower Division States affect landscape character?

Since the No Action Alternative would include minor (0.6 maf) adjustments to the distribution of water for Arizona and Nevada (but no adjustments for California) based on lowering Lake Mead elevations, there would initially be a limited incremental effect on irrigated landscapes, including those in agricultural use. If elevations in Lake Mead were to drop to dead pool (895 feet), flows from Lake Mead would dramatically decrease, resulting in lower water deliveries than currently allocated, affecting all three Lower Division States. As described in **Section 3.4**, Water Deliveries, the No Action Alternative would result in the most futures where dead pool–related reductions may be reached during the modeling period. Depending on the duration of these decreased water deliveries, the character of irrigated and agricultural landscapes within the Lower Division States would be modified through aridification of these areas; this would diminish the vivid greens associated with crops and ornamental plantings. The influence of the Colorado River on adjacent lands would narrow as these areas transition to their natural, arid condition. This would result in large-scale changes to the landscape character compared with the existing condition. The aridification of these lands could also result in more exposed soil, generating fugitive dust affecting visibility within the region, including from GCNP and other highly valued viewsheds. For more details on the impacts related to fugitive dust, please see **Section 3.7**, Air Quality.

The following alternatives all include shortages designed to avoid reaching dead pool, temper the impacts on the character of irrigated and agricultural landscapes within the Lower Division States, and avoid more extensive impacts if Lake Mead reached dead pool. If Lake Mead reaches dead pool elevation during the planning period, impacts for all alternatives would be similar to those described under the No Action Alternative.

The CCS Comparative Baseline would include a series of water supply adjustments for the Lower Division States based on lower elevations of Lake Mead. If water levels in Lake Mead drop below 1,075 feet, effects similar to those described under the No Action Alternative would occur, with conservation measures tempering these effects. As Lake Mead approaches dead pool, to avoid a dramatic decrease in water releases from Hoover Dam affecting all three Lower Division States, more reductions (up to 1.38 maf) could occur. These reductions to avoid reaching dead pool would temper the impacts on the character of irrigated and agricultural landscapes within the Lower Division States, as described under the No Action Alternative.

The Basic Coordination Alternative would have impacts similar to those under the No Action Alternative, as there would be adjustments to the distribution of water for Arizona and Nevada, but no adjustments for California, based on lowering Lake Mead elevations. As the Lake Mead elevation drops below 1,160 feet, shortages would begin; they would increase to 1.48 maf when Lake Mead is below 1,110 feet. Due to increased shortages under this alternative, the Basic Coordination Alternative

would result in the second most futures where dead pool–related reductions may be reached during the modeling period, as described in **Section 3.4**, Water Deliveries.

Under the Enhanced Coordination Alternative, there is a potential for greater shortages than under the No Action Alternative, CCS Comparative Baseline, and Basic Coordination Alternative, with shortages (up to 3.0 maf) being distributed pro rata among mainstream lower Colorado River water users independent of state. These shortages would occur in all three Lower Division States and incrementally affect irrigated landscapes, including those in agricultural use, based on the extent of the shortage. As described in **Section 3.4**, Water Deliveries, the Enhanced Coordination Alternative would result in the second least number of futures where dead pool–related reductions may be reached during the modeling period.

Under the Maximum Operational Flexibility Alternative, there is a potential for greater shortages than under the CCS Comparative Baseline and the Enhanced Coordination, No Action, and Basic Coordination Alternatives, with shortages being based on priority. These shortages would occur based on the total system effective storage and capacity, as described in Appendix S, **Section S.4.1.1**, Shortage Conditions, with shortages up to 4.0 maf. These shortages would occur in all three Lower Division States and incrementally affect irrigated landscapes, including those in agricultural use, based on the extent of the shortage. As described in **Section 3.4**, Water Deliveries, the Maximum Operational Flexibility Alternative would result in the least number of futures where dead pool–related reductions may be reached during the modeling period.

Under the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), there is a potential for larger shortages (up to 2.1 maf) than under the CCS Comparative Baseline and the No Action and Basic Coordination Alternatives, with shortages being distributed based on priority within a state or pro rata within that state as described in Appendix S, **Section S.5.1.1**, Shortage Conditions. If water levels in Lake Mead drop below 1,145 feet, effects similar to those described under the No Action Alternative are anticipated, with conservation measures tempering these effects. As lake levels continue to drop toward 1,000 feet, all three states would receive less water from the Colorado River under this alternative through proposed shortages, up to 2.1 maf, and conservation measures.

The Representative Preferred Alternative would result in shortages up to 3.0 maf, distributed based on Lower Basin consensus arrangements, if they exist, or otherwise distributed based on the priority system, with initial shortages beginning at 1.5 maf in 2027 and 2028. Consultation would occur if Lake Mead elevation were projected to be less than 1,000 feet to determine if additional reductions are needed in the Lower Basin (including Mexico). As described in **TA 4**, Water Deliveries, the Representative Preferred Alternative, similar to the Enhanced Coordination and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives, would be in the group of alternatives with the second-fewest futures involving dead pool–related reductions during the modeling period (Maximum Flexibility has the fewest futures). If Lake Mead reaches dead pool elevation during the planning period, impacts would be similar to those described under the No Action Alternative. These results are within the range analyzed across the other alternatives.

For more information on the impacts on agricultural operations, refer to **Section 3.16**, Socioeconomics, and for more information on the specific, state-level water deliveries, refer to **Section 3.4**, Water Deliveries.

Summary Comparison of Alternatives

In general, alternatives that facilitate higher reservoir elevations, maintain higher flows along the Colorado River, including through Grand Canyon, and support full water deliveries to the Lower Division States would result in the lowest impacts on visual resources and landscape character. While some users may prefer lower lake levels in Lake Powell, to allow Cathedral in the Desert and other attraction features inundated by Lake Powell to be visible and accessible, in general higher water levels would result in lower impacts on landscape character because there would be shorter calcium carbonate rings, less exposed shoreline (including trash and other debris), and smaller sediment deltas.

During wet hydrologic conditions, the range of alternatives would generally produce conditions where lake levels and flows along the Colorado River would result in minimal impacts on landscape character.

Under drier conditions, the Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives would facilitate more futures with higher reservoir elevations and lower flows along the Colorado River to minimize the risk of reaching dead pool. These alternatives also include larger water delivery shortages to the Lower Division States, which were designed to avoid reaching dead pool. These alternatives would result in shortages up to 3.0 maf and 4.0 maf, depending on the alternative, which would incrementally affect irrigated landscapes, including those in agricultural use, as shortages occur.

The CCS Comparative Baseline, No Action, Basic Coordination, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives would result in the most futures where landscape character is affected by lower water levels in Lake Powell and higher flows along the Colorado River, which would increase the risk of reaching dead pool. Based on management to keep water levels higher in Lake Mead than Lake Powell, under the Basic Coordination Alternative and Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), impacts associated with lower Lake Mead reservoir levels would be reduced and impacts would be similar to those under the Enhanced Coordination, Maximum Operational Flexibility, and Representative Preferred Alternatives.

The CCS Comparative Baseline and the No Action and Basic Coordination Alternatives would include smaller shortages in water deliveries to the Lower Division States—0.6 maf, 1.38 maf, and 1.48 maf, respectively—resulting in limited initial effects on irrigated landscapes compared with the Enhanced Coordination Alternative, Maximum Operational Flexibility Alternative, Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), and Representative Preferred Alternative. If dead pool is reached, however, the character of irrigated and agricultural landscapes within the Lower Division States would be more dramatically modified through aridification of agricultural and other irrigated landscapes. The Enhanced Coordination Alternative, Maximum Operational Flexibility Alternative, Supply Driven Alternative, and Representative Preferred Alternative would result in the least number of futures, with Maximum Operational Flexibility resulting in the fewest, where dead pool-related reductions may be reached during the planning period.

Chapter 4. Consultation and Coordination

4.1 Introduction

This chapter summarizes the consultation and coordination between Reclamation and specific federal, state, and local agencies, tribes, and the general public, during the preparation of this Final EIS. A detailed listing of coordination and consultation efforts with Basin Tribes is provided in **Appendix P**, Tribal Consultation and Coordination Efforts.

4.2 General Public Involvement Activities

The public involvement process leading to this Final EIS included a "pre-scoping" effort, scoping, consultation, and coordination with Basin Tribes, Basin States, federal and state agencies, water users, water conservation districts, non-governmental organizations (NGOs), other interested stakeholders, and the public. Reclamation developed and implemented a public involvement plan to satisfy the public participation requirements set forth in NEPA and to establish a consistent and constant level of engagement with interested parties and stakeholders. The multifaceted approach consisted of informational materials, consultation and coordination meetings, general and stakeholder outreach, and media relations.

A variety of informational materials were used to educate and inform audiences about the process and related issues. A website was established and maintained for this EIS process. It contains project documents, points of contact, and recordings of public meetings. An electronic mailing list was used to notify interested parties of website postings, project meetings, and documents. A project email account was maintained throughout the preparation of this Final EIS for interested parties to express opinions, ask questions, and submit comments.

Reclamation discussed the development of the proposed federal action with various agencies and organizations at: (1) agency/organization regular meetings; (2) public conferences and events sponsored by the agencies/organizations; and (3) meetings sponsored by Reclamation. The entities included the Basin States' water resource departments, water agencies within these states, contractors and associations for federal hydroelectric power, and NGOs. Reclamation also consulted with Indian tribes and Mexico.

A synopsis of the NEPA-related outreach efforts for this EIS follows:

Before formally initiating the NEPA process, in June 2022, Reclamation conducted a public "pre-scoping" effort requesting input on suggested mechanisms to ensure a wide range of stakeholder participation in the process and potential substantive elements to be considered for post-2026

operations.[1] Using the input received, on June 16, 2023, Reclamation published an NOI to prepare an EIS in the *Federal Register* (88 *Federal Register* 39455), formally initiating the public scoping process. Reclamation notified interested parties of the NOI and scoping comment period through an email notification to the project mailing list on June 16, 2023. Over the 60-day scoping period, Reclamation engaged with stakeholders through public webinars, tribal consultations, and technical education sessions.

Reclamation held three virtual public webinars during the scoping period. One meeting was attended by 185 people on July 17, 2023, from 1:00 p.m. to 2:00 p.m. mountain daylight time. The second virtual public meeting was attended by 112 people on July 18, 2023, from 10:00 a.m. to 11:00 a.m. mountain daylight time. The third virtual public meeting was attended by 66 people on July 24, 2023, from 6:00 p.m. to 7:00 p.m. mountain daylight time. The webinars included an opening statement, a presentation that summarized the NOI, a range of hydrologic and operational scenarios that informed people about the EIS analysis, an overview of potential alternatives being considered in the EIS, information on the EIS process schedule, and a question-and-answer session. The webinars were recorded and published on the project website. Public comments were accepted during the comment period by email and mail. Reclamation received a total of 24,290 comment letters from a wide range of interested parties, including federal, state, and local entities; tribes; NGOs; other stakeholder groups; and individuals. A Notice of Availability (NOA) for the Scoping Report (Reclamation 2023b) was published in October 2023 in the *Federal Register* (88 *Federal Register* 72535), summarizing all public comments received during the scoping period.

On January 16, 2026, the EPA published a Notice of Availability in the Federal Register for the Draft EIS. This kicked off a 45-day public review and comment period that ended on March 2, 2026. Reclamation hosted two virtual public meetings on January 29, 2026, and February 10, 2026. These meetings were held to provide information on the Draft EIS and answer clarifying questions; public comments were not heard during the meetings. Each meeting presented the same information. The question-and-answer portions of the meetings varied based on the public participants at each meeting. The webinars were recorded and published on the project website. A detailed overview of the public review process and comments received is provided in the Response to Public Comments (**Appendix R**).

4.3 Cooperating Agency Involvement

In compliance with NEPA, Reclamation worked with five cooperating agencies in the preparation of this EIS. As described in **Chapter 1**, cooperating agencies included the BIA, NPS, FWS, USIBWC, and WAPA. In developing the Final EIS, Reclamation hosted bi-weekly cooperating agency virtual

[1] The pre-scoping period began with a Federal Register notice on June 24, 2022 (87 *Federal Register* 37884). The Department received substantial feedback from partners, stakeholders and the public which Reclamation summarized in a Pre-Scoping Summary Report (Reclamation 2023a).

meetings to obtain data, information, resource analysis, and review internal documents. Additionally, individual agencies provided specific assistance, including the following:

- The BIA administers the federal trust responsibility to Indian tribes.
- Given its jurisdiction of NPS units within the Basin and administration of recreation on Lake Powell and Lake Mead, the NPS provided data and analysis of potential impacts on resources under its management.
- The FWS has jurisdiction by law and special expertise with respect to the ESA and biological resources within the study area and its administration of several National Wildlife Refuges in the study area. The FWS is providing resource expertise and is working closely with Reclamation in developing biological assessments to support consultation under Section 7 and Section 10 of the ESA.
- The USIBWC provided guidance and reviewed internal documents to ensure the EIS adequately addressed treaty obligations and international commitments. The USIBWC has worked with Reclamation to ensure that Mexico has been kept informed of all permissibly available information regarding the EIS process.
- The WAPA provided hourly release volume models for Glen Canyon Dam to aid in resource-specific modeling. The WAPA also provided hydroelectric modeling to assess impacts on power generation and revenue across the major generation facilities in the Upper and Lower Basins.

While not a cooperating agency, the USGS also contributed extensive expertise and resource modeling support.

4.4 Tribal Consultation and Coordination

For purposes of this NEPA process, Reclamation is consulting and coordinating with Basin Tribes who have entitlements to or contracts for Colorado River water and those that may be affected by or have interests in the proposed federal action. Tribes provided Reclamation with written comments on the proposed federal action and its potential effects on resources of tribal concern, including Indian trust assets. Reclamation's tribal engagement strategy was comprised of three approaches to tribal coordination and consultation: 1) Reclamation-hosted monthly virtual meetings for all Basin Tribes where updates on the process were provided, 2) regularly attending tribal meetings upon request and invite, including group meetings such as the Ten Tribes Partnership or the Inter-Tribal Council of Arizona, and 3) engaging in and initiating government-to-government consultations. In addition, Reclamation convened a group of interested Basin Tribes throughout 2024 and 2025 to discuss proposed management strategies and review modeling results, which ultimately informed the development of the Enhanced Coordination Alternative. Reclamation has provided the Basin Tribes with technical support during these discussions by modeling various strategies, including protection of key elevations of Lake Powell and Lake Mead. A detailed listing of coordination and consultation efforts with Basin Tribes is provided in **Appendix P**, Tribal Consultation and Coordination Efforts.

4.5 Endangered Species Act Consultation

Reclamation and FWS have historically consulted on Lower Basin and Upper Basin Colorado River operations separately and in alignment with effects related to operations at Glen Canyon Dam, including Lake Powell, and Hoover Dam, including Lake Mead. A Biological Assessment for annual releases from Glen Canyon Dam was completed in the summer of 2026, and a Biological Opinion is anticipated to be issued subsequently. This Biological Opinion will replace the existing 2007 and subsequent 2024 Interim Guidelines Biological Opinions (FWS 2007, 2024); the 2016 Glen Canyon Dam LTEMP Biological Opinion (FWS 2016), which considers monthly, daily, and hourly release volumes, will remain in effect. Section 7 consultations for current and future operations from Lake Mead to the SIB with Mexico were conducted in 2005, 2018, 2022, and 2024, and those Biological Opinions will cover implementation of the ROD for those reaches (FWS 2005, 2018, 2022, 2024). These Biological Opinions provide incidental take analysis and coverage for specific reductions in flow associated with defined operational conditions. The 2024 Biological Opinion provides incidental take analysis and coverage for reductions in flow of up to 3.0 maf from Lake Mead through January 31, 2028, encompassing operations within that timeframe, including anticipated 2027 operations, provided they remain within the analyzed operational conditions. An amendment to the LCR MSCP Habitat Conservation Plan and an associated Biological Assessment are currently being developed, with an anticipated completion in January 2028, to extend Section 7 and Section 10 consultation incidental take coverage for the LCR MSCP's Federal and non-Federal parties until 2055.

4.6 State and Local Water and Power Agency Coordination

Since the June 13, 2023 *Federal Register* notice announcing Reclamation's interest in soliciting comments on the development of the Post-2026 EIS, Reclamation has had various discussions with state and local water agencies regarding the proposed federal action. However, the Basin States have been continuously engaged in drought mitigation discussions related to post-2026 operations since the adoption of the 2019 DCPs. Reclamation has provided the Basin States technical support during these discussions by modeling various strategies, including protection of key elevations of Lake Powell and Lake Mead.

As they did for the 2007 Interim Guidelines NEPA process, the Basin States informed the projections of future depletions of Colorado River water anticipated in each State for this Post-2026 process. The Upper Colorado River Commission compiled Upper Basin depletions and submitted them to Reclamation, and Reclamation consulted with the Lower Division States regarding their respective depletions. These projections were used as input to Reclamation's operational modeling analysis, as discussed in this EIS.

The Upper Division States and Lower Division States each submitted proposals for alternatives to be considered in the Draft EIS in the spring of 2024. The Upper Division States submitted a revised proposal in December 2024, and the Lower Division States submitted a revised proposal in January 2025. Reclamation worked extensively with the Basin States to not only understand and gather additional information, but also to model and perform detailed preliminary analyses of their original and revised proposals. Reclamation discussed these results and potential refinements on numerous occasions with the Basin States prior to releasing the Draft EIS.

During the Draft EIS public comment period, Reclamation received individual comments from each of the seven Basin States, including proposed operational strategies. Subsequently, in May 2026, both the Upper Division States and Lower Division States submitted additional proposals. Throughout spring and summer 2026, Reclamation and the Department have engaged extensively with the Basin States to facilitate alignment among all seven states and the Secretary on key aspects of post-2026 operations for consideration in this NEPA process.

4.7 Non-Government Organizations

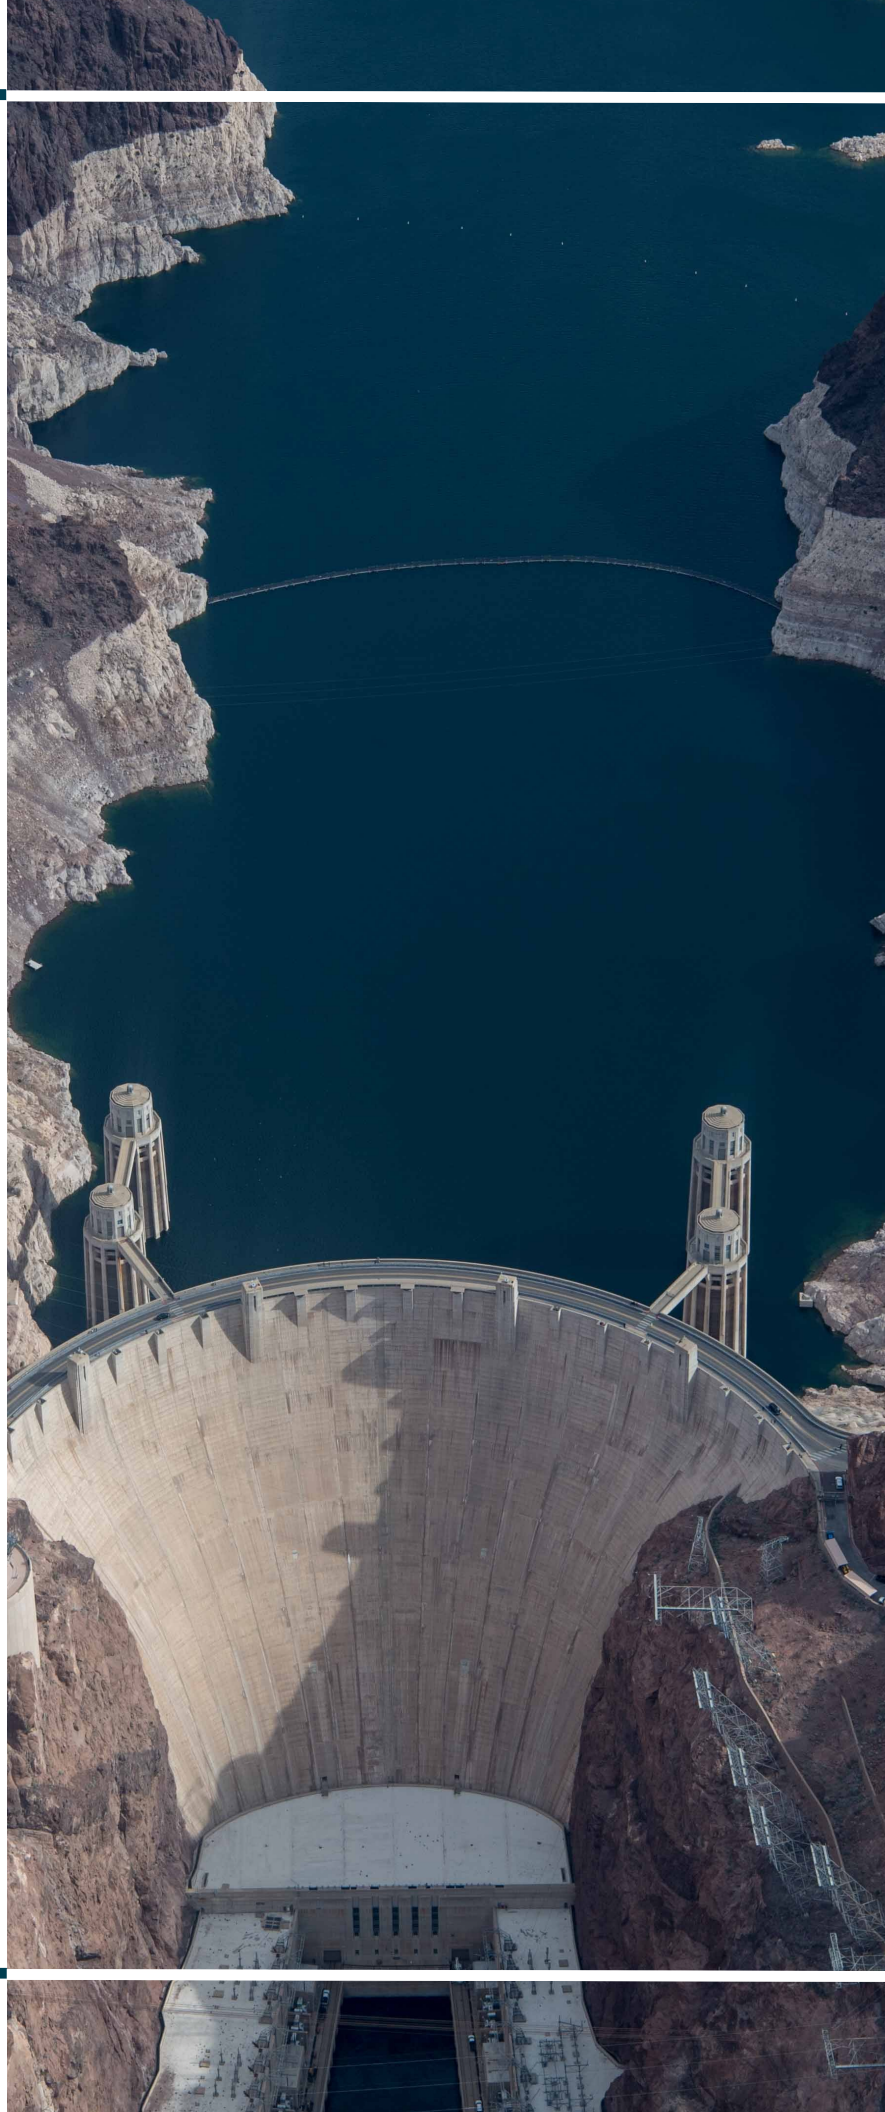
Reclamation contacted and coordinated the preparation of this Final EIS with multiple recreational and environmental groups. A consortium of environmental organizations that included the National Audubon Society, Western Resource Advocates, Theodore Roosevelt Conservation Partnership, American Rivers, The Nature Conservancy, Environmental Defense Fund, and Trout Unlimited developed what became the Maximum Operational Flexibility Alternative analyzed in this Final EIS. This consortium of environmental organizations developed and submitted its first proposal, "Cooperative Conservation Alternative," on March 29, 2024. As with the Upper Division and Lower Division States proposals, Reclamation worked extensively with these organizations to not only understand and gather additional information, but also to model and perform detailed preliminary analyses of their proposal. From 2024 through 2025, Reclamation met with representatives of the consortium of environmental organizations and worked with them to formulate what became the Maximum Operational Flexibility Alternative, as analyzed herein.

4.8 Other Consultations

Per Section 106 of the NHPA and its implementing regulations (36 CFR 800), Reclamation is consulting with the Arizona, California, Nevada, and Utah SHPOs; THPOs; affected tribes without THPOs; and consulting parties regarding the effects of the undertaking on historic properties. Reclamation developed a project specific programmatic agreement, in consultation with the SHPOs, THPOs, tribes without THPOs, cooperating agencies, and other consulting parties per 36 CFR 800.14 to outline a process to resolve any adverse effect on historic properties from Reclamation's operation of the Glen Canyon and Hoover Dams under the new operating guidelines for annual releases.

4.9 Consultations with the Government of Mexico Agencies

The USIBWC has engaged in consultation with agencies of Mexico regarding the proposed federal action and development of a new Minute to the 1944 Water Treaty. Reclamation has assisted USIBWC in conducting this consultation by providing information on the proposed federal action and by participating in briefings with the Mexican Section of the IBWC, the Mexico National Water Commission, and Mexico Secretariat of Foreign Relations. Consistent with these consultations, Section 397 of Public Law 109-432 directs Reclamation to use these treaty-related processes to identify potential impacts beyond the borders of the U.S. Accordingly, meetings with representatives of Mexico were conducted, during which representatives of Mexico provided their views, input, and concerns regarding the potential effects of the proposed federal action.



This Final EIS documents the hydrologic and water quality effects of the proposed federal action on water deliveries to Mexico (see **Chapter 3** and **Appendix N**, International Border Region of the Colorado River). Reclamation's modeling assumptions in this Final EIS are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Mission Statements

The **Department of the Interior** protects and manages the Nation's natural resources and cultural heritage; provides scientific and other information about those resources; and honors its trust responsibilities or special commitments to American Indians, Alaska Natives, and affiliated island communities.

The mission of the **Bureau of Reclamation** is to manage, develop, and protect water and related resources in an environmentally and economically sound manner in the interest of the American public.

Appendix A. CRSS Model Documentation

A.1 Background

The Colorado River Simulation System (CRSS), developed by the Bureau of Reclamation (Reclamation) in the 1980s, has long been a foundational tool for long-term policy and planning studies on the Colorado River. Initially built in Fortran and run on a Cyber mainframe, the original CRSS modeled twelve major reservoirs and approximately 115 aggregate diversion points across the Upper Colorado River Basin (Upper Basin) and Lower Colorado River Basin (Lower Basin) on a monthly time step. However, a key limitation of the Fortran-based CRSS was that the operating policies or rules were hardwired into the modeling code, making modification of those policies difficult.

To address emerging needs of the Interim Surplus Criteria Environmental Impact Statement (EIS) in the early 1990s, particularly for surplus and shortage studies in the Lower Basin, Reclamation created CRSSez, a simplified annual time step model implemented in Visual Basic (Bureau of Reclamation 1998). This model focused on Lake Powell and Lake Mead, simplifying upstream and downstream systems.

In 1994, Reclamation partnered with the University of Colorado and the Tennessee Valley Authority to develop RiverWare™, a more flexible and general-purpose modeling tool. Unlike its predecessors, RiverWare™ allowed users to define and prioritize operational rules through a graphical interface, enabling more dynamic and efficient scenario analysis (Zagona et al. 2001). By 1996, CRSS was fully transitioned into RiverWare™, maintaining the original model's structure and data while allowing for more adaptable rule sets.

Since then, CRSS has continued to evolve, with new rule sets developed to reflect current policies and improvements made to physical process methodologies. In 2005, CRSS-Lite was introduced as a faster, more efficient alternative to CRSSez, built within RiverWare™. It retained the complexity and accuracy of CRSS while significantly reducing execution time, making it a valuable tool for evaluating a wide range of operational strategies in the Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead Final EIS (2007 Final EIS).

In the 2010s, CRSS was used in various studies to identify current and future imbalances in water supply and demand across the Colorado River Basin (Basin) as part of the Colorado River Basin Water Supply and Demand Study and Tribal Water Study. CRSS also facilitated decision-making during the negotiation of the 2019 Drought Contingency Plan (DCP) and Minute 323 in 2017.

In 2023, Reclamation revised CRSS to reduce model bias and better characterize the variability and range of Upper Basin depletions. To address these issues, the updated model includes "not pre-

shorted" Upper Basin demands (rather than "pre-shorted" demands), as well as logic that limits the natural flow available for diversion by the Upper Basin agricultural water users by calibrating to historical Upper Basin gage records. This effort also included adding three new Upper Basin reservoirs to better model exports from the Basin and to more accurately model the seasonal timing of tributary water use. This version of CRSS – deemed CRSS version 6 – served as the baseline model used for this Final EIS.

A.2 Overview

CRSS simulates the operation of the major reservoirs on the Colorado River system and provides information regarding the projected future state of the system on a monthly basis. CRSS models 15 reservoirs, as shown in **Map A-1**, and approximately 359 water users aggregated on 184 modeled diversions (demands and return flows). The model is initialized on December 31, 2026, and run for 34 years, simulating conditions through December 31, 2060. Output variables include the volume of water in storage, reservoir elevations, releases from the dams, energy generation, streamflow, and diversions to and return flows from water users throughout the system.

CRSS requires a broad range of input data. Modeled reservoirs require physical parameters such as individual storage capacity, evaporation rates, bank storage, and release capabilities. Storage capacity and evaporation rates are derived from reservoir-specific studies or pan evaporation-based estimates, and Reclamation continues to fund work to improve these inputs. Reservoir evaporation assumptions and parameters are summarized in **Section A.10**. Other inputs include initial reservoir conditions (**Appendix G**), demand schedules for entities in the Upper Division States (**Appendix L**), Lower Division States (**Appendix M**) and the United Mexican States (Mexico), and future hydrologic natural flows at 29 locations (**Section A.3** and **Appendix F**). This appendix focuses on the assumptions regarding reservoir operations, particularly at Lake Powell and Lake Mead, as those vary by alternative, and other physical process calculations in CRSS (energy generation and salinity). Additional modeling assumptions had to be developed to model the storage and delivery mechanisms for conserved water and are included in **Appendix B**.

A.2.1 Model Uncertainty

CRSS projections are subject to multiple sources of uncertainty. One source is the model, which is a simplified representation of a complex system. Another component of uncertainty is the need to estimate physical processes, such as reservoir evaporation and transpiration from plants. The most impactful source of uncertainty is the future itself; models rely on assumptions about how the hydrology, water demand, and policy and operations will unfold. Reclamation works with stakeholders and scientists to develop the best modeling practices and most appropriate assumptions in light of the purpose of the model. It is important to understand the purpose, approach, and assumptions associated with projections and their inherent uncertainty to properly interpret the information they provide. Within this context, CRSS remains the most suitable and robust tool available for the comparative purposes of this Final EIS.

Map A-1
CRSS Modeled Reservoirs

Reservoir modeled in CRSS

Colorado River

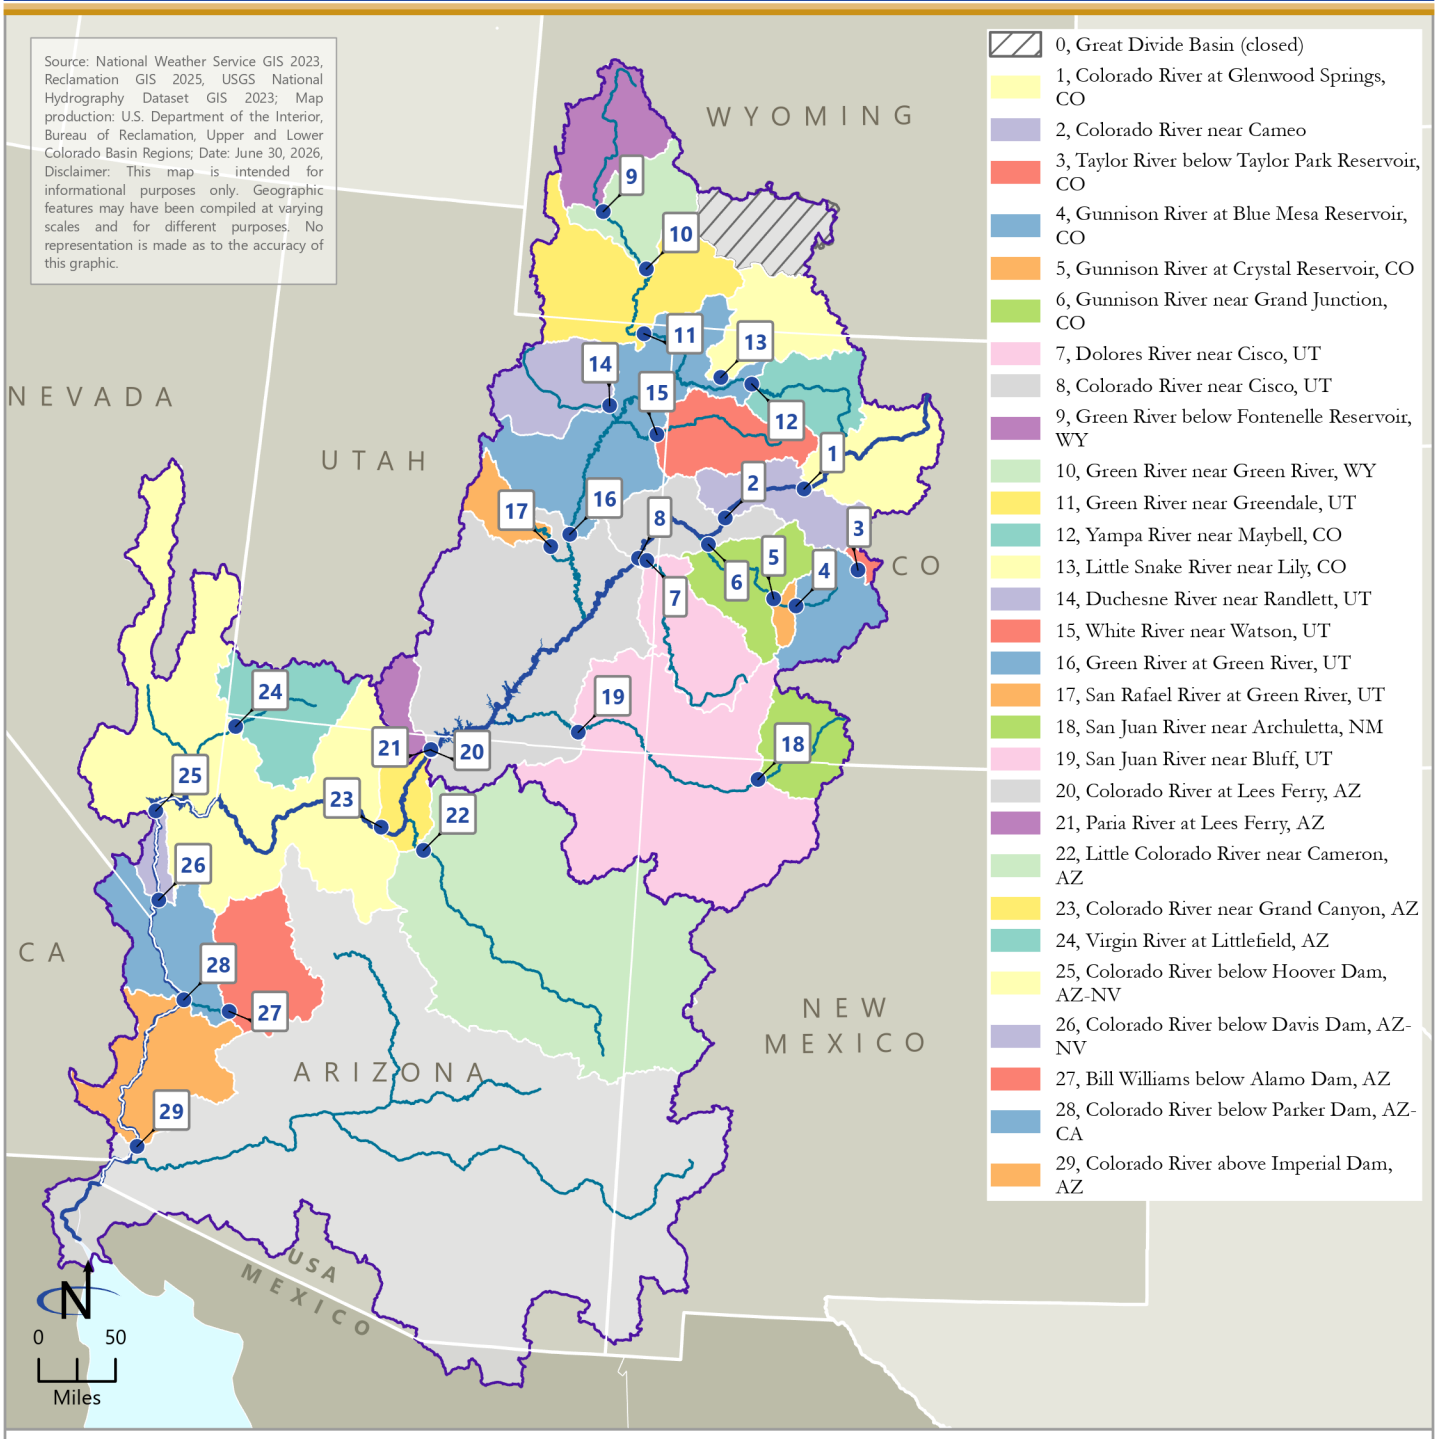
Major Colorado River tributary

Colorado River Basin, Upper and Lower Basins

States in the Colorado River Basin (Wyoming, Colorado, Utah, and New Mexico are Upper Division states, and Arizona, California, and Nevada are Lower Division states)

The TMD Reservoir was excluded because it represents an aggregation of Colorado western slope transmountain diversion storage facilities, including Lake Granby, Willow Creek Reservoir, Dillon Reservoir, and Homestake Reservoir.

Projections are most sensitive to assumptions about future hydrology, and future flows are highly uncertain. Assumptions about future hydrology can produce very different pictures of risk. To address this challenge, the EIS applies a Decision Making under Deep Uncertainty framework, described in **Appendix E**, which enables evaluation of outcomes across a wide range of plausible future hydrologic conditions.



A.3 Hydrology

Hydrology inputs to CRSS are natural flows, which are the flows that would have been observed at a stream gage adjusted to remove the effects of upstream reservoirs and depletions. There are 21 Upper Basin natural flow points and 8 Lower Basin natural flow points as shown in **Map A-2**. The historical natural flow record was developed using the method published in Prairie and Callejo (2005). Historical natural flows are computed using streamflow gauges, reservoir regulation, reservoir evaporation losses, and water use from the Upper Basin Consumptive Use and Loss reports (Reclamation 2022) and Lower Basin Water Accounting Reports (Reclamation 2023). The natural flows include gains and losses from natural process such as gains from tributaries, seepage, transit losses, and riparian evapotranspiration along the river corridor. Starting with the release of the 1906-2020 natural flows in December 2022, the Lower Basin phreatophyte losses are no longer explicitly modeled in the development of natural flows. As such, these losses are now reflected in the computed intervening natural flows in the three reaches downstream of Hoover Dam.

There are several methods for projecting possible future natural flow sequences or hydrology scenarios for the 29 natural flow points in CRSS. Because CRSS is a long-term model capable of projecting decades into the future, hydrologic inputs are derived from methods designed to represent future uncertainty in hydrologic variability and long-term change. These methods include resampling the historical record (either from the measured record or a derived record using a "proxy" such as tree-ring data), deriving future inflow data by preserving key statistics from the historical record while adding a random component, and using physically based hydrology models to simulate runoff based on general circulation model projections of temperature and precipitation. Reclamation chose 400 unique hydrologic sequences, or traces, to run through CRSS for the purposes of this Final EIS to explore basin conditions under a broad range of flow characteristics and patterns. For more information about these traces and how they were selected, see **Appendix F**.

Map A-2
Colorado River Natural Flow Basins

A.3.1 Glen Canyon Dam to Lees Ferry Accretion Flows

Geographically, the Lees Ferry subbasin (**Map A-2**) encompasses areas both upstream and downstream of Glen Canyon Dam, with the Lees Ferry gage serving as the downstream boundary. In CRSS, the Lees Ferry intervening natural flow is split such that a portion of the estimated gains and losses is introduced into the model above Glen Canyon Dam and a portion is introduced below it. The portion of the flow added to the reach below Glen Canyon Dam follows a monthly pattern based on historical data as shown in **Table A-1**, while the remaining portion of the Lees Ferry intervening natural flow is introduced to the reach above Glen Canyon Dam. The data in **Table A-1** are derived from the average difference between the Lees Ferry gaged flow and the Glen Canyon Dam releases from 2006 through 2021. Using this distribution, approximately 70 percent of the Lees Ferry intervening natural flow occurs above Lake Powell, with the remaining 30 percent below Glen Canyon Dam.

Table A-1
Gains & Losses for the Glen Canyon Dam to Lees Ferry Reach

Month	Average Gains & Losses (acre-feet [af])
January	11,200
February	8,800
March	9,700
April	12,200
May	13,100
June	13,500
July	19,400
August	19,100
September	14,300
October	11,300
November	6,000
December	7,900

A.4 Initial Reservoir Conditions

CRSS was initialized using a single set of reservoir conditions projected for December 31, 2026. The initial conditions are described in **Appendix G**.

The changes in volume of water storage in all reservoirs are calculated by CRSS using relationship curves that are programmed into the model. These relationship curves relate the water surface elevation to live capacity, total capacity, and surface area for each respective reservoir. The latest available curves for Lake Powell and Lake Mead are available in Bradley and Collins (2022) and Reclamation (2011), respectively. The assumed maximum capacity of reservoirs that are used in one or more alternatives to determine Lake Powell or Lake Mead operations is provided in **Table A-2.**

Table A-2
Assumed Maximum Reservoir Storage from CRSS

Reservoir	Maximum Storage (1000 acre-ft)
Flaming Gorge	3,671
Blue Mesa	828
Navajo	1,648
Lake Powell	23,314
Lake Mead*	26,120
Lake Mohave	1,810
Lake Havasu	619

*Excluding 1.5 million acre-feet (maf) exclusive flood control space.

A.5 Operations Upstream of Lake Powell

In CRSS, 12 Upper Basin reservoirs and 222 Upper Basin water users are modeled. Upper Basin water users are distributed among the tributaries of the Upper Basin and aggregated by use sector. These sectors include agriculture, energy, environment, reservoir evaporation, exports, lease, municipal and industrial, and minerals. Each water user has a corresponding diversion and depletion schedule input into CRSS (see **Appendix L**). To achieve the full scheduled depletion, sufficient natural flow must be available within the corresponding reach to meet all scheduled diversions. When available natural flow is not available, users are unable to meet their "not pre-shorted" depletion schedules.

Upper Basin reservoirs modeled operations are consistent with their individual operation plans. Some facilities are operated to meet storage or elevation targets, while others feature environmentally regulated, controlled, consistent releases. Within the model, each reservoir has a set of rules to guide the specific operations. The model solves by using the logic in those operating rules. The following briefly describes the various Upper Basin reservoirs along with a high-level description of the logic in RiverWare™ for simulating operations within the Upper Basin. The operations of the Upper Basin reservoirs above Lake Powell are modeled the same for all alternatives except during Lake Powell infrastructure protection (PIP) releases (**Section A.5.11**).

In a rule-based model, general assumptions must be made for the model to solve. The rules developed for CRSS are, ideally, the best representation of operations that can be projected. In practice, however, there are sometimes differences between the projected operations produced by the model and actual operations. For example, many reservoirs in the Upper Basin are operated following the principles of adaptive management. As such, operations may be altered to meet various objectives of the reservoirs' adaptive management work groups on an ad hoc or

experimental basis. Such ad hoc or experimental operations cannot be known in advance. As such, CRSS projections may differ from actual operations, even under similar hydrologic conditions.[1]

A.5.1 Available Water to Upper Basin Agricultural Water Users

Upper Basin agricultural water users are subject to limits on the natural flow available for diversion. CRSS applies a "percent available" factor, which represents that only a limited volume of natural flow is available to users on high tributaries that are not explicitly modeled. The "percent available" factors are calibrated in each reach to minimize streamflow bias at gaged locations during the historical verification period (2000 through 2024). In reaches where modeled streamflow underestimates observed flows (i.e., exhibits a negative bias), calibration reduces the percentage of natural flow available for diversion. This adjustment decreases depletions, increases modeled Upper Basin shortages and streamflow, and thereby reduces bias between modeled and historical streamflow.

A.5.2 Fontenelle Reservoir

Fontenelle Reservoir is on the Green River about 24 miles southeast of La Barge, Wyoming. Fontenelle Reservoir is operated to meet various target elevations throughout the year while staying within practical and authorized limits.

A.5.3 Flaming Gorge Reservoir

Flaming Gorge Reservoir is on the Green River about 32 miles downstream of the Utah-Wyoming border and upstream of the confluence with the Yampa River. The operations of Flaming Gorge Reservoir meet the requirements detailed in the 2006 Record of Decision for the Operation of Flaming Gorge Dam Final EIS (2006 Flaming Gorge ROD; Reclamation 2006a) that were designed to achieve the authorized purposes of the Colorado River Storage Project Act, while addressing environmental requirements. The 2006 Flaming Gorge ROD outlines the operational guidelines of Flaming Gorge and implements, to the extent possible, recommendations to assist in the recovery of four endangered fish species, outlined in the 2000 Flow and Temperature Recommendations for Endangered Fish in the Green River Downstream of Flaming Gorge Dam (Muth et al. 2000).

Flaming Gorge operations are governed by the April through July unregulated inflow into the reservoir, which determines the corresponding hydrologic classification, spring peak, and base flow targets from the 2006 Flaming Gorge ROD (Reclamation 2006a) for the year. The April through July releases are modeled at the daily time step in CRSS to approximate the sub-monthly component of the spring peak targets. The model logic determines typical daily operations from April through July before summing up to a monthly release. During the March to April transition period, Flaming Gorge operations try to achieve a May 1 storage target (upper limit drawdown elevation). Actual annual operations at Flaming Gorge are determined in a consultation process with other agencies.

[1] The UIU elevations reflected in this appendix are provided for National Environmental Policy Act analysis purposes only and do not reflect a federal position on what operations are appropriate or possible at low reservoir elevations. At Flaming Gorge, for example, operations that approach the low elevations described would likely reflect emergency operations where there is enough water remaining in Flaming Gorge for approximately one year of operations above minimum operating levels. Flaming Gorge operations at such low levels are likely inappropriate for non-emergency operations.

CRSS cannot model these adaptive management decisions; therefore, model results do not include possible future adaptive management decision changes to the logic described above.

A.5.4 Strawberry Reservoir

Strawberry Reservoir is located in central Utah and is the terminal reservoir of the Strawberry Aqueduct and Collection System, which is part of the Central Utah Project. Releases from Strawberry Reservoir operate to meet downstream flow targets and storage objectives. Diversions from the reservoir are made to the Utah Lake System based on the available volume in storage. Diversions are adjusted when Strawberry Reservoir's pool elevation is greater than 7,576.34 feet. Flood control releases are made from March through October if the storage exceeds 1.02 million acre-feet (maf).

A.5.5 Starvation Reservoir

Starvation Reservoir is on the Strawberry River downstream of Strawberry Reservoir near Duchesne, Utah. Releases from Starvation Reservoir are set based on monthly flow targets and flood control operations. Flood control releases are made from March through October if the storage exceeds 165 thousand acre-feet (kaf).

A.5.6 TMD Reservoir

The TMD Reservoir is an aggregate representation of Colorado western slope transmountain diversion (TMD) storage facilities, including Lake Granby, Willow Creek Reservoir, Dillon Reservoir, and Homestake Reservoir. TMD Reservoir storage varies monthly based on hydrologic conditions and is reduced when downstream senior water rights, such as the Shoshone Powerplant or Grand Valley, experience shortages. Diversions from the TMD Reservoir are adjusted according to natural flow conditions, decreasing when supplies are abundant and increasing when they are limited. Outflows occur when the reservoir nears capacity and must release excess water. These modeled outflows are not meant to directly represent operations at the individual reservoirs.

A.5.7 Taylor Park Reservoir

Taylor Park Reservoir is on the Taylor River, a tributary of the Gunnison River on the western slope of Colorado's Rocky Mountains. Taylor Park Reservoir is operated with a rule curve to meet various target elevations throughout the year, while staying within practical and authorized limits.

A.5.8 Aspinall Unit Reservoirs – Blue Mesa, Morrow Point, and Crystal

The Aspinall Unit consists of three reservoirs—Blue Mesa, Morrow Point, and Crystal—in series along the Gunnison River in western Colorado. The operations of the Aspinall Unit meet the requirements detailed in the April 2012 Record of Decision for the Aspinall Unit Operations Final EIS (2012 Aspinall ROD; Reclamation 2012) and the decree quantifying the Federal Reserved Water Right for the Black Canyon of the Gunnison, which specify the spring peak outflow hydrographs and base flows for the rest of the year based on the hydrologic conditions upstream of Blue Mesa Reservoir. The 2012 Aspinall ROD provides specifications to avoid jeopardizing the continued existence of fish listed under the Endangered Species Act and to ensure the dam's operations do not result in the destruction or adverse modification of critical habitat in the Gunnison River.

Aspinall Unit operations are governed by the April through July unregulated inflow into the reservoir, which determines spring peak and base flow targets for the rest of the year based on the hydrologic conditions above Blue Mesa Reservoir. CRSS approximates daily flow targets in the 2012 Aspinall ROD and Federal Reserved Water Right for the Black Canyon of the Gunnison by first modeling typical daily operations for both the spring and baseflow periods and then summing to a monthly release. Morrow Point and Crystal Reservoirs are modeled to maintain elevation targets of 7,153.73 and 6,753.04 feet, respectively.

A.5.9 McPhee Reservoir

McPhee Reservoir is the primary storage facility of the Dolores Project, located on the Dolores River in southwestern Colorado. Inflows to the McPhee Reservoir are derived from the Cisco-Dolores natural flow with volumes split between the Dolores River and McPhee Reservoir based on hydrologic conditions. An environmental pool is tracked in McPhee Reservoir and can be used to meet target monthly environmental releases. The environmental pool is reset every October to the minimum of either 13 percent of the previous month's storage or the maximum environmental pool capacity of 29,300 acre-feet (af). Water stored in McPhee Reservoir is primarily used to meet the demands of the Dolores Project, with inflows used first and stored water, excluding the environmental pool, used when inflows are insufficient.

A.5.10 Navajo Reservoir

Navajo Reservoir is on the San Juan River above the confluence with the Animas River. The reservoir is operated to meet environmental requirements outlined in the July 2006 Record of Decision for the Navajo Reservoir Operations, Navajo Unit-San Juan River New Mexico, Colorado, Utah Final EIS (Reclamation 2006b). Navajo Reservoir also provides for the diversion of Navajo Indian Irrigation Project (NIIP) water from Navajo Reservoir, and other municipal and industrial uses throughout the San Juan Basin. The minimum active storage at Navajo Reservoir is at 5,990 feet; at that point, the NIIP can no longer divert water.

Navajo Reservoir operations are modeled to first meet the environmental baseflow requirements at downstream gages stated in the July 2006 Record of Decision for the Navajo Reservoir Operations, Navajo Unit-San Juan River New Mexico, Colorado, Utah Final EIS (Reclamation 2006b); because of the CRSS spatial scale, it is assumed that all flow targets are for the San Juan River near Bluff, New Mexico. If available additional water is released as a spring peak, a spring release pattern is selected to bring Navajo Reservoir closest to the September 30 storage target, while staying within practical and authorized limits, including maintaining NIIP diversions. If the reservoir pool elevation is projected to go below 5,990 feet, the minimum elevation for NIIP diversions, the outflow, and NIIP diversions are proportionally reduced.

A.5.11 Powell Infrastructure Protection Releases

PIP releases are modeled as releases from Upper Initial Units (UIUs) under low elevation conditions at Lake Powell in the Continued Current Strategies (CCS) Comparative Baseline, Basic Coordination Alternative, and Supply Driven Alternative. The PIP release modeling assumptions are simplifications of the actual PIP process, which, like the Drought Response Operations Agreement, involves collaborative decision-making among stakeholder workgroups and includes subjective judgments that cannot be captured in a model. The modeled PIP releases represent a potential range

of releases; actual releases may be lower, higher, or may not occur, and do not reflect the views of all stakeholders. These modeling assumptions are intended solely for National Environmental Policy Act analysis and do not reflect a position by Reclamation on operations that might be implemented under a PIP collaborative process.

CCS Comparative Baseline

The PIP release method under CCS Comparative Baseline is described below.

Powell Trigger

PIP releases from the UIUs (Flaming Gorge, Blue Mesa, and Navajo Reservoirs) are triggered when Lake Powell is projected to fall below an elevation of 3,525 feet. In April and August, CRSS uses a regression model to project the following March 31 Lake Powell pool elevation by estimating Powell inflows based on monthly natural flow and Upper Basin demands (see **Section A.6.2**, *Lake Powell Inflow Forecast*). Using these projected inflows and the projected Lake Powell release, CRSS determines the expected Lake Powell pool elevation. If the projection indicates that Lake Powell will drop below 3,525 feet, CRSS calculates the volume needed to reach the protection elevation of 3,525 feet (deficit volume) and initiates PIP releases to address the deficit.

Available Volume

The total volume from each UIU available for contribution to PIP releases is limited to the amount of water stored above the designated lower limit elevation. For each reservoir, a forecasting algorithm estimates the elevation for the future annual operating target month. These forecasts assume daily spring flow release patterns followed by baseflow releases under the same hydrologic conditions throughout the forecast period.

The lower limit elevation and annual operating target month for each reservoir is listed below:

- Flaming Gorge: 5,890 feet in April (May 1), which is 19 feet above minimum power pool. Typical May 1 targets range from 6,027 to 6,023 feet depending on the hydrologic conditions.
- Blue Mesa: 7,424.21 feet in December, reflecting the minimum water surface elevation (7,393 feet) plus 80 kaf of Uncompahgre Project contract water storage. In a typical year, Blue Mesa is operated to achieve a December elevation of 7,490 feet to prevent icing.
- Navajo: Minimum end of water year storage target (EOWYST) in September, which increases from 6,030 feet in 2027 to 6,052 feet in 2045. These elevations are based on minimum water surface elevation of 5,990 feet, and account for contract water storage (33.5 kaf for the Jicarilla Apache Nation and 23 kaf for the Hammond Water Conservancy District) and NIIP build-out. In years without PIP releases, CRSS forecasts whether sufficient water will be available above the EOWYST elevation of 6,050 feet to conduct a spring release. After 2043, Navajo will no longer participate in PIP releases because its minimum EOWYST will exceed the 6,050-foot threshold required for a standard spring release.

Lower limit elevations are used to determine the available volume and the annual operational targets, but rules do not protect and/or maintain lower limit storage on a month-to-month basis. UIUs can fall below lower limits, which may prevent them from meeting future environmental targets.

Releases

Maximum Annual Release
There is no maximum annual release specified.

Distribution of Releases
The total contribution to PIP releases is determined by the volume needed to reach 3,525 feet or by the total volume available in the UIUs, whichever is smaller. CRSS allocates this total contribution proportionally between Flaming Gorge and Blue Mesa based on the volume available above each reservoir's lower elevation limit. Navajo contributes during spring operations using any volume available beyond the volume used in a normal spring release. This contribution is factored into the proportional distribution between Flaming Gorge and Blue Mesa. Flaming Gorge's assigned contribution is increased if the proportional contributions do not equal the forecast deficit.

UIU Operational Adjustments
Each UIU's operations are adjusted within their Records of Decision to release an additional volume equal to the assigned contribution by modifying their operating targets. Annual contributions for each UIU are estimated at the end of each UIU's operating year.

Flaming Gorge
Flaming Gorge's May 1 target is lowered by its assigned contribution. If the reservoir did not reach its normal May 1 target in the previous year due to PIP releases, the prior May 1 elevation is adjusted by the new assigned contribution. The May 1 target elevation cannot be lower than 5,890 feet (lower limit elevation). Operations are adjusted based on the sub annual flow regime as follows:

- Spring: No changes to the Spring operations are modeled. Spring operations are modeled by a daily hydrograph which ramps up from baseflow to peak and back to baseflow. Operations vary by hydrologic classification and peak timing.
- Baseflow: The release in baseflow is the greater of the steady release to achieve the May 1 target or the minimum for Reach 2 (Jensen, Utah) for the hydrologic classification. The release in all baseflow months is constrained further by the minimum and maximum for Reach 1 (below Flaming Gorge). All maximum and minimum flows are from the 2022 Drought Response Operation Plan[2], which uses the +/- 40 percent or 25 percent flexibility in the Record of Decision and varies by season.

[2] Attachment C - Appendix 1, Estimated Normal / Maximum / Minimum Summer to Winter Baseflows in the Green River downstream from Flaming Gorge Dam, page 84-85.

Transition: Releases during the transition period in March and April are constrained to a maximum of 2,000 cubic feet per second (cfs), which is based on an operator estimate of United States (U.S.) Fish and Wildlife Service Recovery Program preference[3].

Blue Mesa

Monthly releases from Blue Mesa are the greater of three criteria: the flow required to meet the Whitewater Target for the current hydrologic classification under the Record of Decision, the Federal Reserve Water Right in the Black Canyon of the Gunnison National Park, and the flow needed to meet the guide curve storage target. Blue Mesa operations are adjusted by lowering the monthly guide curve by the assigned contribution; therefore, PIP releases only occur when the modified guide curve becomes the controlling factor. If PIP releases occurred in the prior year, the starting elevation is adjusted downward. The guide curve reduction increases gradually each month until December, when the full assigned volume is reached. The monthly guide curve storage target cannot drop below 7,424.21 feet. Releases from August through April are further limited by the Crystal Powerplant capacity.

Navajo

Navajo's PIP releases occur only during the spring release period and are based on the volume available above the EOWYST of 6,050 feet after meeting baseflow requirements. Increased releases outside of spring do not help achieve Record of Decision operational targets. Navajo's total assigned contribution is the volume above its lower limit EOWYST minus the volume used in normal spring operations. Navajo will only participate in UIU contributions in April, not August and must recover before contributing again, which occurs once it is at or above 6,063 feet at the end of the water year or conducts a spring peak release lasting at least 21 days.

Recovery

Recovery of the UIUs is not explicitly modeled. Instead, the reservoirs naturally recover in years without PIP releases as they return to their normal annual operating targets.

No Action Alternative

There are no PIP releases modeled in the No Action Alternative.

Basic Coordination Alternative

The PIP release method under the Basic Coordination Alternative is identical to that of CCS Comparative Baseline.

Enhanced Coordination Alternative

There are no PIP releases modeled in the Enhanced Coordination Alternative.

Maximum Operational Flexibility Alternative

There are no PIP releases modeled in the Maximum Operational Flexibility Alternative.

[3] Typically, the transition period is the unconstrained release to achieve the May 1 target.

Supply Driven Alternative

The PIP release method under the Supply Driven Alternative is the same as that of CCS Comparative Baseline except as noted in the following sections.

Powell Trigger

PIP releases are triggered when Lake Powell falls below elevation 3,525 feet in any month. If Lake Powell is below the protection elevation of 3,525 feet, CRSS calculates the volume needed to reach the protection elevation and initiates PIP releases to address the deficit.

Available Volume

The modeling assumptions for the Available Volume are the same as CCS Comparative Baseline except only Flaming Gorge is assumed to participate in PIP releases.

Releases

Maximum Annual Release

The maximum annual release from Flaming Gorge is 500 kaf.

Distribution of Releases

The total contribution to PIP releases is determined by the volume needed to reach 3,525 feet or by the total volume available in Flaming Gorge, whichever is less.

UIU Operational Adjustments

The UIU operational adjustments for Flaming Gorge are identical to assumptions in CCS Comparative Baseline.

Recovery

Flaming Gorge can naturally recover by returning to its normal annual operating targets once Lake Powell is above 3,535 feet.

Representative Preferred Alternative

The PIP release method under the Representative Preferred Alternative is identical to that of CCS Comparative Baseline.[4]

[4] During preparation of the Final EIS, Reclamation identified a discrepancy in the implementation of the PIP logic in CRSS used to support this analysis. While correcting the discrepancy results in small changes to the quantitative results, it does not affect the comparative evaluation of alternatives, the environmental impact analysis, or the conclusions presented in this Final EIS. Modeling to support the analysis in **TA 3**, Hydrologic Resources, and **TA 4,** Water Deliveries, was updated to reflect this PIP logic. All other resource categories rely on modeling that did not include PIP releases.

A.6 Lake Powell Operation

Lake Powell is the most downstream reservoir in the Upper Basin; it is impounded by Glen Canyon Dam near Page, Arizona, Glen Canyon Dam is 17 miles upstream of Lee Ferry, the delineation point between the Upper and Lower Basins.

Section A.6.1 describes modeling assumptions common to all alternatives. **Sections A.6.2** through **A.6.7** describe model assumptions for Lake Powell operating strategies for the comparative baseline and each alternative. The Lake Powell mechanism for the storage and delivery of conserved system and non-system water is summarized in **Appendix B**.

A.6.1 Assumptions Common to All Alternatives

Lake Powell operates on a water year (October through September) basis with an annual release set at the beginning of the water year with possible adjustments throughout the water year.

Disaggregation from Annual to Monthly Release

Lake Powell water year releases are disaggregated to monthly releases using the Long-Term Experimental and Management Plan (LTEMP) release patterns. The Lake Powell assumed monthly releases for CRSS are in **Table Attachment A1-1**. In CRSS, the water year release pattern that is less than or equal to the water year release is selected from **Table Attachment A1-1**. The monthly release is then calculated by multiplying the remaining water year release by the proportion of flow released in the given month relative to the remainder of the water year for the determined release pattern. The minimum monthly release is set to 6,521 cfs, which is consistent with the daily minimum LTEMP release.

Safe Operating Capacity Operations

If Lake Powell is nearing maximum capacity, Lake Powell's outflow is set to a volume needed to reach seasonal storage targets designed to maintain a safe operating capacity. For January through July, the model calculates the monthly release needed to meet the July Powell storage target (500 kaf below live capacity). Likewise, for August through December, the model calculates a monthly outflow needed to meet the December Powell storage target (2.422 maf below live capacity). The monthly constrained release (i.e., through the powerplant and river outlet works) is a maximum of 48,100 cfs.

Infrastructure Constraints at Low Elevations

The monthly releases can be constrained due to physical limitations at Glen Canyon Dam. Water can be released through the powerplant turbines until the pool elevation drops below 3,490 feet. Once Lake Powell is below 3,490 feet, releases are made through four river outlet works. The capacity of the river outlet works varies with the elevation of Lake Powell; the higher the pool elevation, the higher the potential release through the river outlet works. CRSS computes the maximum monthly release based on the Lake Powell elevation using **Table A-3** and interpolates for the capacity between elevations. The release capacity for each river outlet work is provided in the LaFond (2024) technical decision memorandum. For modeling purposes, three out of four river outlet works are assumed to be available for use at any given time; this is because of the need for periodic inspections and any associated maintenance activities. Reclamation believes this is a reasonable estimation given the historical and future operations and maintenance requirements for

the river outlet works. If a monthly release is constrained, the volume is tracked and is attempted to be released later in the water year to maintain the desired water year release, if possible.

Table A-3
CRSS Modeled River Outlet Works' Capacity by Lake Powell Elevation

Lake Powell Elevation	Capacity (1 river outlet work)		Capacity (3 river outlet works)	
feet	cfs	kaf/yr	cfs	kaf/yr
3,390	0	0	0	0
3,400	1,200	869	3,600	2,606
3,410	1,800	1,303	5,400	3,909
3,420	2,200	1,593	6,600	4,778
3,430	2,439	1,766	7,317	5,297
3,440	2,580	1,868	7,740	5,604
3,450	2,711	1,963	8,133	5,888
3,460	2,837	2,054	8,511	6,162
3,470	2,958	2,141	8,874	6,424
3,480	3,073	2,225	9,219	6,674
3,490	3,185	2,306	9,555	6,918

A.6.2 CCS Comparative Baseline

The CCS Comparative Baseline assumes that existing agreements, including the Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead (2007 Interim Guidelines), 2017 Minute 323, and 2019 DCP continue through the analysis period (2027-2060). In January, Lake Powell operating tiers are determined based on the previous end of calendar year (EOCY) pool elevation at Lake Powell. This is a modeling simplification, rather than using an August based projection of December 31 conditions, as specified in the 2007 Interim Guidelines. For October through December of the current water year, 2.0 maf is released consistent with 8.23 maf monthly release pattern unless Lake Powell is in Safe Operating Capacity Operations (**Section A.6.1**) or otherwise specified based on water year releases at 7.48 maf or lower (**Table Attachment A1-1**). In January, CRSS sets the Lake Powell operating tier and water year release as follows:

- If the Lake Powell EOCY pool elevation is greater than or equal to the Equalization Level (**Table A-6**), the Equalization Tier operations govern the water year releases.
- If the Lake Powell EOCY pool elevation is less than the Equalization Level and greater than or equal to 3,575 feet, the Upper Elevation Balancing Tier governs the water year releases.
- If the Lake Powell EOCY pool elevation is less than 3,575 feet and greater than or equal to 3,525 feet, the Mid-Elevation Release Tier governs the water year releases.
- If the Lake Powell EOCY pool elevation is less than 3,525 feet, the Lower Elevation Balancing Tier governs the water year releases.

Additional details on modeled operations in each of these tiers are included in the following sections.

Lake Powell Inflow Forecast

The Lake Powell inflow forecast is used to estimate future Lake Powell storage. The unregulated Lake Powell inflow forecast from the current month through the forecasted month is computed as:

$$unregulated\ Lake\ Powell\ inflow = natural\ flow\ above\ Lake\ Powell\ -\ estimated\ Upper\ Basin\ depletions + the\ forecast\ error$$

The *estimated Upper Basin depletions* (consumptive use) are computed using a logistic regression equation. The following formula operates at a monthly level, using the parameters outlined in **Table A-4**. The coefficients were estimated using modeled CRSS depletions as the predicant, and monthly input natural flow and Upper Basin demands as the predictors using data from the Colorado River Post-2026 Operations Exploration Tool[5].

$$UBDep_i = p1_i * (1.0 - \frac{1.0}{1 + e^{2.718 - p3_i * (NF_i - p2_i)}}) - p4_i * (\frac{UBDem_{Ann}}{1 + e^{2.718 - p6_i * (NF_i - p5_i)}})$$

where:

i = month,
UBDep = estimated total Upper Basin depletion (use) for month *i* in maf,
NF = total natural flow above Lees Ferry for month *i* in af,
$UBDem_{Ann}$ = total Upper Basin demand for the year in maf, and
p1, p2, p3, p4, p5, p6 = coefficients for the logistic regression equation (**Table A-4**).

Table A-4
Monthly Estimated Upper Basin Depletion Equation Coefficients

Month	p1 (af)	p2 (af)	p3 (1/af)	p4 (none)	p5 (af)	p6 (1/af)
January	0.7775	-4.5631	0.6096	0.7962	8.6430	0.5274
February	0.5652	-13.4136	0.1904	0.1406	8.5226	0.3441
March	0.0582	-2.3241	-5.5242	0.0121	-0.1326	2.8745
April	0.0900	0.2109	-6.1404	0.0347	-0.3668	1.0723
May	0.7588	0.1828	-0.8157	2.348E-09	-6.9129	-4.9230
June	1.1473	0.6672	-0.7058	2.129E-05	-7.4173	-13.9783
July	3.5042	-6.7974	4.8519	0.1977	0.5144	1.2987
August	0.2381	-5.7046	-3.7719	0.0797	0.4006	3.0123

[5] www.crbpost2026dmdu.org

The *forecast error* is computed using equations derived from an analysis of past Colorado River forecasts and runoff data for the period 1947 to 1983. An analysis of these data reveals two strongly established patterns: (1) high runoff years are under-forecast, and low runoff years are over-forecast; and (2) the error in the current month's seasonal forecast is strongly correlated with the error in the preceding month's forecast (Reclamation 1985). A regression model was developed to aid in determining the error to be incorporated into the seasonal forecast for each month from January to June. The error in months after June is assumed to be negligible compared to the error during the runoff season. The error is the sum of a deterministic component and a random component. The deterministic component is computed from the regression equation. The random component is computed by multiplying the standard error of the regression equation by a random mean deviation selected from a standard normal distribution. The forecast error equation has the following form (all runoff units are maf):

$$E_i = a_i X_i + b_i E_{(i-1)} + c_i + Z_r d_i$$

where:

i = month,
E_i = error in the forecast for month i,
X_i = natural runoff into Lake Powell from month i through July,
a_i = linear regression coefficient for X_i,
$E_{(i-1)}$ = previous month's forecast error,
b_i = linear regression coefficient for $E_{(i-1)}$,
c_i = constant term in regression equation for month i,
Z_r = randomly determined deviation, and
d_i = standard error of estimate for regression equation for month i.

Table A-5 summarizes the regression equation coefficients for each month.

Table A-5
Lake Powell Inflow Forecast Regression Equation Coefficients

Month	a_i	b_i	c_i	d_i
January	0.70	0.00	-8.195	1.270
February	0.00	0.80	-0.278	0.977
March	0.00	0.90	0.237	0.794
April	0.00	0.76	0.027	0.631
May	0.00	0.85	0.132	0.377
June	0.24	0.79	0.150	0.460

The magnitude of the June forecast error is constrained to not exceed 50 percent of the May forecast error and the July forecast error is equal to 25 percent of the June forecast error.

Predicting End of Water Year Volumes of Lake Powell and Lake Mead

Lake Powell end of water year (EOWY) volume is predicted each month by taking the end of the previous month's storage, adding the forecasted inflow as described in the previous section, subtracting the estimated release, and subtracting the estimate of evaporation and change in bank

storage. All estimated values are for the period from the current month through September. The estimated release is based on the operation of the alternative. The estimated evaporation and bank storage losses are based on an initial estimate of the EOWY volume.

Similarly, the Lake Mead EOWY volume is predicted each month by taking the end of the previous month's volume, adding the estimated Lake Powell release, subtracting the estimated Lake Mead release, adding the average gain between Lake Powell and Lake Mead, subtracting the Southern Nevada depletion, and subtracting the estimate of evaporation and change in bank storage. Again, all values are for the period from the current month through September. Lake Mead's release is estimated as the sum of the depletions downstream of Lake Mead and the reservoir regulation requirements (including evaporation losses) for Lake Mohave and Lake Havasu minus/plus the gains/losses below Lake Mead.

Equalization Tier

Under CCS Comparative Baseline, the equalization of storage between Lake Powell and Lake Mead is modeled with a rule that first determines if equalization needs to occur, and if so, then the rule determines how much water would be released to equalize Lakes Powell and Mead. The rule is in effect from January through September of each year. The rule states that equalization occurs if two criteria are met: (1) if the previous end-of-year Lake Powell elevation is greater than or equal to the Equalization Level (see **Table A-6**); and (2) if the projected EOWY storage in Lake Powell is greater than or equal to the projected EOWY storage in Lake Mead (the previous section describes EOWY projections). For modeling purposes, the Equalization Level used in CCS Comparative Baseline extends the 2007 Interim Guidelines Equalization Level through 2060, using the same calculation and parameters that were used to develop the 2007 Interim Guidelines Equalization Level. **Appendix J** describes the 602(a) storage calculation, which forms the basis for the Equalization Level under the 2007 Interim Guidelines. It documents the parameters used in the 2007 calculation, which are also used in this extension through 2060. **Appendix J** also presents a comparison illustrating how different parameter assumptions would influence the resulting 602(a) storage values.

If operating in the Equalization Tier, the water year release is computed as the release required to balance the contents of Lake Powell and Lake Mead by the end of the water year and constrained such that the release does not cause Lake Powell to decline below the Equalization Level unless Lake Mead is less than 1,105 feet. If Lake Mead is projected to decline below 1,105 feet, then Lake Powell's release is increased until the first of the following three conditions occurs: 1) the reservoirs storage is equal, 2) Lake Mead EOWY storage is 1,105 feet, or 3) Lake Powell EOWY elevation is 20 feet below the Equalization Level Line. The monthly release from Lake Powell is then calculated using the method as described under **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

Upper Elevation Balancing Tier

Operations in the Upper Elevation Balancing Tier differ depending on the month. In January through March, if the Lake Mead EOCY pool elevation is less than 1,075 feet, the water year release necessary to balance Lake Powell and Lake Mead projected EOWY storage (as calculated in **Section A.6.2**, *Predicting End of Water Year Volumes of Lake Powell and Lake Mead*) is calculated but constrained to be within the range of 7.0 to 9.0 maf. If the Lake Mead EOCY pool elevation is greater than or equal to 1,075 feet, then set the water year release to 8.23 maf.

Table A-6
Lake Powell Equalization Level Table

Year	Equalization Elevation (feet)	Year	Equalization Elevation (feet)
2027	3,667	2044	3,688
2028	3,668	2045	3,689
2029	3,670	2046	3,690
2030	3,671	2047	3,691
2031	3,672	2048	3,692
2032	3,673	2049	3,693
2033	3,674	2050	3,694
2034	3,675	2051	3,695
2035	3,677	2052	3,695
2036	3,678	2053	3,696
2037	3,679	2054	3,696
2038	3,680	2055	3,697
2039	3,682	2056	3,697
2040	3,683	2057	3,697
2041	3,684	2058	3,698
2042	3,686	2059	3,698
2043	3,687	2060	3,698

In April, Lake Powell can switch to equalization operations if the projected Lake Powell EOWY pool elevation is above the Equalization Level and the projected Lake Powell EOWY storage is greater than the projected Lake Mead EOWY storage. If operating in equalization, the water year release is set based on equalization logic (described in the previous section) and constrained to a minimum of 8.23 maf.

Otherwise, if Lake Powell's projected EOWY pool elevation is less than or equal to the Equalization Level, Lake Powell's releases are modeled as follows:

- If the year started by balancing contents between Lake Powell and Lake Mead constrained between 7.0 and 9.0 maf, continue these operations for the remainder of the water year
- If the April projected Lake Mead EOWY pool elevation is less than 1,075 feet and the April projected Lake Powell EOWY pool elevation is greater than 3,575 feet, then compute the water year release necessary to balance Lake Powell and Lake Mead projected EOWY storage, constrained between 8.23 maf and 9.0 maf.
- Otherwise (the April projected Lake Mead EOWY pool elevation is greater than 1,075 feet or the April projected Lake Powell EOWY pool elevation is less than 3,575 feet), continue with a water year release of 8.23 maf.

The monthly release from Lake Powell is then calculated using the method as described under **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

Mid-Elevation Release Tier

At the beginning of the water year, if Lake Powell elevation is less than 3,575 feet and greater than or equal to 3,525 feet, and Mead is greater than or equal to 1,025 feet, Lake Powell will release 1.58 maf over the months of October through December, as opposed to a 2.0 maf release. At the beginning of the calendar year, the Lake Powell operating tier is set. If the operating tier is the Mid-Elevation Release Tier, CRSS will check the Lake Mead EOCY pool elevation. If the Lake Mead EOCY pool elevation is greater than or equal to 1,025 feet, Lake Powell's water year release is set to 7.48 maf. Otherwise, the water year release is set to 8.23 maf. The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

Lower Elevation Balancing Tier

The Lower Elevation Balancing Tier (Lake Powell elevation less than 3,525 feet) is modeled by calculating the release necessary to balance Lake Powell and Lake Mead's projected EOWY storage (as calculated in **Section A.6.2**, *Predicting End of Water Year Volumes of Lake Powell and Lake Mead*) but constrained to be within the range of 7.0 to 9.5 maf. The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

Reduced Releases in the Mid-Elevation Release and Lower Elevation Balancing Tiers

The 2024 Near-term Colorado River Operations Final Supplemental EIS (Reclamation 2024) states:

> When operating in the Mid-Elevation Release Tier or the Lower Elevation Balancing Tier, Reclamation will consider all tools that are available during the interim period to avoid Lake Powell elevation declining below 3,500 feet. If the minimum probable 24-Month Study projects in any month an elevation below 3,500 feet in the next 12 months, the Secretary shall begin planning to reduce releases, as needed, to not less than 6.0 maf from Lake Powell in the Water Year to maintain an elevation of 3,500 feet[6].

In CRSS, this is modeled by assuming Lake Powell operations can be adjusted to protect 3,500 feet in any month when Lake Powell is operating in the Mid-Elevation Release Tier or Lower Elevation Balancing Tier. CRSS first checks the current month's Lake Powell pool elevation and the projected EOWY Lake Powell pool elevation with an assumed 6 maf release to determine the monthly release.

- If the projected EOWY Lake Powell pool elevation with a 6 maf is less than 3,500 feet, the water year release is set to 6.0 maf and the monthly release is calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*
- If the current Lake Powell pool elevation is below 3,500 feet but the projected EOWY Lake Powell pool elevation is greater than 3,500 feet, the current month's release is decreased such that the Lake Powell pool elevation is maintained at or above 3,500 feet; however, it is

[6] The Secretary reserves the right to operate Reclamation facilities to protect the Colorado River system if hydrologic conditions require such action as described in Sections 6 and 7(D) in the 2007 Interim Guidelines ROD.

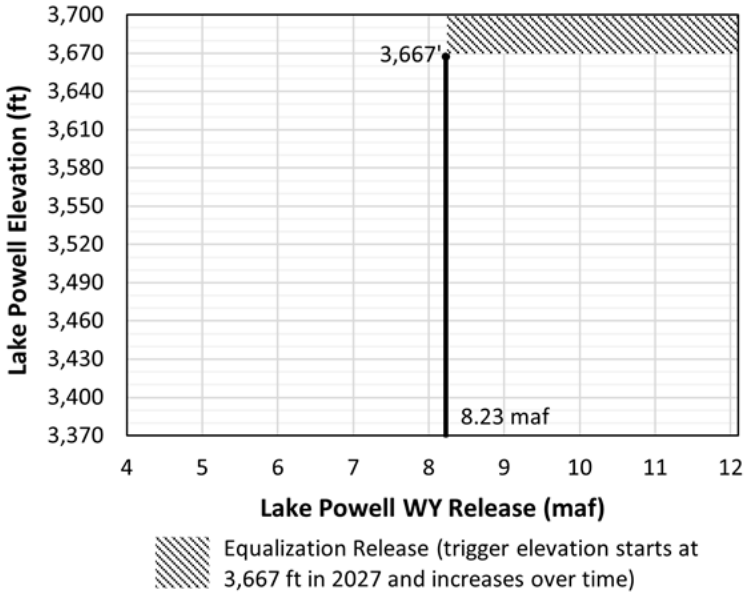
subject to the following constraints: the minimum water year release is 6.0 maf, and the monthly release will be no less than the volume necessary to meet the minimum daily LTEMP release (6,521 cfs).

If releases are adjusted to protect 3,500 feet during a given month of the water year and Lake Powell pool elevation increases above 3,500 feet, monthly releases can be increased to release up to the original water year release for the given Lake Powell operating tier.

A.6.3 No Action Alternative

In the No Action Alternative, Lake Powell annual operations are assumed to be based on the EOCY pool elevation at Lake Powell (**Figure A-1**). For October through December, 2.0 maf is released consistent with 8.23 maf monthly release pattern (**Table Attachment A1-1**) unless Lake Powell is in Safe Operating Capacity Operations (**Section A.6.1**, *Safe Operating Capacity Operations*). In January, CRSS sets the Lake Powell operations using the EOCY pool elevation:

- If the Lake Powell EOCY pool elevation is greater than or equal to the Equalization Level (**Table A-6**), the equalization operations govern the water year releases. For modeling purposes, the Equalization Level used in the No Action Alternative extends the 2007 Interim Guidelines Equalization Level through 2060, using the same calculation and parameters that were used to develop the 2007 Interim Guidelines Equalization Level. **Appendix J** describes the 602(a) storage calculation, which forms the basis for the Equalization Level under the 2007 Interim Guidelines. It documents the parameters used in the 2007 calculation, which are also used in this extension through 2060. **Appendix J** also presents a comparison illustrating how different parameter assumptions would influence the resulting 602(a) storage values.
- If the Lake Powell EOCY pool elevation is less than the Equalization Level, the water year release is set to 8.23 maf.



Coordination at High Elevations

Under the No Action Alternative, equalization releases are made from January to September. The water year release is computed as the release required to balance the contents of Lake Powell and Lake Mead by the end of the water year with a minimum release of 8.23 maf and constrained such that the release does not cause Lake Powell to decline below the Equalization Level (**Table A-6**). The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

Primary Operations

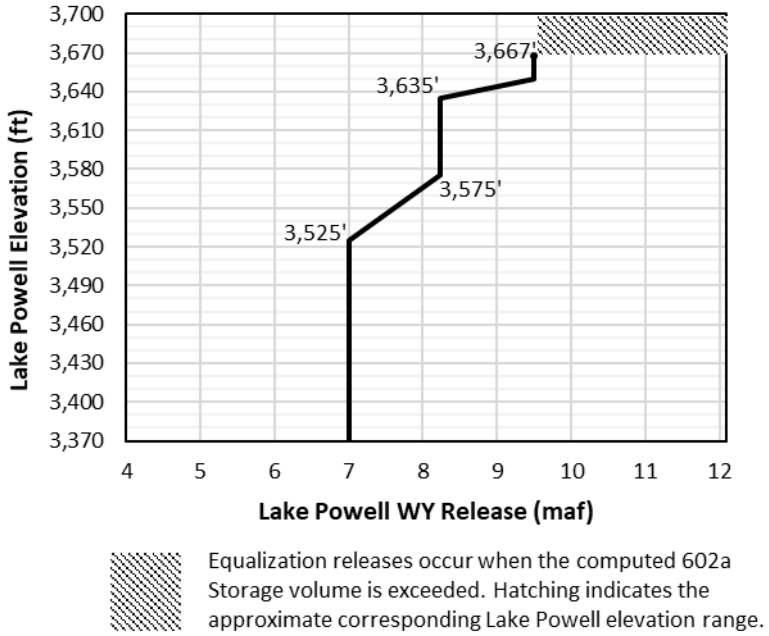
Minimum objective release operations set the water year release to 8.23 maf. The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

Figure A-1
Lake Powell Operations, No Action Alternative

A.6.4 Basic Coordination Alternative

The Lake Powell water year release is determined in October based on the previous EOWY Lake Powell storage/pool elevation (September 30).

- If the Lake Powell previous EOWY storage is greater than or equal to the 602(a) storage volume and Lake Powell EOWY storage is greater than Lake Mead EOWY storage, the equalization operations govern the water year releases.
- If the Lake Powell previous EOWY storage is less than the 602(a) storage volume or Lake Powell EOWY storage is less than Lake Mead EOWY storage, the water year release is set based on the EOWY pool elevation as shown in **Figure A-2**.



Coordination at High Elevations

If the combined Colorado River Storage Project (CRSP) storage is above the 602(a) storage volume at the previous EOWY and Lake Powell EOWY storage is greater than Lake Mead EOWY storage, equalization operations determine the water year release. A detailed description of the 602(a) storage volume calculation and parameters used in the calculation is found in **Appendix J**. For modeling purposes, the same parameters that were used to compute the 602(a) storage volume for the 2007 Interim Guidelines Equalization line are used for the Basic Coordination Alternative. In this alternative, the 602(a) storage volume is not converted to a Powell elevation. The water year release is set to the minimum of the volume needed to bring the CRSP storage down to the calculated 602(a) storage volume[7] or to balance the Lake Powell and Lake Mead projected EOWY storage, but no lower than 9.5 maf (the maximum release in primary operations). The modeled 602(a) storage

[7] The modeled logic erroneously referenced the CCS Comparative Baseline and No Action Alternative Equalization Level, rather than the intended 602(a) storage volume.

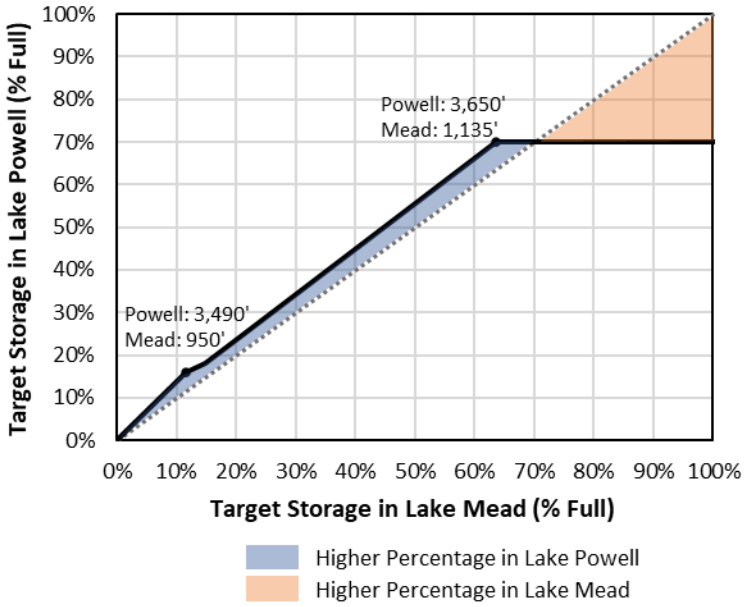
volume grows over time; in 2027, the volume is 25,082,344 af, and in 2060 it reaches 29,647,144 af. Equalization may only be triggered at the start of the water year, and once an equalization determination is made, Lake Powell operates in the Equalization Tier for the remainder of the water year. **Appendix J** also presents a comparison illustrating how different parameter assumptions would influence the resulting 602(a) storage values.

Figure A-2
Lake Powell Operations Diagram, Basic Coordination Alternative

Primary Operations

The water year release when Lake Powell is not in equalization is calculated as follows:

- If the previous EOWY Lake Powell elevation is above elevation 3,650 feet and an equalization determination has not been made, the water year release is 9.5 maf.
- If the previous EOWY Lake Powell elevation is between 3,635 feet and 3,650 feet, the water year release volume linearly increases from 8.23 maf at elevation 3,635 feet to 9.5 maf at elevation 3,650 feet.
- If the previous EOWY Lake Powell elevation is between 3,575 feet and 3,635 feet, the water year release is 8.23 maf.
- If the previous EOWY Lake Powell elevation is between 3,525 feet and 3,575 feet, the water year release volume linearly increases from 7.0 maf at elevation 3,525 feet to 8.23 maf at elevation 3,575 feet.
- If the previous EOWY Lake Powell elevation is below 3,525 feet, the water year release is 7.0 maf.



The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

A.6.5 Enhanced Coordination Alternative

Lake Powell operations target a specific distribution of storage across Lake Powell and Lake Mead for any given total volume of water as shown in **Figure A-3**. The dotted diagonal line marks a 50/50 split for reference, and the target storage curve is variable across that line, indicating the portion where Lake Powell is at higher percent capacity than Lake Mead (emphasized with blue shading) and the portion where Lake Mead is at higher percent capacity than Lake Powell (emphasized with orange shading).

- From 0 percent to 63 percent combined storage, operations would target keeping more water in Lake Powell.
- Above 63 percent full, a greater portion of water would be proactively sent to Lake Mead to prevent unplanned spill-avoidance releases and protect Glen Canyon Dam at high elevations.

Figure A-3
Coordinated Operations of Lake Powell and Lake Mead, Enhanced Coordination Alternative

The targets for coordinated operations can also be represented in a tabular format as shown in **Table A-7**.

Table A-7
Target Storages for Coordination Operations of Lake Powell and Lake Mead, Enhanced Coordination Alternative

Mead Storage (af)	Powell Storage (af)	Combined Storage (af)
0	0	0
2,005,585	3,742,714	5,748,299
3,156,353	4,215,805	7,372,158
4,475,301	5,544,923	10,020,224
15,107,119	16,309,410	31,416,529
23,143,714	16,321,726	39,465,440

Primary Operations

In October, an initial water year release is determined; in April, a one-time mid-year adjustment can be made to the water year release. The Lake Powell initial water year release is calculated based on the following factors:

- Previous EOWY physical storage of Lake Powell and Lake Mead (V_{EOWY}^{Powell}, V_{EOWY}^{Mead}, respectively)
- Target storage distribution (from **Figure A-3**)
- Preceding 10-year running average inflow to Lake Powell ($\bar{I}_{10}$)
- Lower Basin shortage for upcoming calendar year (S; see **Section A.7.5**)

CRSS first calculates the EOWY Lake Powell Target Storage (V_{target}^{Powell}) by linearly interpolating values in **Table A-7** based on the combined previous EOWY storage of Lake Powell and Lake Mead (i.e., $V_{EOWY}^{Powell} + V_{EOWY}^{Mead}$). The initial water year release (R) is then calculated as:

$$R = (V_{EOWY}^{Powell} - V_{target}^{Powell}) + I_{10} - S$$

The water year release volume must be greater than or equal to 4.72 maf, which is LTEMP daily minimum release converted to a water year volume, and less than or equal to 10.8 maf, which is the water year volume consistent with the monthly flow of 900 kaf to prevent large release volumes causing sand evacuation below Glen Canyon Dam. The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

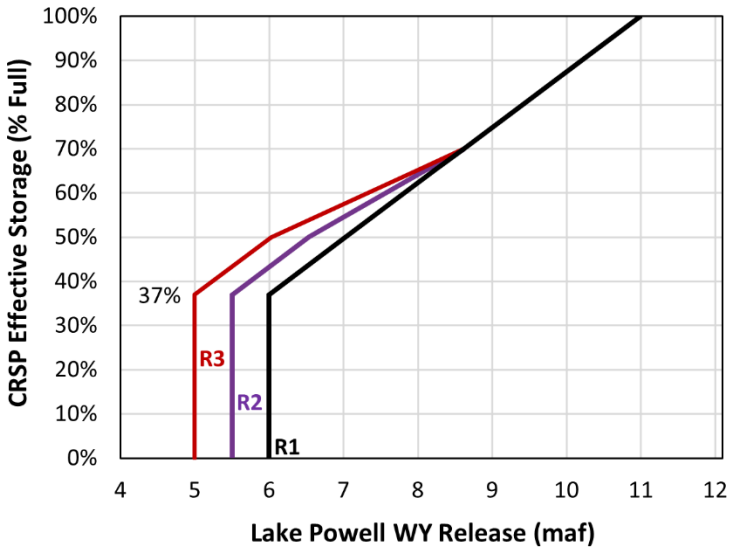
In April, a mid-year adjustment to the water year release can be made if the Lake Powell projected storage is too far off target. A new V_{target}^{Powell} is calculated using the method summarized above, but the forecasted EOWY combined Lake Powell and Lake Mead storage (i.e., $V_{EOWY}^{Powell} + V_{EOWY}^{Mead}$) is used instead of the previous year's values. The adjustment volume is then calculated as the difference between the forecasted EOWY Lake Powell storage and V_{target}^{Powell}.

There is no adjustment to the water year release if any of the following conditions are met:

- The absolute value of adjustment volume is less than 1.0 maf.
- If the projected EOWY or end-of-March Lake Powell storage is less than or equal to 3,525 feet and the release adjustment is greater than zero.
- If the projected EOWY or end-of-March Lake Powell storage is greater than 3,650 feet and the release adjustment is less than zero.

An adjusted water year volume is determined by adding the adjustment volume to the initial water year release, and is still subject to the minimum and maximum water year release volumes of 4.72 and 10.8 maf, respectively.

A.6.6 Maximum Operational Flexibility Alternative



The Lake Powell water year release is set in October using the previous EOWY effective[8] storage of CRSP reservoirs (Lake Powell, Flaming Gorge, Blue Mesa, and Navajo) and a climate response indicator[9], as described below. The Conservation Reserve, which is a storage mechanism for conserved water in Lake Powell and/or Lake Mead, is assumed to be subtracted from the physical storage so that it does not affect Lake Powell operations. The Conservation Reserve modeling assumptions are described in **Appendix B**.

Lake Powell operations are shown in **Figure A-4** and are determined based on the following release regimes:

- If the CRSP effective storage is less than or equal to 100 percent and greater than 37 percent, releases range from 11 maf to 6 maf.
- If the CRSP effective storage is less than 37 percent, the water year release is set to 6 maf unless run-of-river operations are triggered.
- Releases can be adjusted by up to one maf, depending on the previous 3-year average Lees Ferry natural flow, as described in the following section.

[8] "Effective" elevation or storage is calculated as physical elevation (storage) minus any conserved volume that is held in the respective reservoir(s).
[9] For modeling purposes, the previous 3-year average Lees Ferry natural flow is used.

Figure A-4
Lake Powell Operations Diagram, Maximum Operational Flexibility Alternative

Primary Operations

The Lake Powell water year release is based on CRSP effective storage and the previous 3-year average natural flow at Lees Ferry, Arizona. Base water year releases are decreased by up to 1.0 maf consistent with **Table A-8**, and are summarized below. Natural flow and consumptive use data for a given year become available mid-following year, so a one-year lag is applied to align inputs with operational availability. For example, 2027 operations would be informed by the 2023-2025 average natural flow.

- When the CRSP effective storage is at or below 100 percent of capacity and at or above 70 percent of capacity, a release volume would be determined for that year based on a function of storage, with 11.0 maf release at 100 percent of capacity decreasing linearly to 8.6 maf at 70 percent of capacity.
- When the CRSP effective storage is at or below 70 percent of capacity and at or above 50 percent of capacity, the release volume depends on the previous 3-year average Lees Ferry natural flow:
    - If the previous 3-year average Lees Ferry natural flow is greater than or equal to 10.0 maf, a release volume would be determined for that year based on a function of storage, with a release of 8.6 maf at 70 percent of capacity decreasing linearly to 7.0 maf at 50 percent of capacity (R1 curve in **Figure A-4**).
    - If the previous 3-year average Lees Ferry natural flow is less than 10.0 maf and greater than or equal to 8.0 maf, a release volume would be determined for that year based on a function of storage, with a release of 8.6 maf at 70 percent of capacity decreasing linearly to 6.5 maf at 50 percent of capacity (R2 curve in **Figure A-4**).
    - If the previous 3-year average Lees Ferry natural flow is less than 8.0 maf, a release volume would be determined for that year based on a function of storage, with a

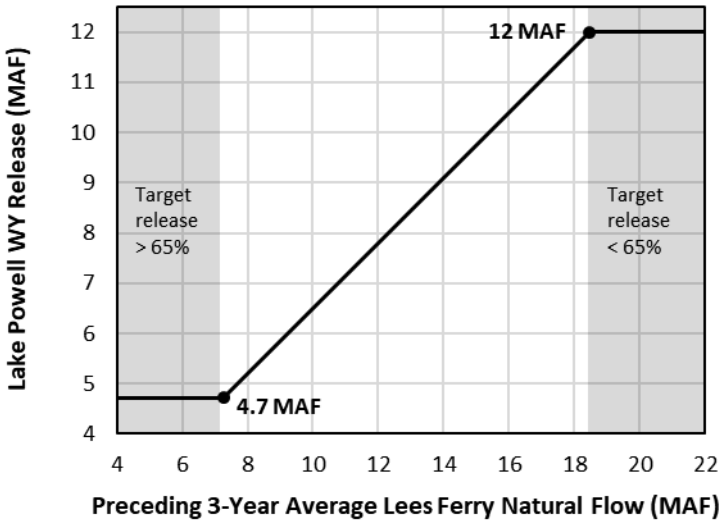
release of 8.6 maf at 70 percent of capacity decreasing linearly to 6.0 maf at 50 percent of capacity (R3 curve in **Figure A-4**).

- When the CRSP effective storage is at or below 50 percent of capacity, the release volume depends on the previous 3-year average Lees Ferry natural flow:
    - If the previous 3-year average Lees Ferry natural flow is greater than or equal to 10.0 maf, a release volume would be determined for that year based on a function of storage, with a release of 7 maf at 50 percent of capacity decreasing linearly to 6.0 maf at 37 percent of capacity (R1 curve in **Figure A-4**). Below 37 percent of capacity, the determined release would be 6.0 maf.
    - If the previous 3-year average Lees Ferry natural flow is less than 10.0 maf and greater than or equal to 8.0 maf, a release volume would be determined for that year based on a function of storage, with a release of 6.5 maf at 50 percent of capacity decreasing linearly to 5.5 maf at 37 percent of capacity (R2 curve in **Figure A-4**). Below 37 percent of capacity, the determined release would be 5.5 maf.
    - If the previous 3-year average Lees Ferry natural flow is less than 8.0 maf, a release volume would be determined for that year based on a function of storage, with a release of 6.0 maf at 50 percent of capacity decreasing linearly to 5.0 maf at 37 percent of capacity (R3 curve in **Figure A-4**). Below 37 percent of capacity, the determined release would be 5.0 maf.

Table A-8
Release Curves and Relevant Conditions, Cooperative Conservation Alternative

Lake Powell Release Curve	Previous 3-Year Average Lees Ferry Natural Flow (maf)	Release Decrease Compared to R1 Curve at 50% Full (kaf)
R1	≥ 10	N/A
R2	< 10 to ≥ 8	500
R3	< 8	1,000

The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.



Run-of-River Operations

In any month, if the Lake Powell elevation is projected to be below 3,510 feet under primary operations, Lake Powell will operate in run-of-river operations to protect infrastructure. Lake Powell monthly releases would be calculated as the minimum of Powell's inflow minus gains and losses and the calculated release to achieve the water year release determined in the previous section. The minimum monthly release is assumed to be 5,000 cfs.

A.6.7 Supply Driven Alternative

The Lake Powell water year release is calculated in October based on the preceding 3-year natural flow and is depicted in **Figure A-5**.

Figure A-5
Lake Powell Operations Diagram, Supply Driven Alternative

Primary Operations

The Lake Powell water year release is calculated using the following equation:

$$Release = NF\% \; x \; 3 \; Year \; Avg \; NF$$

where:

NF% = 65%

3-Year Avg NF = 3-year preceding average natural flow is available at a one-year lag to align with the operational availability of natural flow and consumptive use data, which is available mid-following year for a given year. For example, 2027 operations would be informed by the 2023-2025 average natural flow.

Appendix D explores the implications of using different natural flow percentages.

The release is constrained to between 4.72 maf and 12.00 maf. The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release.*

Gap Water

In years when Lake Powell cannot meet its required water year release because of low elevation infrastructure constraints, additional water is introduced into the system to (partially) make up the shortfall. For modeling purposes, this supplemental volume is termed "gap water." In CRSS, this volume is computed monthly, when the monthly release is reduced based on the low elevation infrastructure constraints (**Section A.6.1**, *Infrastructure Constraints at Low Elevations*). If this occurs, gap

water is injected above Lake Powell with limits on the annual volume based on the following calculation:

$$G_i = max\left(min\left(O_{i,u} - O_{i,c}\,,\, G_{max} - \sum_{n=j}^{i} G_n\right), 0\ af\right)$$

where:

i = month
G = gap water injected in a given month
$O_{i,u}$ = monthly release volume before constrained by infrastructure
$O_{i,c}$ = monthly release volume after constrained by infrastructure
j = October

The maximum water year gap water volume is assumed to be:

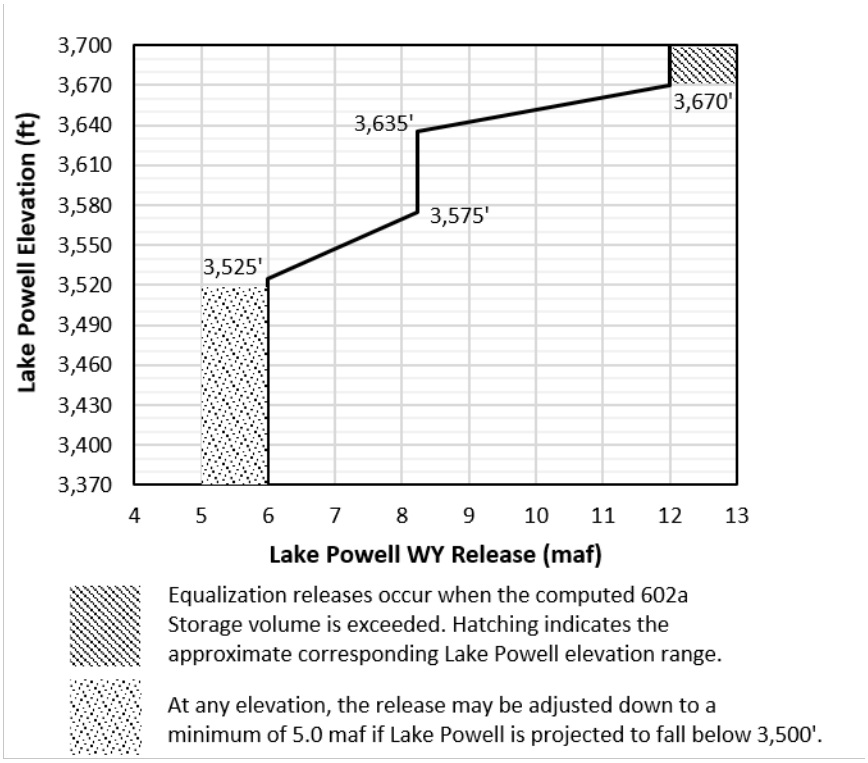
$$G_{max} = 23\% * Annual\ WY\ Estimated\ UB\ Depletion - UB\ Conservation$$

where:

23% = Lower Basin maximum shortage in this alternative divided by the total Lower Basin apportionment to the U.S. and Mexico (2.1/9 maf)

Annual WY Estimated UB Depletion = sum of the current year's projected Upper Basin depletion (estimated using the logistic regression described in **Section A.6.2**, *Lake Powell Inflow Forecast*) and the previous year's Upper Basin CRSS reservoir evaporation.

UB Conservation = water year Upper Basin conservation defined in **Appendix B**.



If the water year release volume cannot be released due to infrastructure constraints, the volume not released is tracked as 'Carryover'. The maximum carryover is constrained by the annual gap water volume. The model will try to release the Carryover volume in the following year(s) within the maximum release constraint of 12 maf.

A.6.8 Representative Preferred Alternative

The Lake Powell water year release is determined in October based on the previous EOWY Lake Powell storage/pool elevation (September 30).

- If the Lake Powell previous EOWY storage is greater than or equal to the 602(a) storage volume and Lake Powell EOWY storage is greater than Lake Mead EOWY storage, the equalization operations govern the water year releases.
- If the Lake Powell previous EOWY storage is less than the 602(a) storage volume or Lake Powell EOWY storage is less than Lake Mead EOWY storage, the water year release is set based on the EOWY pool elevation as shown in **Figure A-6**.

Figure A-6
Lake Powell Operations Diagram, Representative Preferred Alternative

Coordination at High Elevations

The Representative Preferred Alternative assumes equalization operations occur at high elevations in Lake Powell. The equalization operations modeled in the Representative Preferred Alternative are identical to the Basic Coordination Alternative (**Section A.6.4**, *Coordination at High Elevations*) except the minimum equalization release during equalization is assumed to be equal to the maximum release in the primary operation based on Lake Powell's EOWY elevation, which is typically 12 maf.

Primary Operations

The water year release when Lake Powell is not in equalization is calculated as follows:

- If the previous EOWY Lake Powell elevation is above elevation 3,670 feet and an equalization determination has not been made, the water year release is 12.0 maf.
- If the previous EOWY Lake Powell elevation is between 3,635 feet and 3,670 feet, the water year release volume linearly increases from 8.23 maf at elevation 3,635 feet to 12.0 maf at elevation 3,670 feet.
- If the previous EOWY Lake Powell elevation is between 3,575 feet and 3,635 feet, the water year release is 8.23 maf.
- If the previous EOWY Lake Powell elevation is between 3,525 feet and 3,575 feet, the water year release volume linearly increases from 6.0 maf at elevation 3,525 feet to 8.23 maf at elevation 3,575 feet.

- If the previous EOWY Lake Powell elevation is below 3,525 feet, the water year release is 6.0 maf.

The monthly release from Lake Powell is then calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.

Reduced Releases for Infrastructure Protection

Lake Powell releases can be reduced to a minimum of 5.0 maf if Lake Powell is projected to drop below 3,500 feet during the water year. In the model, CRSS first checks the current month's Lake Powell pool elevation and the projected EOWY Lake Powell pool elevation with an assumed 5.0 maf release to determine the monthly release.

- If the projected EOWY Lake Powell pool elevation with a 5.0 maf is less than 3,500 feet, the water year release is set to 5.0 maf and the monthly release is calculated using the method described in **Section A.6.1**, *Disaggregation from Annual to Monthly Release*.
- If the current Lake Powell pool elevation is below 3,500 feet but the projected EOWY Lake Powell pool elevation is greater than 3,500 feet, the current month's release is decreased such that the Lake Powell pool elevation is maintained at or above 3,500 feet; however, it is subject to the following constraints: the minimum water year release is 5.0 maf, and the monthly release will be no less than the volume necessary to meet the minimum daily LTEMP release (6,521 cfs).

If releases are adjusted to protect 3,500 feet during a given month of the water year and Lake Powell pool elevation increases above 3,500 feet, monthly releases can be increased to release up to the original water year release.

A.7 Lake Mead Operation

Lake Mead is the uppermost reservoir in the Lower Basin. Located 35 miles southeast of Las Vegas, the 726-foot-high Hoover Dam impounds Lake Mead. In CRSS, Lake Mead operations are modeled by solving for the Lower Basin condition, Lower Basin and Mexico diversions, including the conservation, storage, and delivery of conserved system and non-system water, and then setting Lake Mead's outflow to meet all downstream diversions.

Section A.7.1 describes the CRSS modeling assumptions common to all alternatives. **Sections A.7.2** through **A.7.7** describe assumptions for Lake Mead operating strategies for each alternative. The assumptions for the Lake Mead mechanism for storage and delivery of conserved system and non-system water are summarized in **Appendix B**.

A.7.1 Assumptions Common to All Alternatives

CRSS solves for the Lower Basin operating condition for the calendar year in January using a specified system condition that varies between alternatives. Each month, the rule computes downstream depletions based on scheduled inputs that are adjusted as necessary for shortage, surplus, conservation storage, and conservation delivery, as well as the volume of water needed to

meet storage targets at Lake Mohave and Lake Havasu and to offset evaporation losses at those lakes. The rule then determines the total monthly release required from Lake Mead to satisfy downstream demand, taking into account gains and losses below Lake Mead.

Water User Depletions

The depletions from Lake Mead and downstream of Hoover Dam are affected by the determination of the water supply conditions (Normal, Surplus, or Shortage) as described below in each alternative's section. Individual water users' monthly depletions are adjusted using the following equation:

$$Depletion = Schedule - Shortage + Surplus - Conservation\ Creation + Conservation\ Delivery$$

Annual volumes of shortage, surplus, and conservation activities are disaggregated to monthly volumes proportionally to a user's monthly and annual scheduled water use:

$$MonthlyVolume = AnnualVolume * \left(\frac{Monthly\ WaterUseSchedule}{AnnualWaterUseSchedule}\right)$$

Water to Mexico in Excess of Treaty Requirements and Water Bypassed Pursuant to International Boundary and Water Commission Minute 242

In CRSS, Lake Mead may release additional water to account for two types of flows to Mexico beyond the treaty-scheduled deliveries: (1) water passing to Mexico in excess of monthly schedules which reflects the treaty requirements and (2) water bypassed pursuant to International Boundary and Water Commission (IBWC) Minute 242.

Assumed annual volumes for these purposes are derived from historical data, relying on the Lower Colorado Basin Decree Accounting Reports when available, or from Reclamation's provisional estimates. The assumed annual volume for water passing to Mexico in excess of treaty requirements is based on a 5-year average updated as data become available. For this EIS, the most recent 5-year average relied on data from 2019-2023; however, 2023 was excluded because it was a flood year on the Gila River, so the value is based on 2019-2022 and was computed to be 32,413 af[10]. The assumed annual volume for water bypassed pursuant to IBWC Minute 242 is based on the long-term average from 1990-2023 and was computed to be 118,474 af[11].

For both water passing to Mexico in excess of treaty requirements and water bypassed pursuant to IBWC Minute 242, the annual averages are used for all years of the model simulation and are disaggregated to monthly volumes using monthly distribution coefficients in **Table A-9**.

[10] 2019-2021 data were obtained from the published Decree Accounting Reports and a provisional value for 2022 of 8,982 af was used, although final 2022 data were available at the time of the calculation.
[11] 1990-2021 data were obtained from the published Decree Accounting Reports. Provisional values of 141,047 and 116,738 af were used for 2022 and 2023, respectively. Although final 2022 data were available at the time of the calculation, the provisional value was used.

Table A-9
Monthly Distribution Coefficients (percent) and Annual Volume (af) of the Water Passing to Mexico in Excess of Treaty Requirements and Water Bypassed Pursuant to IBWC Minute 242

Month Distribution Coefficients	Water Passing to Mexico in Excess of Treaty Requirements	Water Bypassed Pursuant to IBWC Minute 242
Jan	5.3%	8.6%
Feb	6.3%	8.3%
Mar	20.4%	8.9%
Apr	12.5%	8.6%
May	4.0%	8.6%
Jun	0.9%	8.0%
Jul	1.2%	7.7%
Aug	2.1%	7.4%
Sep	11.5%	8.0%
Oct	8.3%	9.2%
Nov	17.8%	8.5%
Dec	9.7%	8.3%
Annual Volume	32,423 af	118,474 af

Lake Mead/Hoover Dam Flood Control

Under certain conditions, Lake Mead may release water in addition to downstream demand. This condition is termed "flood control" and is guided by the U.S. Army Corps of Engineers' (USACE's) flood control regulations as contained in the USACE's Water Control Manual for Flood Control, Hoover Dam and Lake Mead, Colorado River, Nevada and Arizona (Water Control Manual) dated December 1982.

In CRSS, there are three flood control procedures currently in effect for different times of the year. These procedures were developed in the original CRSS and are based on the Field Working Agreement between Reclamation and the USACE (USACE 1982). The first procedure is in effect throughout the year. Its objective is to maintain a minimum space of 1.5 maf in Lake Mead, primarily for extreme rain events. This space is referred to as the exclusive flood control space and is represented by the space above elevation 1,219.64 feet. The second procedure is used during the period from January through July. The objective during this period is to route the maximum inflow forecast through the reservoir system using specific rates of Hoover Dam discharge, assuming that Lake Mead will fill to elevation 1,219.64 feet at the end of July. The third procedure is used during the space building or drawdown period (August through December). The objective during this period is to gradually draw down the reservoir system to meet the total system space requirements in each month in anticipation of the next year's runoff.

Exclusive Flood Control Space Requirement

This requirement states that there must be a minimum space of 1.5 maf in Lake Mead at all times. If the release computed to meet downstream demand results in a Lake Mead storage that would violate this space requirement, the rule computes the additional release necessary to maintain that space.

January through July Operation

The flood control policy requires that the maximum forecast be used where that forecast is defined as the estimated inflow volume that, on average, will not be exceeded 19 times out of 20 (a 95 percent non-exceedance). The rule first computes the inflow forecast to Lake Mead by taking the Lake Powell forecast (**Section A.6.2**, *Lake Powell Inflow Forecast*) and adds the long-term, average tributary inflows between Lake Powell and Lake Mead. The maximum forecast is then estimated by adding an additional volume (the "forecast error term") to that inflow forecast. The forecast error term (in maf) is provided in **Table A-10**, taken from the original CRSS data.

Table A-10
Lake Mead January through July Forecast Error Forecast

Forecast Period	Forecast Error Term (maf)
January – July	4.980
February – July	4.260
March – July	3.600
April – July	2.970
May – July	2.525
June – July	2.130
July – July	0.750

The Field Working Agreement defines an iterative algorithm by which the current month's release (in cfs) is determined. Certain release levels are specified, as listed in **Table A-11**.

Table A-11
Lake Mead Flood Control Release Levels

Release Level	Release (cfs)	Description
1	19,000	Parker Powerplant capacity
2	28,000	Davis Powerplant capacity
3	35,000	Hoover Powerplant capacity (in 1987)
4	40,000	Approximate maximum flow non-damaging to streambed
5	73,000	Hoover Dam controlled discharge capacity

The flood control release needed for the current month is determined by:

$$
\begin{aligned}
&release\ needed\ for\ the\ current\ month \\
&= maximum\ forecast\ inflow \\
&- current\ storage\ space\ in\ Lake\ Powell\ (below\ the\ live\ capacity\ of\ 23{,}313{,}829\ af) \\
&- current\ storage\ space\ in\ Lake\ Mead\ (below\ the\ live\ capacity\ of\ 27{,}620{,}000\ af) \\
&+ 1.5\ maf\ (exclusive\ space) \\
&- evaporation\ and\ bank\ storage\ losses\ from\ Lake\ Powell\ and\ Lake\ Mead \\
&- Southern\ Nevada\ depletion\ - V_{t-July})
\end{aligned}
$$

where V_{t-July} is the future volume of water released, assuming a release level from **Table A-11** for the current month through July.

If the computed release for the current month is greater than that assumed for the future months, the future level is increased, and the current month release is re-computed. The computation stops once the computed release for the current month is less than or equal to that assumed for the future months. If the computed release is greater than the previously assumed level, that release is used for the current month; otherwise, the previously assumed level is used. The rule sets Lake Mead's release to the flood control release if it is greater than the release previously computed to meet downstream demands.

Space Building (August to December)

The flood control policy states the flood control storage space (in maf) in Lake Mead (storage below elevation 1,229 feet) required at the beginning of each month from August through January, as listed in **Table A-12**.

Table A-12
Lake Mead Flood Control Required Storage Space

Date	Required Storage Space (maf)
August	1.50
September	2.27
October	3.04
November	3.81
December	4.58
January	5.35

However, these targets may be reduced to the minimum of 1.5 maf in each month if additional space is available upstream in live storage. Certain upstream reservoirs are specified with a maximum creditable space (in maf) that can be applied towards the total required flood control space. The creditable storage space allowed for each of these reservoirs is listed in **Table A-13**.

Table A-13
Lake Mead Flood Control Maximum Creditable Storage Space

Reservoir	Maximum Creditable Storage Space (maf)
Powell	3.8500
Navajo	1.0359
Blue Mesa	0.7485
Flaming Gorge plus Fontenelle	1.5072

In each month (July through December), if the release computed to meet downstream demands results in an end-of-month Lake Mead storage that would violate the space requirement adjusted for upstream storage, the rule computes the additional release necessary to maintain that space. However, these releases are constrained to be less than or equal to 28,000 cfs.

Flood Control Surplus

If the modeled January 1 system volumes projects Hoover Dam flood control releases based on the Field Working Agreement between Reclamation and the USACE for the flood control operation of Hoover Dam and Lake Mead (USACE 1982), the model assigns the Full Surplus schedules to Metropolitan Water District (MWD), Southern Nevada Water Authority (SNWA), Central Arizona Project (CAP), Imperial Irrigation District, and Coachella Valley Water District (CVWD). In addition, the model assigns an additional delivery of up to 200 kaf to Mexico. All other diversion points remain at Normal schedules.

Infrastructure Constraints at Low Elevations

Lake Mead monthly releases can be constrained due to physical limitations at Hoover Dam. If Lake Mead is below approximately 950 feet in any month, releases are assumed to be constrained to the capacity of the two outlet works.

The capacity of the outlet works varies with the elevation of Lake Mead; the higher the pool elevation, the higher the potential release through the outlet works. CRSS computes the maximum monthly release based on the Lake Mead elevation using **Table A-14** and interpolates for the capacity between elevations.

Table A-14
Mead Outlet Capacity

Pool elevation (feet)	Capacity per 2 Outlet Work (cfs)	Capacity for 4 Outlet Works (cfs)
895	0	0
900	4,800	9,600
925	5,400	10,800
950	6,000	12,000
975	6,600	13,200

Dead Pool-Related Reductions

Dead pool-related reductions occur when Lake Mead is unable to release the volume of water needed to satisfy all downstream demands due to infrastructure or water availability constraints. Dead pool-related reductions are modeled on a monthly basis and for modeling purposes only, are assumed to be distributed using the priority-based shortage scheme; no alternative included any specific criteria or methodology for the distribution of dead pool-related reductions. The following sections describe the assumptions and implementation of the priority-based shortage scheme in CRSS. The implementation was designed to reflect the method described in **Appendix C**. Dead pool-related reductions also follow the **Appendix C** method; however, these reductions are applied at the monthly level because the associated reduction volumes are not known at the beginning of the year, unlike the shortage volumes in alternatives triggered by Lake Mead or other system conditions.

Conservation Activity

All ongoing conservation activities are assumed to be canceled from the month of the first occurrence of a dead pool-related reduction throughout the remainder of the calendar year. In Nevada, Tributary Conservation creation, which occurs in the reaches above Lake Mead, is assumed to be delivered to SNWA for the remainder of the calendar year.

Dead Pool-Related Reductions Volume Computation

After the cancellation of all conservation activity, the dead pool-related reduction volume is computed as the desired release from Lake Mead, i.e., the release that would be made if there were no infrastructure or water availability constraints, minus the volume of water Lake Mead is able to release.

The desired release aims to satisfy all demands that cannot be satisfied via Lower Basin inflows and the releases made from Lake Mohave and Lake Havasu and are calculated as:

$$Desired\ Release = \sum DesiredLBDepl + \sum \Delta LBStorage + \sum \Delta LBEvap - \sum LB\ Inflows$$

where:

DesiredLBDepl = Current month's desired depletions for all water users in the Lower Division States and Mexico, including miscellaneous uses and losses, after adjustments have been made for shortages

$\Delta Storage$ = Sum of the current month's change in storage for Lake Mohave and Lake Havasu

$\Delta Evap$ = Sum of the current month's evaporation for Lake Mohave and Lake Havasu

LB Inflows = Sum of the current month's Lower Basin inflows from the Davis, Alamo, Parker, and Imperial natural flow sites and the Arizona forebeared return flows

Dead Pool-Related Reduction Distribution

Dead pool-related reductions are dynamically applied to water users in the Lower Division States and Mexico based on the current month's desired depletions after adjustments have been made for shortage and existing other assumptions (e.g., shortage, system conservation, fallowing, etc.). Although it draws directly from Lake Mead, SNWA is assumed to be included in the group of water users that dead pool-related reductions are distributed to. CRSS water users that represent other

system losses, e.g., excess flows to Mexico are represented as a water user, are assumed to not be in the users that dead pool-related reductions are distributed to.

Dead pool-related reductions are assumed to use the Lower Basin-wide priority scheme (see **Appendix C** for details), which follows an approximation of the Lower Basin priority system. This scheme is implemented in CRSS using three stages, described in detail below. The assumed CRSS water users' priorities[12] are shown in **Attachment A2**. All water users' desired depletion in each stage is shorted to zero before progressing to the next stage. The three stages are:

Stage 1: Arizona Priority 4 water users and Nevada Stage 1

Stage 2: All remaining water users who do not hold present perfected rights (PPR), which includes Arizona Priorities 4, 3, and 2, California Priorities 4, 3b, 3a, 2, and 1, and Nevada Priorities 8, 7, 4, and 2.

Stage 3: All PPR water users, shorted by priority date (junior to senior)

Mexico is not included in the stages but does is assumed to be included in the distribution of dead pool-related reductions[13]. The portion of the total dead pool-related reduction applied to Mexico is assumed to be proportional to their desired depletions compared to total Lower Basin depletions in each month and is calculated as:

$$MXDeadPoolReduc\% = \frac{Desired\ Depletion_{MX}}{Desired\ Depletion_{MX} + \sum Desired\ Depletions_{LDS\ Contractors}}$$

where:

$Desired\ Depletion_{MX}$ = Desired depletion of the Mexico water user
$Desired\ Depletions_{LDS\ Contractors}$ = Desired depletions of the Lower Division State contractor water users

When distributing the dead pool-related reductions, CRSS first calculates Mexico's assumed portion of dead pool-related reduction by multiplying *MXDeadPoolReduc%* by the total dead pool-related reduction volume. The remaining dead pool-related reduction is then assigned to the Lower Division States and distributed through each stage of reductions until the full volume has been met.

To distribute dead pool-related reductions within the Lower Division States, CRSS computes the water available in each stage and determines the maximum stage that will be impacted by the dead pool-related reduction. For example, if there were 100 kaf of desired depletions in Stage 1, 500 kaf of desired depletions in Stage 2, and 200 kaf of desired depletions in Stage 3, and the dead pool-

[12] There are several CRSS "water users" that aggregate multiple real-world users. In those cases, the assumed priority used in CRSS may not match the priority of all users; the assumed priority is chosen as a modeling simplification. The shortage allocation model provides more detail on the distribution of shortages (**Appendix C**).

[13] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

related reduction was 300 kaf, the maximum stage impacted would be Stage 2. In this example, Stage 1 would satisfy 100 kaf of the dead pool-related reduction and Stage 2 would satisfy the remaining 200 kaf of dead pool shortage, with 300 kaf still available for use to users in the Stage 2 group.

When CRSS has determined the maximum stage that the dead pool-related reduction will impact, all water users with water use in the prior stages have their depletion set to 0 (i.e., fully reduced to meet the dead pool-related reduction). The remaining Lower Division State dead pool-related reduction is computed by subtracting off the total desired depletions for all stages up to the maximum stage, e.g., total desired depletions for Stage 1 and Stage 2 water users for a dead pool-related reduction that is computed to affect Stage 3 water users.

The remaining dead pool-related reduction is then applied to the water users with use included in the maximum stage. The following sections describe how the dead pool-related reduction is divided among water users in each stage. In each stage, all water of equal priority is divided proportionally using the following formula:

$$Proportion\ \%_{Specific\ Water\ User/Group} = \frac{\sum Desired\ Depletion_{Specific\ Water\ User/Group}}{\sum Desired\ Depletion_{All\ Applicable\ Water\ Users}}$$

Stage 1 Dead Pool-Related Reductions

Stage 1 dead pool-related reductions are applied to the Arizona Priority 4 water users and Nevada water users. Stage 1 dead pool-related reduction ends when Arizona Priority 4 uses are reduced to zero. Nevada's maximum stage 1 dead pool related reductions is calculated as:

$$NV_{Stage\ 1\ max} = AZ_{P4}\left(\frac{\sum NV_{non-PPR}}{\sum AZ_{non-PPR} + \sum CA_{non-PPR} + \sum NV_{non-PPR}}\right)$$

where:

$NV_{Stage\ 1\ max}$ is Nevada's maximum stage 1 dead pool-related reduction
AZ_{P4} = Desired depletions from all Arizona Priority 4 water users and Arizona's maximum stage 1 dead pool-related reduction
$AZ_{non\text{-}PPR}$ = Desired depletions from all Arizona water users who do not have PPR
$CA_{non\text{-}PPR}$ = Desired depletions from all California water users who do not have PPR
$NV_{non\text{-}PPR}$ = Desired depletions from all Nevada water users who do not have PPR

The ratio between the Nevada and Lower Division State non-PPR water for the shortage allocation model is roughly 7 percent; however, for modeled dead pool-related reductions this ratio does not always hold. Policy actions prior to the determination of dead pool-related reduction may have already shorted some non-PPR water users, changing the distribution of non-PPR desired depletions between Nevada and the rest of the Lower Division States. Additionally, dead pool-related reduction is a monthly computation, not an annual computation, so different monthly distributions can change the ratio between the Nevada non-PPR water users and the Lower Division State non-PPR water users.

The Stage 1 dead pool-related reduction is distributed to Arizona and Nevada proportional to their maximum stage 1 reduction volume, where Arizona's maximum stage 1 dead pool-related reduction

is their total P4 desired depletion. The volumes of dead pool-related reductions for Arizona and Nevada are:

$$AZ_{Stage\ 1} = DPRR * \frac{AZ_{P4}}{AZ_{P4} + NV_{Stage\ 1\ max}}$$

$$NV_{Stage\ 1} = DPRR * \frac{NV_{Stage\ 1\ max}}{AZ_{P4} + NV_{Stage\ 1\ max}}$$

where:

$AZ_{Stage\ 1}$= Arizona's portion of the Stage 1dead pool-related reduction
$NV_{Stage\ 1}$ = Nevada's portion of the Stage 1 dead pool-related reduction
$DPRR$ = the dead pool-related reduction volume

Nevada's Stage 1 dead pool-related reduction ($NV_{Stage\ 1}$) is distributed as per the state priority system from junior to senior priority, excluding the PPR water users. The shortages are first applied to the Priority 8 water users until either the Nevada portion of dead pool-related reduction is satisfied, or all Nevada Priority 8 water users have been completely shorted. If all Priority 8 water users are fully shorted and there is still a portion of the Stage 1 dead pool-related reduction remaining, then Priority 7 water users are reduced, continuing in this manner until Nevada's Stage 1 dead pool-related reduction volume has been distributed. When there are multiple users with the same priority, the dead pool-related reduction is distributed proportionally to users with the same priority.

Arizona's Stage 1 dead pool-related reduction ($AZ_{Stage\ 1}$) is distributed proportionally between all Arizona Priority 4 water users.

Stage 2 Dead Pool-Related Reductions

Stage 2 dead pool-related reductions are applied to all remaining non-PPR water users. The dead pool-related reduction is distributed to each state proportional to their remaining non-PPR desired depletions after the Stage 1 dead pool-related reductions have been applied.

Within each state, dead pool-related reductions are distributed from the most junior to the most senior priority water users excluding PPR water users. Dead pool-related reductions are first applied to the most junior priority group (Arizona Priority 3[14], California Priority 4, and Nevada Priority 8) until either the state's assigned dead pool-related reduction volume is met or all users within the priority group have been fully reduced. If the priority group is fully reduced and there is remaining dead pool-related reduction, then reductions are distributed to the next most junior priority group continuing sequentially until the state's total dead pool-related reduction obligation has been satisfied. Within each priority group, the dead pool-related reduction is applied proportionally among all water users in that group.

[14] Arizona Priority 2 and 3 are modeled as co-equal in the Shortage Allocation Model, and should be modeled as such in CRSS to be consistent with the Shortage Allocation Model.

Stage 3 Dead Pool-Related Reductions

Dead pool-related reductions in Stage 3 are applied to PPR water users using a priority list organized by priority date such that the junior water users are fully shorted before the senior water users are impacted. CRSS does not have a water user to represent each Lower Basin PPR contract and has 8 water users that represent the aggregate of several PPR contracts. When PPR contracts are aggregated to one water user, the water user is placed on the PPR list as the priority date of the PPR contract with the highest volume diversion entitlement.

Remaining Dead Pool-Related Reductions

There are very few instances when the dead pool-related reduction volume is greater than the sum of the desired use from all contract water users in the Lower Division States and Mexico. When this occurs, all water users in the Lower Basin and Mexico are fully shorted (i.e., 0 af of depletions that month), and so CRSS must short the water users that represent other uses and losses in the Lower Basin, such as the assumed excess flows to Mexico.

A.7.2 CCS Comparative Baseline

The CCS Comparative Baseline assumes that existing agreements, including the 2007 Interim Guidelines, 2017 Minute 323, and 2019 DCP continue through the analysis period (2027-2060). Lake Mead operations and Lower Basin conditions are set based on the previous EOCY pool elevation at Lake Mead. This is a modeling simplification, rather than using an August based projection of December 31 conditions, as specified in the 2007 Interim Guidelines.

Surplus

The Lower Basin is assumed to operate in a Surplus Condition if the Lake Mead elevation starts the year above 1,145 feet or if it exceeds an elevation that would trigger space-building or flood control releases pursuant to the 1984 Field Working Agreement between Reclamation and the USACE (Flood Control surplus; described in **Section A.7.1**, *Lake Mead/Hoover Dam Flood Control*) anytime in the year. There are two additional levels of Surplus in CCS Comparative Baseline: Domestic and Quantified. Increased deliveries to Mexico due to high reservoir conditions are assumed to occur and are consistent with volumes prescribed in Minute 323 Section II.

Domestic Surplus

A Domestic Surplus is determined if the Lake Mead elevation is above 1,145 feet and below the elevation that triggers a Quantified Surplus. Under a Domestic Surplus, depletion schedules are modified in the Lower Division States by the surplus volume as follows:

- For use by MWD, 250,000 af per year in addition to the amount of California's basic apportionment available to MWD.
- For use by SNWA, up to 100,000 af per year in addition to the amount of Nevada's basic apportionment available to SNWA.
    - SNWA is assumed to only take delivery of the volume of surplus water needed to satisfy their demands that exceed apportionment (see Appendix B)
- For use in Arizona, 100,000 af per year in addition to the amount of Arizona's basic apportionment available to Arizona Contractors.

These volumes are reduced by the same volume that Mexico's delivery is increased as described in a subsequent section. The reduction volume is split proportionally among these three users.

Quantified Surplus

A Quantified Surplus is assumed to occur when water needs to be delivered to reduce the risk of potential reservoir spills based on the 70R Strategy (described below). Under a Quantified Surplus, depletion schedules are modified in the Lower Division States consistent with the 2007 Interim Guidelines Section 2.B.3.

Under the 70R Strategy, a surplus condition is based on the system space requirement at the beginning of each year. Based on the 70th percentile historical runoff, a normal 7.5 maf delivery to the Lower Division States, the Upper Basin scheduled use, and Lake Powell and Lake Mead volumes at the beginning of the year, the volume of water in excess of the system space requirement at the end of the year is estimated. If that volume is greater than zero, a Surplus is declared. The quantity of the surplus volume (SurVol) is computed as follows:

$$SurVol = (PowellStorage + MeadStorage - maxStorage + ConsMechVol) * (1 + aveBankStorCoef) + runoff - UBDemand - LBDemand$$

where:

Powell Storage = Lake Powell storage at the beginning of the year
Mead Storage = Lake Mead storage at the beginning of the year
maxStorage = maximum combined storage of Lake Powell and Lake Mead that will meet the system space requirement at the beginning of the year, assuming 30% of that requirement will be met by the reservoirs upstream of Lake Powell (computed as live capacity of Lake Powell and Lake Mead – 70% * Lake Mead space requirement at the beginning of the year)
ConsMechVol = previous year's conservation mechanism volume[15]
aveBankStorCoef = average of Lake Powell and Lake Mead bank storage coefficients
runoff = assumed percentile runoff (70%) based on the historical record of 1931 through the previous year
UBDemand = Upper Basin depletion scheduled for the year (estimated using the logistic regression described in **Section A.6.2** + the estimated evaporation loss in the Upper Basin. The estimated evaporation is the sum of the previous year's evaporation at Lake Powell and calculated evaporation based on target storage at all other Upper Basin reservoirs except McPhee and the TMD reservoir which take the average of the previous 5 years of evaporation.
LBDemand = sum of depletions below Lake Powell[16] + the evaporation losses in the Lower Basin (previous year's evaporation at Lake Mead and calculated evaporation at

[15] In the Enhanced Coordination and Supply Driven Alternatives only, the modeled logic erroneously excluded new conservation mechanism volumes.
[16] The modeled logic erroneously excluded 378,700 af of MWD's annual scheduled depletion when calculating the sum of depletions below Lake Powell.

Lake Mohave and Lake Havasu, based on target storage) – average of the last 5-years of gains between Lake Powell and Lake Mead – average gains below Lake Mead

Once the quantity of surplus volume is known, the model computes each state's share (50 percent to California, 46 percent to Arizona, and 4 percent to Nevada). The model then assigns the Full Domestic Surplus schedules to MWD and SNWA. Arizona's share of the surplus is assigned to CAP, up to their Full Surplus schedule. If surplus water is still available for California, up to 300 kaf is made available to Imperial Irrigation District and CVWD.

Minute 323 Distribution of Flows Under High Elevation Reservoir Conditions

Distribution of flows to Mexico under high-elevation reservoir conditions is modeled based on the volumes in Minute 323 Section II, when the Lake Mead EOCY pool elevation is at or above 1,145 feet. Mexico's annual delivery is increased by the volumes shown in **Table A-15**.

Table A-15
Minute 323 Annual Increased Delivery To Mexico

Mead Elevation (ft)	Volume (af)
<1,145	0
1,145 to 1,170	40,000
1,170 to 1,200	55,000
>1,200	80,000

Normal Conditions

The Lower Basin operates in a Normal Condition if the Lake Mead elevation is above 1,075 feet and below 1,145 feet. DCP contributions are assumed to continue when Lake Mead is less than or equal to 1,090 feet. The modeled DCP contributions are described in the following section.

Shortage Conditions and Contributions

2007 Interim Guidelines Shortages

A 2007 Interim Guidelines Lower Basin Shortage Condition is modeled if the Lake Mead pool elevation is less than or equal to 1,075 feet. A rule solves for the Shortage Condition in January by comparing Lake Mead's previous EOCY pool elevation to defined pool elevations, as shown in **Table A-16**. The annual shortage volumes are distributed between states as shown in **Table A-16**.

Table A-16
2007 Interim Guidelines Lower Division State Shortage Volumes

Lake Mead Elevation (feet)	Arizona Shortage (af)	Nevada Shortage (af)	Total Shortage (af)
>1,075	0	0	0
1,075 to 1,050	320,000	13,000	333,000
<1,050 to 1,025	400,000	17,000	417,000
<1,025	480,000	20,000	500,000

Minute 323 Distribution of Flows Under Low Elevation Reservoir Conditions

Minute 323 defines annual reductions to Mexico under low-elevation reservoir conditions based on the Lake Mead EOCY pool elevation. **Table A-17** shows the modeled reductions to Mexico.

Table A-17
Mexico Minute 323 Reductions

Lake Mead Elevation (feet)	Mexico Reduction (af)
>1,075	0
1,075 to 1,050	50,000
<1,050 to 1,025	70,000
<1,025	125,000

2019 Drought Contingency Plan and Binational Water Scarcity Contingency Plan

CRSS models the 2019 DCP contributions in accordance with Exhibit 1 to the Lower Basin DCP agreement and the Binational Water Scarcity Contingency Plan (BWSCP) contributions in accordance with Minute 323. The contribution volumes (**Table A-18**) are based on the Lake Mead previous EOCY pool elevation. For modeling purposes, DCP contributions can be made through conversion of existing Intentionally Created Surplus (ICS), simultaneous ICS creation and conversion to DCP-ICS, and/or reducing depletions to create system water. CRSS ICS assumptions for CCS Comparative Baseline are described in **Appendix B**.

Table A-18
2019 DCP and Minute 323 BWSCP Contribution Volumes

Lake Mead Elevation (feet)	DCP (1,000 af)			Minute 323 BWSCP (1,000 af)
	Arizona	Nevada	California	
>1,090	0	0	0	0
1,090 – 1,075	192	8	0	41
1,075 – 1,050	192	8	0	30
<1,050 – >1,045	192	8	0	34
1,045 – >1,040	240	10	200	76
1,040 – >1,035	240	10	250	84
1,035 – >1,030	240	10	300	92
1,030 – 1,025	240	10	350	101
<1,025	240	10	350	150

Shortage Distribution

The shortage and DCP contributions are distributed to the Lower Division States as shown in **Table A-16** and **Table A-18**. In Nevada, the Southern Nevada Water Providers water user incurs the entire shortage volume and DCP contribution. The Nevada state apportionment is reduced by the shortage volume, so the Southern Nevada Water Providers depletion requested is not affected by the shortage volume until their demand is closer to the state apportionment (see **Appendix M** for assumed depletion schedules). In California, the DCP contribution is split such that 93 percent is applied to MWD and 7 percent to CVWD. In Arizona, the shortage volume is distributed

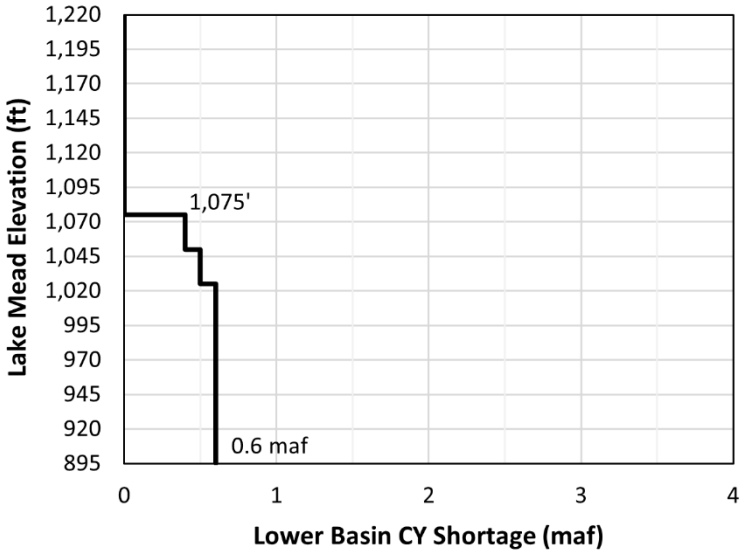
proportionally between Priority 4 water users and DCP contribution volumes are made by the CAP water user.

A.7.3 No Action Alternative

The Lake Mead operations and Lower Basin conditions for the No Action Alternative are assumed to be determined based on the previous EOCY pool elevation at Lake Mead.

Surplus

The No Action Alternative models two levels of surplus for the Lower Basin: Quantified Surplus and Flood Control Surplus. The Quantified Surplus modeling assumptions under the No Action Alternative are identical to CCS Comparative Baseline (**Section A.7.2**). Flood Control Surplus is described in **Section A.7.1**, *Flood Control Surplus*.



Normal Conditions

The Lower Basin operates in a Normal Condition if the Lake Mead elevation is above 1,075 feet and not in a surplus condition.

Shortage Condition

A Shortage Condition is modeled in the Lower Basin under the No Action Alternative when Lake Mead ended the previous year below 1,075 feet. The shortage volumes by Lake Mead elevation are shown in **Figure A-7** and are the same as the total Lower Basin volume under the 2007 Interim Guidelines Shortages, not including DCP and BWSCP contributions, in CCS Comparative Baseline.

Figure A-7
Shortage Guidelines to Reduce Deliveries from Lake Mead, No Action Alternative

Note: Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the U.S.-Mexico Treaty on Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande (1944 Water Treaty) or to

> represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Shortage Distribution

The No Action Alternative distributes shortages using the priority system. The following describes the assumptions and implementation of the priority-based shortage scheme in CRSS. The implementation was designed to reflect the method described in **Appendix C**. Shortages are applied to water users in the Lower Division States and Mexico based on the current year's scheduled demand. The priority-based shortage scheme follows an approximation of the priority system (see **Appendix C** for details). It is implemented in CRSS using three stages, described in detail below. The assumed CRSS water users' priorities[17] are shown in **Attachment A2**. All water users' scheduled demand in each stage is shorted to zero before progressing to the next stage. The three stages are:

Stage 1: Arizona Priority 4 water users and Nevada Stage 1

Stage 2: All remaining water users who do not hold PPR, which includes Arizona Priorities 4, 3, and 2, California Priorities 4, 3b, 3a, 2 and 1, and Nevada Priorities 8, 7, 4, and 2

Stage 3: All PPR water users, shorted by priority date (junior to senior)

Mexico is not included in the stages but is assumed to be included in the distribution of shortages. Mexico's portion of the total Lower Basin shortage is assumed to be 16.67 percent, proportional to Mexico's apportionment relative to the combined apportionments of the Lower Division States and Mexico[18].

In CRSS, Mexico's assumed portion of the total Lower Basin shortage is computed. The remainder of the shortage is then distributed to the Lower Division States using a modeling estimation of the priority system as described above. This is similar to the method used to distribute dead pool-related reductions (**Section A.7.1**, *Dead Pool-Related Reductions*), except that the shortages are distributed at an annual scale and are based on the input depletion schedules/state apportionments whereas dead pool-related reductions are distributed monthly and rely on desired use.

A.7.4 Basic Coordination Alternative

The Lake Mead operations and Lower Basin conditions for the Basic Coordination Alternative are assumed to be based on the previous EOWY pool elevation at Lake Mead.

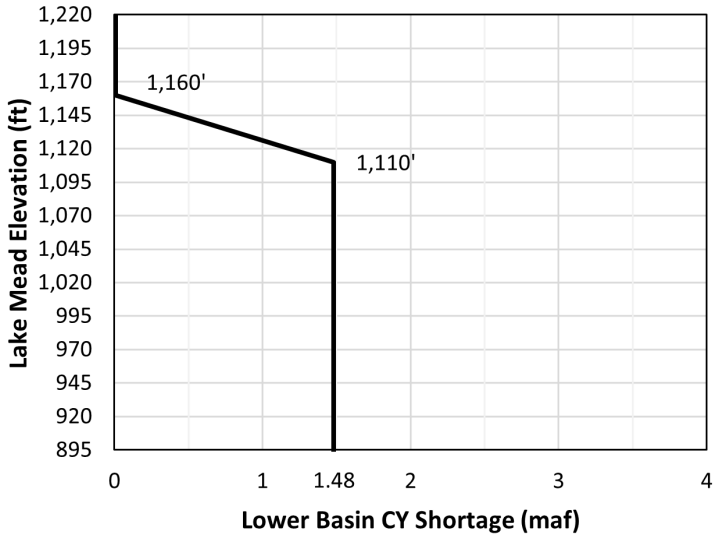
[17] There are several CRSS "water users" that aggregate multiple real-world users. In those cases, the assumed priority used in CRSS may not match the priority of all users; the assumed priority is chosen as a modeling simplification. **Appendix C** provides more details on the distribution of shortages.

[18] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico.

Surplus

The Surplus method under the Basic Coordination Alternative is modeled identically to that of the No Action Alternative.

Normal Conditions



The Lower Basin operates in a Normal Condition if the Lake Mead elevation is above 1,160 feet and not in a surplus condition.

Shortage Condition

A Shortage Condition is modeled in the Lower Basin under the Basic Coordination Alternative when Lake Mead ended the previous water year below 1,160 feet. The shortage zones are summarized below and shown in **Figure A-8**.

- When Lake Mead is at or below elevation 1,160 feet and at or above 1,110 feet, a shortage volume would be imposed for that year based on a function of elevation, with 0.0 maf of shortage at 1,160 feet increasing linearly to 1.48 maf at 1,110 feet.
- When Lake Mead is below elevation 1,110 feet, a shortage of 1.48 maf would be imposed for that year.

Figure A-8
Shortage Guidelines to Reduce Deliveries from Lake Mead, Basic Coordination Alternative

Note: Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Shortage Distribution
Shortage volumes in the Basic Coordination Alternative are distributed among mainstream Lower Colorado River users based on the priority system, identical to the No Action Alternative.

A.7.5 Enhanced Coordination Alternative

The Lake Mead operations and Lower Basin conditions for the Enhanced Coordination Alternative are assumed to be based on the previous EOWY sum of effective storage[19] in Lake Powell and physical storage in Lake Mead. The combined storage percentage is computed as:

$$S_{eff} = \frac{P_{EOWY} - C_{UB} + M_{EOWY}}{P_{max} + M_{max}}$$

where:

S_{eff} = the total Lake Powell effective storage and Lake Mead physical storage as a percentage of capacity
P_{EOWY} = Lake Powell physical storage at the end of the previous water year
C_{UB} = the total volume of conserved water in Lake Powell
M_{EOWY} = Lake Mead physical storage at the end of the previous water year
P_{max} = Lake Powell live capacity (23.31 maf)
M_{max} = the Lake Mead live capacity excluding exclusive flood control space (26.12 maf)

Surplus

The Surplus method under the Enhanced Coordination Alternative is modeled identically to that of the No Action Alternative.

Normal Conditions

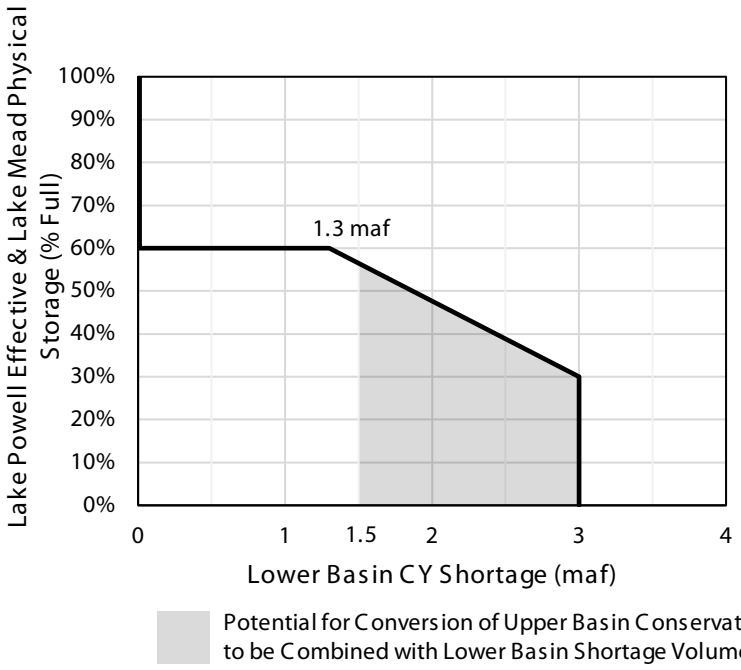
The Lower Basin operates in a Normal Condition if the sum of Lake Powell effective storage and Lake Mead physical storage at the end of the previous water year is above 60 percent and not in a Surplus Condition.

Shortage Condition

A Shortage Condition is modeled in the Lower Basin under the Enhanced Coordination Alternative when the sum of Lake Powell effective storage and Lake Mead physical storage at the end of the previous water year is below 60 percent.

Required shortages could be partially or fully offset by converting previously conserved Upper Basin water, subject to provisions described below. The shortage zones are summarized below and shown in **Figure A-9**.

- When the sum of Lake Powell effective storage and Lake Mead physical storage is equal to or less than 60 percent of combined capacity and greater than or equal to 30 percent combined capacity, a shortage volume would be imposed for that year based on a function



[19] "Effective" storage is calculated as physical storage minus any conserved volume that is held in the respective reservoir(s).

of storage, with 1.3 maf of shortage at 60 percent of capacity increasing linearly to 3.0 maf at 30 percent of capacity.

- When the sum of Lake Powell effective storage and Lake Mead physical storage is less than 30 percent of combined capacity, a shortage volume of 3.0 maf would be imposed for that year.

When Lower Basin shortages are greater than 1.5 maf, a volume equal to one-third of the volume above 1.5 maf would be converted from the Lake Powell conservation pool into system water such that the total of Lower Basin shortages and conversion of Upper Basin water equal the required total shortage volume (i.e., above 1.5 maf, there is a 2-to-1 Lower Basin shortage-to-Upper Basin conversion ratio) If the prescribed 2-to-1 volume is not available in the Lake Powell conservation pool, 100 percent of the available volume would be converted, and the Lower Basin would take the balance of shortages. The Upper Basin conservation pool modeling assumptions are described in **Appendix B**.

Figure A-9
Shortage Guidelines to Reduce Deliveries from Lake Mead, Enhanced Coordination Alternative

Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Shortage Distribution

Shortages in the Enhanced Coordination Alternative are assumed to be distributed pro rata among mainstream Lower Colorado River users independent of state. The CRSS implementation of the pro rata shortage approach distributes the shortage volume proportionally to all Lower Division State water users and Mexico[20] using the equation:

$$Water\ User\ Proportion\ \% = \frac{Annual\ Depletion\ Schedule_{\ Water\ User}}{\sum Annual\ Depletion\ Schedule_{\ All\ Applicable\ Water\ Users}}$$

where:

$Annual\ Depletion\ Schedule_{Water\ User}$ = Annual depletion schedule volume for the water user being shorted

$\sum Annual\ Depletion\ Schedule_{All\ Applicable\ Water\ Users}$ = Sum of the annual depletion schedules for all contract water users in the Lower Basin and Mexico (i.e., 9.0 maf)

A.7.6 Maximum Operational Flexibility Alternative

The Lake Mead operations and Lower Basin conditions for the Maximum Operational Flexibility Alternative are assumed to be based on the previous EOWY total system effective storage (Lake Powell, Flaming Gorge, Blue Mesa, and Navajo, Lake Mead, Lake Mohave, and Lake Havasu) and a climate response indicator[21]. The Conservation Reserve, which is a storage mechanism for conserved water in Lake Powell and/or Lake Mead, is assumed to be subtracted from the physical storage so that it does not affect Lake Mead operations. The Conservation Reserve modeling assumptions are described in **Appendix B**. The EOWY total system effective storage as a percentage is computed as:

$$S_{eff} = \frac{(\sum_{r \in R} r_{EOWY}) - C_{CR}}{\sum_{r \in R} r_{max})}$$

where:

S_{eff} = the total system effective storage as a percentage of capacity
R = the set of system reservoirs: Lake Powell, Flaming Gorge, Blue Mesa, and Navajo, Lake Mead, Lake Mohave, and Lake Havasu
r_{EOWY} = the EOWY physical storage at the reservoir
r_{max} = the assumed maximum capacity of the reservoir from **Table A-2**
C_{CR} = the total volume of conserved water in the Conservation Reserve

[20] Shortage distributions include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

[21] For modeling purposes, the previous 3-year average Lees Ferry natural flow is used.

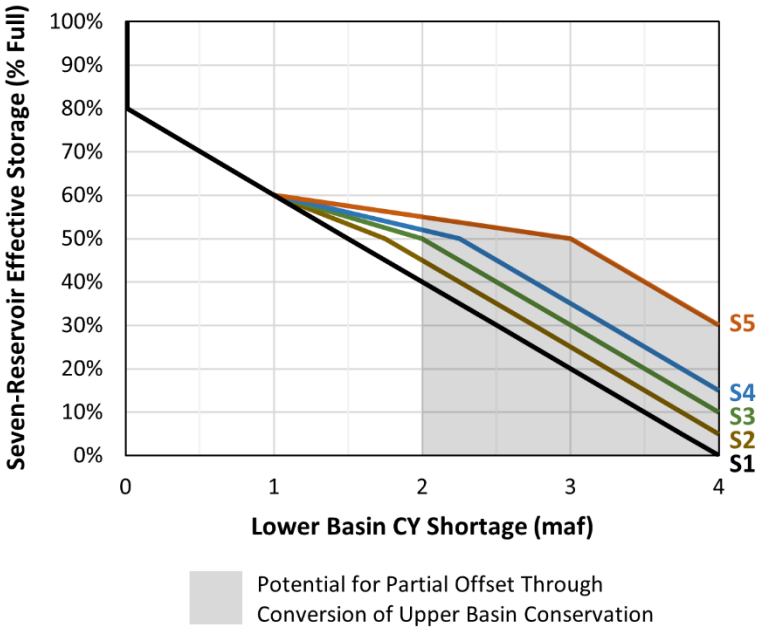
Surplus

The Maximum Operational Flexibility Alternative assumes that Surplus Conditions only occur during Flood Control Surplus. Flood Control Surplus is described in **Section A.7.1**, *Flood Control Surplus*.

Normal Conditions

The Lower Basin operates in a Normal Condition if the total system effective storage is greater than 60 percent and Lake Mead is not in a Flood Control Surplus Condition.

Shortage Condition



A Shortage Condition is modeled in the Lower Basin under the Maximum Operational Flexibility Alternative when the total system effective storage is less than 60 percent at the end of the previous water year. The shortage zones and previous 3-year average Lees Ferry natural flow values are summarized below and shown in **Figure A-10** and **Table A-19**.

- When total system effective storage is at or below 80 percent of capacity and at or above 60 percent of capacity, a shortage volume would be imposed for that year based on a function of storage, with 0.0 maf of shortage at 80 percent of capacity increasing linearly to 1.0 maf at 60 percent of capacity.
- When total system effective storage is at or below 60 percent of capacity and at or above 50 percent of capacity, the shortage volume depends on the previous 3-year average Lees Ferry natural flow:
    - If the previous 3-year average Lees Ferry natural flow is greater than 14.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 1.0 maf of shortage at 60 percent of capacity increasing linearly to 1.5 maf at 50 percent of capacity (S1 curve in **Figure A-10**).
    - If the previous 3-year average Lees Ferry natural flow is less than 14.0 maf and greater than or equal to 12.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 1.0 maf of shortage at 60 percent of capacity increasing linearly to 1.75 maf at 50 percent of capacity (S2 curve in **Figure A-10**).
    - If the previous 3-year average Lees Ferry natural flow is less than 12.0 maf and greater than or equal to 10.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 1.0 maf of shortage at 60 percent of capacity increasing linearly to 2.0 maf at 50 percent of capacity (S3 curve in **Figure A-10**).
    - If the previous 3-year average Lees Ferry natural flow is less than 10.0 maf and greater than or equal to 8.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 1.0 maf of shortage at 60 percent of capacity increasing linearly to 2.25 maf at 50 percent of capacity (S4 curve in **Figure A-10**).
    - If the previous 3-year average Lees Ferry natural flow is less than 8.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 1.0 maf of shortage at 60 percent of capacity increasing linearly to 3.0 maf at 50 percent of capacity (S5 curve in **Figure A-10**).

- When total system effective storage is 50 percent of capacity or less, the shortage volume depends on the previous 3-year average Lees Ferry natural flow:
    - If the previous 3-year average Lees Ferry natural flow is greater than 14.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 1.5 maf of shortage at 50 percent of capacity increasing linearly to 4.0 maf at 0 percent of capacity (S1 curve in **Figure A-10**).
    - If the previous 3-year average Lees Ferry natural flow is less than 14 maf and greater than or equal to 12.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 1.75 maf of shortage at 50 percent of capacity increasing linearly to 4.0 maf at 5 percent of capacity (S2 curve in **Figure A-10**). Below 5 percent of capacity, a shortage of 4.0 maf would be imposed for that year.
    - If the previous 3-year average Lees Ferry natural flow is less than 12.0 maf and greater than or equal to 10.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 2.0 maf of shortage at 50 percent of capacity increasing linearly to 4.0 maf at 10 percent of capacity (S3 curve in **Figure A-10**). Below 10 percent of capacity, a shortage of 4.0 maf would be imposed for that year.
    - If the previous 3-year average Lees Ferry natural flow is less than 10.0 maf and greater than or equal to 8.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 2.25 maf of shortage at 50 percent of capacity increasing linearly to 4.0 maf at 15 percent of capacity (S4 curve in **Figure A-10**). Below 15 percent of capacity, a shortage of 4.0 maf would be imposed for that year.
    - If the previous 3-year average Lees Ferry natural flow is less than 8.0 maf, a shortage volume would be imposed for that year based on a function of storage, with 3.0 maf of shortage at 50 percent of capacity increasing linearly to 4.0 maf at 30 percent of capacity (S5 curve in **Figure A-10**). Below 30 percent of capacity, a shortage of 4.0 maf would be imposed for that year.

Upper Basin users' conserved water is assumed to be converted to system water based on the shortage curve in **Figure A-10**. When Lower Basin shortages are greater than 2.0 maf, the volume above 2.0 maf would be converted from Upper Basin users' Conservation Reserve water to system water, subject to availability in the Reserve. The required Lower Basin shortage volume would be reduced by whatever volume of previously conserved Upper Basin water is converted. The Upper Basin Conservation Reserve modeling assumptions are described in **Appendix B**.

Figure A-10
Shortage Guidelines to Reduce Deliveries from Lake Mead, Maximum Operational Flexibility Alternative

Note: Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Table A-19
Shortage Curves and Relevant Conditions, Maximum Operational Flexibility Alternative

Shortage Curve	Previous 3-Year Average Lees Ferry Natural Flow (maf)	Shortage Increase Compared to S1 Curve at 50% Full (kaf)
S1	≥ 14	N/A
S2	< 14 to ≥ 12	250
S3	< 12 to ≥ 10	500
S4	< 10 to ≥ 8	750
S5	< 8	1,500

Shortage Distribution

Shortages in the Maximum Operational Flexibility Alternative are assumed to be based on priority as described in the Lower Basin Priority method of the Supply Driven Alternative (refer to **Section A.7.7**, *Shortage Condition*).

A.7.7 Supply Driven Alternative

The Lake Mead operations and Lower Basin conditions for the Supply Driven Alternative are assumed to be based on the July 31 effective pool elevation at Lake Mead.

Surplus

The Supply Driven Alternative assumes three levels of surplus for the Lower Basin: Domestic Surplus, Quantified Surplus and Flood Control Surplus. Flood Control Surplus is described in **Section A.7.1**, *Flood Control Surplus*.

Domestic Surplus

Domestic Surplus is assumed to occur anytime the July 31 Lake Mead effective elevation is at or above 1,165 feet and not in a Quantified or Flood Control Surplus Condition. Surplus volumes are assumed to be distributed as shown in **Table A-20**, with Arizona's volume delivered to CAP, California's volume delivered MWD, and Nevada's volume delivered SNWA in CRSS.

Table A-20
Lower Basin Domestic Surplus Assumptions

Mead Pool Elevation (feet)	Arizona Surplus (af)	California Surplus (af)	Nevada Surplus (af)	Total US Surplus (af)	Mexico Surplus* (af)	Total (af)
<1,165	0	0	0	0	0	0
1,165	80,000	0	3,333	83,333	16,667	100,000
1,170	160,000	0	6,667	166,667	33,333	200,000
1,175	240,000	0	10,000	250,000	50,000	300,000
1,180	240,000	80,000	13,334	333,334	66,666	400,000
1,185+	240,000	160,000	16,667	416,667	83,333	500,000

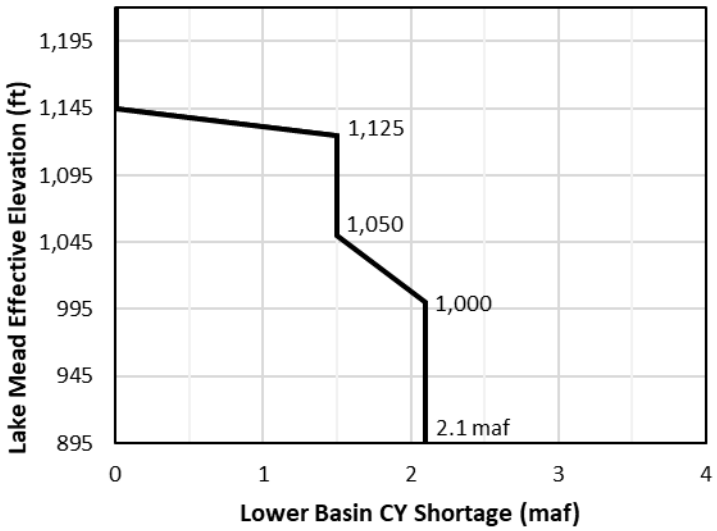
*Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current United States policy or a determination of future United States policy regarding deliveries to Mexico.

Quantified Surplus

The Quantified Surplus model assumptions are identical to the CCS Comparative Baseline (**Section A.7.2**, *Surplus*, *Quantified Surplus*), except the quantity of surplus volume is assumed to be distributed among states as follows: 41.6 percent to California, 38.33 percent to Arizona, 3.33 percent to Nevada, and 16.67 percent to Mexico[22].

Normal Conditions

The Lower Basin operates in a Normal Condition if the Lake Mead effective elevation is above 1,145 feet and below 1,165 feet.



[22] The modeled logic erroneously determines Quantified Surplus as the maximum of the Domestic Surplus schedules developed under the Interim Guidelines and the updated Domestic Surplus logic developed for the Supply Driven Alternative. Instead, it should determine Quantified Surplus as the maximum of the Domestic Surplus allocation and the Quantified Surplus volume calculated using the 70R spill avoidance strategy.

Shortage Condition

A Shortage Condition is modeled in the Lower Basin under the Supply Driven Alternative when the Lake Mead effective elevation on July 31 is below 1,145 feet. The shortage zones are summarized below and shown in **Figure A-11**.

- When Lake Mead effective elevation is at or below 1,145 feet and at or above 1,125 feet, a shortage volume would be imposed for that year based on a function of elevation, with 0.0 maf of shortage at 1,145 feet increasing linearly to 1.5 maf at 1,125 feet.
- When Lake Mead effective elevation is at or below 1,125 feet and at or above 1,050 feet, a shortage volume of 1.5 maf would be imposed for that year.
- When Lake Mead effective elevation is at or below 1,050 feet and at or above 1,000 feet, a shortage volume would be imposed for that year based on a function of elevation, with 1.5 maf of shortage at 1,050 feet increasing linearly to 2.1 maf at 1,000 feet.
- When Lake Mead effective elevation is below 1,000 feet a shortage volume of 2.1 maf would be imposed for that year.

Figure A-11
Shortage Guidelines to Reduce Deliveries from Lake Mead, Supply Driven Alternative

Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Shortage Distribution

Shortage volumes in this alternative are modeled using two different approaches to the distribution of shortages among mainstream Lower Colorado River users:

1. Lower Basin Priority: up to 1.5 maf, intra-state priority using state distributions submitted by Lower Division States; above 1.5 maf, intra-state priority using state distribution based on the CRSS model implementation of priority as described in the No Action Alternative (**Section A.7.3**, *Shortage Condition*, *Shortage Distribution*).

2. Lower Basin Pro Rata: up to 1.5 maf, intra-state pro rata using state distributions submitted by Lower Division States; above 1.5 maf, intra-state pro rata distributed to states proportionally based on unreduced apportionments as described in the Enhanced Coordination Alternative (**Section A.7.5**, *Shortage Condition*, *Shortage Distribution*).

"State distributions" refers to how total shortage volumes up to 1.5 maf are assumed to be distributed in the Lower Basin. **Table A-21** reports the assumed distributions of shortage volumes up to 1.5 maf.

Table A-21
Supply Driven Shortage Distribution Assumptions Submitted by the Lower Division State

Total Shortage (af)	Arizona (af)	California (af)	Nevada (af)	Mexico* (af)
1,500,000	760,000	440,000	50,000	250,000
300,000	240,000	0	9,990	50,010
0	0	0	0	0

*Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current United States policy or a determination of future United States policy regarding deliveries to Mexico.

A.7.8 Representative Preferred Alternative

The Lake Mead operations and Lower Basin conditions for the Representative Preferred Alternative are assumed to be based on the December 31 pool elevation at Lake Mead.

Surplus

The Representative Preferred Alternative assumes three levels of surplus for the Lower Basin: Domestic Surplus, Quantified Surplus and Flood Control Surplus. Flood Control Surplus is described in **Section A.7.1**, *Flood Control Surplus*.

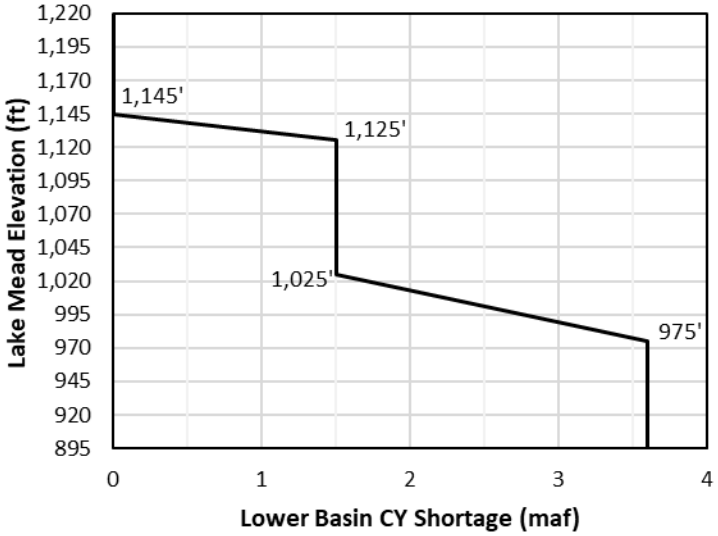
Domestic Surplus

Domestic Surplus model assumptions are identical to the Supply Driven Alternative (**Section A.7.7**, *Surplus*, *Domestic Surplus*), except it is assumed to occur anytime the December 31 Lake Mead elevation is at or above 1,165 feet and not in a Quantified or Flood Control Surplus Condition.

Quantified Surplus

The Quantified Surplus model assumptions are identical to the Supply Driven Alternative (**Section A.7.7**, *Supply Driven Alternative*).

Normal Conditions



The Lower Basin operates in a Normal Condition if the Lake Mead elevation is above 1,145 feet and below 1,165 feet.

Shortage Condition

A Shortage Condition is modeled in the Lower Basin under the Representative Preferred Alternative when the Lake Mead elevation on December 31 is below 1,145 feet. The shortage zones are summarized below and shown in **Figure A-12**.

- When Lake Mead elevation is at or below 1,145 feet and at or above 1,125 feet, a shortage volume would be imposed for that year based on a function of elevation, with 0.0 maf of shortage at 1,145 feet increasing linearly to 1.5 maf at 1,125 feet.
- When Lake Mead elevation is at or below 1,125 feet and at or above 1,025 feet, a shortage volume of 1.5 maf would be imposed for that year.
- When Lake Mead elevation is at or below 1,025 feet and at or above 975 feet, a shortage volume would be imposed for that year based on a function of elevation, with 1.5 maf of shortage at 1,025 feet increasing linearly to 3.6 maf at 975 feet.
- When Lake Mead elevation is below 975 feet a shortage volume of 3.6 maf would be imposed for that year.

Figure A-12
Shortage Guidelines to Reduce Deliveries from Lake Mead, Representative Preferred Alternative

Shortage volumes include modeling assumptions for reductions in water deliveries to Mexico. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current United

States policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Shortage Distribution

Two different approaches for distributing shortages are assumed in the Representative Preferred Alternative. In 2027 and 2028 shortage volumes up to 1.5 maf are distributed using the approach developed by the Lower Division States and shortage volumes above 1.5 maf up to 3.6 maf are distributed using the priority system. These assumptions match the assumptions in the Lower Basin Priority method, as described in the Supply Driven Alternative (**Section A.7.7**, *Shortage Distribution*). Shortage volumes for 2029 through 2060 are distributed among mainstream Lower Colorado River users based on the priority system, identical to the No Action Alternative (**Section A.7.3**, *Shortage Distribution*).

A.8 Lake Mohave and Lake Havasu Operations

Lake Mohave and Lake Havasu are operated to meet user-specified storage targets at the end of each month. These operations remain consistent for all alternatives. The storage targets and the corresponding elevations for Lake Mohave and Lake Havasu are provided in the following sections.

A.8.1 Lake Mohave/Davis Dam

Lake Mohave is operated to meet monthly elevation targets (**Table A-22**). These elevation targets are based on storage space targets set by the USACE for Lower Basin flood control purposes, as well as for endangered species operations developed in conjunction with the U.S. Fish and Wildlife Service.

Table A-22
Lake Mohave Monthly Elevation and Storage Targets

Month	Lake Mohave Target Elevation (feet)	Lake Mohave Target Storage (1,000 af)
January	641.8	1,666
February	641.8	1,666
March	642.5	1,685
April	643.0	1,699
May	643.0	1,699
June	643.0	1,671
July	642.0	1,658
August	642.0	1,658
September	640.0	1,617
October	630.5	1,371
November	635.0	1,486
December	638.7	1,583

A.8.2 Lake Havasu/Parker Dam

Lake Havasu is operated to meet monthly elevation targets (**Table A-23**). These elevation targets are based on storage space targets set by the USACE for Lower Basin flood control purposes, as well as for seasonal needs to meet downstream water demands.

Table A-23
Lake Havasu Monthly Elevation and Storage Targets

Month	Lake Havasu Target Elevation (feet)	Lake Havasu Target Storage (1,000 af)
January	446.5	552
February	446.5	552
March	446.7	555
April	448.7	593
May	448.7	593
June	448.7	593
July	448.0	580
August	447.5	571
September	447.5	571
October	447.5	571
November	447.5	571
December	446.5	552

A.9 Energy Generation

RiverWare™ includes a variety of methods that can be chosen to compute electrical power generation and estimate generation capacity. All methods compute power and energy on a monthly basis. In addition to power and energy, these results can be used to estimate revenue and total economic value of hydropower. The following sections describe the methods used to compute power at Glen Canyon Dam, Hoover Dam, Davis Dam, and Parker Dam.

A.9.1 Glen Canyon Dam

While CRSS includes a RiverWare™ method to compute electrical power generated from Glen Canyon Dam, the power generation data used in **Section 3.15** are computed using Generation Transmission Maximization Model Lite.

If the previous month's elevation is less than 3,490 feet, there is no power or energy generated for the current month. This elevation reflects the minimum power pool elevation at Lake Powell.

A.9.2 Hoover Dam

The method that computes power and energy generated at Hoover Dam assumes two levels of power generation. The lower level of generation occurs at base flow, while the upper level occurs at peak flow. The method computes the fraction of the month that the powerplant is operated at peak flow and base flow. The peak flow is the most efficient flow through the turbines for the current

operating head, while the base flow represents the minimum flow through the turbines to produce energy.

The base flow and corresponding power generation are based on the outflow for the current month. The peak flow must be computed through an iterative procedure using operating head, tailwater elevation, and turbine release. The initial turbine release is assumed to be that corresponding to maximum power production. Tailwater elevation at Hoover Dam is computed as a function of Lake Mohave elevation and Hoover Dam release.

The monthly Hoover Dam release volume at the base flow is computed by applying the base flow over the month. The monthly release volume at the peak flow is computed as:

$$PeakFlowVolume = TurbineReleaseVolume - BaseFlowVolume$$

Next, the number of hours required for operation at base and peak flows are computed as:

$$PeakHours = \frac{PeakFlowVolume}{(PeakFlow - BaseFlow) * 3600}$$

$$BaseHours = \frac{SecondsInMonth}{3600} - PeakHours$$

where 3,600 is the amount of seconds per hour.

If the peak hours are greater than the length of the month, the peak hours' value is set equal to the length of the month, and the base hours value is set to zero. The peak and base hours are then multiplied by the powerplant capacity at each level and added together to obtain the total energy produced for the month. Power is computed as the energy divided by the length of the month in hours.

The algorithm described above allows power generation at elevations below approximately 950 feet, which is the minimum power pool at Lake Mead. According to the algorithm, power is generated as long as the minimum operating head of 305 feet is available, corresponding to an elevation of about 950 feet. Because there is no operating experience at these elevations, it is impossible to verify whether CRSS mimics the actual turbine performance at such low heads. It is, therefore, critical to interpret energy results from CRSS in a relative, comparative manner rather than as absolute quantities.

Power capacity is the power that could be generated if the flow is directed through the penstock turbine(s) with a given operating head. This is computed to distinguish between actual power production and the power that could be produced.

A.9.3 Davis Dam

The method that computes power and energy generation at Davis Dam uses an empirical relationship as a function of flow, operating head, plant efficiency, and user-specified power coefficients. This empirical relationship is estimated by Reclamation and was last updated in 2019

using January 2012–September 2018 historical data. Energy is computed using this empirical relationship as:

$$Energy\ (MWH) = \left(C_1 * \frac{62.4}{737.5} * Outflow\ (1000\ cfs) * HoursInMonth * \frac{OperatingHead\ (ft)}{1000} - C_2 \right) * eff * 1000$$

where:

62.4 = the unit weight of water in pounds per cubic foot

737.5 = foot-pounds per second per kilowatt

C_1 = representations of the efficiency of the powerplant, estimated to be 0.88 based on historical data; C_1 must be a static value through the entire simulation

C_2 = represents any energy consumed within the powerplant and is set to 0 because Reclamation does not have necessary data to determine C_2

eff = representations of the efficiency of the powerplant estimated to be 1.0 and can vary (by month and/or year)

This energy method is different from the method used in CRSS for the 2007 Final EIS; this is because the analysis of energy methods in RiverWare™ indicated the new method simulates historical energy generation better than the method previously used in CRSS. This new method does not currently estimate the power capacity at Davis Dam, which was computed by the method used for the 2007 Final EIS.

A.9.4 Parker Dam

The method that computes power and energy generation at Parker Dam is the same method used for Davis Dam, except C_1 is set to 1.0; C_2 is estimated to be 0; and eff varies by month, as shown in **Table A-24**. The monthly efficiency coefficients are based on an analysis of historical data from Power, Operations, and Maintenance reports (January 2000–April 2021).

Table A-24
Parker Dam Monthly Efficiency Coefficients

Month	Coefficient
January	0.8192
February	0.8583
March	0.8645
April	0.8732
May	0.8705
June	0.8703
July	0.8658
August	0.8631
September	0.8588

Month	Coefficient
October	0.8636
November	0.8369
December	0.7710

A.10 Reservoir Evaporation

Evaporation in CRSS is calculated for the reservoirs listed in **Table A-25** and represents either net or gross evaporation depending on the reservoir and basin. Net evaporation is defined as evaporation after accounting for pre-reservoir (salvage) evaporation, whereas gross evaporation represents total evaporation from the reservoir surface without adjustment for pre-reservoir conditions. Upper Basin reservoirs (excluding Lake Powell; see **Section A.10.2**) use net evaporation coefficients and therefore produce net evaporation volumes, while Lower Basin reservoirs use gross evaporation coefficients and, therefore, produce gross evaporation volumes. Evaporation is computed for all reservoirs explicitly modeled in CRSS except for Strawberry, Starvation, and Taylor Park reservoirs.

Two RiverWare™ evaporation methods are applied within CRSS: Monthly Evaporation and Periodic Net Evaporation. The Monthly Evaporation method is described in **Section A.10.1**, and the Periodic Net Evaporation method is described in **Section A.10.2**.

Table A-25 summarizes the selected evaporation method and evaporation type for each reservoir.

Table A-25
Selected Evaporation Method Specified in CRSS

Reservoir	Evaporation Type	Selected Evaporation Method
Fontenelle	Net	Monthly Evaporation
Flaming Gorge	Net	Monthly Evaporation
TMD Reservoir*	Net	Monthly Evaporation
Blue Mesa	Net	Monthly Evaporation
Morrow Point	Net	Monthly Evaporation
Crystal	Net	Monthly Evaporation
McPhee	Net	Monthly Evaporation
Navajo	Net	Monthly Evaporation
Powell	Net	Periodic Net Evaporation
Mead	Gross	Monthly Evaporation
Mohave	Gross	Monthly Evaporation
Havasu	Gross	Monthly Evaporation

*TMD (Trans-Mountain Diversion) Reservoir combines Lake Granby, Willow Creek Reservoir, Dillon Reservoir, and Homestake Reservoirs.

A.10.1 Monthly Evaporation Method

In RiverWare™, the Monthly Evaporation method calculates monthly reservoir evaporation using reservoir surface area and reservoir-specific monthly evaporation coefficients, as shown below:

$$Evaporation = Evaporation\ Coefficient \times \left(\frac{Surface\ Area_t + Surface\ Area_{t-1}}{2}\right)$$

where:

Evaporation Coefficient = monthly evaporation coefficient in ft/month
Surface Area = average reservoir surface area calculated from the current end of month (t) and previous end of month ($t-1$) expressed in acres
Evaporation = monthly evaporation expressed in acre-ft/month

Monthly evaporation coefficients for reservoirs using the Monthly Evaporation method are provided in **Table A-26**.

Table A-26
Monthly Evaporation Coefficients for Reservoirs Using the Input Evaporation and Monthly Evaporation Methods

Month	Evaporation Coefficient (ft/month)										
	Fontenelle	Flaming Gorge	TMD Reservoir*	Blue Mesa	Morrow Point	Crystal	McPhee	Navajo	Mead	Mohave	Havasu
January	0.10	0.05	0.00	0.02	0.02	0.02	0.00	0.05	0.32	0.33	0.34

*TMD (Trans-Mountain Diversion) Reservoir combines Lake Granby, Willow Creek Reservoir, Dillon Reservoir, and Homestake Reservoirs.

A.10.2 Periodic Net Evaporation Method

Lake Powell is the only reservoir in CRSS that uses the Periodic Net Evaporation method. Under this method, evaporation is calculated as the difference between gross evaporation and salvage evaporation:

$$Evaporation = Gross\ Evaporation - Salvage\ Evaporation$$

Gross evaporation represents the total evaporation from Lake Powell and is calculated using average monthly surface area and gross evaporation coefficients, consistent with the calculation presented in **Section A.10.1**. The gross evaporation coefficients used for Lake Powell differ from the net evaporation coefficients used for the other Upper Basin reservoirs under the Monthly Evaporation method, and therefore require an additional step to calculate net evaporation. Monthly gross evaporation coefficients for Lake Powell are provided in **Table A-27**.

Table A-27
Lake Powell Monthly Evaporation Related Coefficients

Month	Gross Evaporation Coefficient (ft/month)	River Evaporation Coefficient (ft/month)	Streamside Coefficient (ft/°F)	Terrace Coefficient (ft/°F)	Average Precipitation (ft/month)	Average Air Temperature (°F)
January	0.17	0.17	0.006	0.005	0.06	37
February	0.18	0.18	0.006	0.005	0.05	42
March	0.27	0.27	0.008	0.006	0.05	50
April	0.38	0.38	0.008	0.007	0.03	59
May	0.44	0.44	0.009	0.007	0.03	69
June	0.63	0.63	0.009	0.007	0.02	80
July	0.77	0.77	0.009	0.008	0.04	86
August	0.77	0.77	0.009	0.007	0.05	83
September	0.72	0.72	0.008	0.007	0.06	74
October	0.53	0.53	0.007	0.006	0.08	61
November	0.49	0.49	0.006	0.006	0.06	47
December	0.38	0.38	0.006	0.005	0.04	37

Salvage evaporation is the evaporation that would have occurred within the reservoir inundation area under pre-reservoir conditions. The salvage evaporation calculation includes the sum of river evaporation, streamside evaporation, terrace evaporation, and a precipitation-related adjustment (remaining evaporation) used to estimate conditions that would have existed prior to the construction of Glen Canyon Dam. **Table A-27** includes the coefficients referenced in the following equations for the different components of salvage evaporation.

$$Salvage\ Evaporation = River\ Evaporation + Terrace\ Evaporation + Remaining\ Evaporation$$

$$River\ Evaporation = River\ Evaporation\ Coefficient \times \left(\frac{River\ Area_t + River\ Area_{t-1}}{2}\right)$$

$$Streamside\ Evaporation = Streamside\ Coefficient \times \left(\frac{Streamside\ Area_t + Stramside\ Area_{t-1}}{2}\right) \times Average\ Air\ Temperature$$

$$Terrace\ Evaporation = Terrace\ Coefficient \times \left(\frac{Terrace\ Area_t + Terrace\ Area_{t-1}}{2}\right) \times Average\ Air\ Temperature$$

$$Remaining\ Evaporation = Average\ Precipitation \times Remaining\ Area$$

$$Remaining\ Area = \left(\frac{Surface\ Area_t + Surface\ Area_{t-1}}{2}\right) - \left(\frac{River\ Area_t + River\ Area_{t-1}}{2}\right) - \left(\frac{Streamside\ Area_t + Stramside\ Area_{t-1}}{2}\right) - \left(\frac{Terrace\ Area_t + Terrace\ Area_{t-1}}{2}\right)$$

The river area, streamside area, and terrace area are all looked up using the specified month's elevation and a table that relates elevation to the specific area.

A.11 Salinity Method

The salinity module within CRSS is designed for long-term simulation over a horizon of 15 years and beyond and is the same for all alternatives. Results are particularly sensitive to initial conditions during the first 10 to 12 years. The method treats salinity as a conservative water quality parameter, and reservoirs are represented as fully mixed systems. Inputs include salinity associated with hydrologic inflows, initial reservoir salinity concentrations, estimates of salt loading from agricultural return flows, and salt removed by salinity control projects or trans-basin exports out of the basin[23]. Using these inputs, the CRSS produces annual average salinity concentrations at key numeric criteria stations located below Hoover Dam, below Parker Dam, and at Imperial Dam and at 17 locations above Hoover Dam. Salinity concentrations at Hoover Dam and above are computed using RiverWare™ model's water quality module, while concentrations at Parker Dam, Imperial Dam, and at the Northerly International Boundary (NIB) with Mexico are based on the calculations described below.

Salinity concentrations below Parker Dam and at Imperial Dam are projected as functions of concentrations below Hoover Dam using USGS-developed equations (Anning et al. 2018). Below Parker Dam, concentrations are estimated using a simple linear regression informed by Hoover Dam values, while concentrations at Imperial Dam are determined using a numerical model that incorporates tributary inflows and diversions. These equations were identified as the best available representation of downstream salinity concentrations relative to Hoover Dam concentrations.

The concentration below Parker Dam, C_{Parker} is calculated as:

$$C_{Parker} = 1.019 * C_{Hoover}$$

[23] The Yuma Desalting Plant is assumed to remain non-operational for the duration of the simulation.

The following equation and **Table A-28** are used to calculate concentration at Imperial Dam, $C_{Imperial}$:

$$C_{Imperial} = \frac{c_{12}c_{13}C_{Hoover}Q_{Main\ stem} + c_3C_{Parker}c_2Q_{Diversions} + c_6c_5(c_4 - Q_{Main\ stem}) + c_9c_8(P - c_7)}{c_1Q_{Main\ stem} + c_2Q_{Diversions} + c_5(c_4 - Q_{Main\ stem})} - c_{10}\frac{dc}{dt}$$

where:

$c_{1\text{-}13}$ = defined in **Table A-28**
C_{Hoover}, = salinity concentration at Hoover
C_{Parker} = 627 mg/L
$Q_{Main\ stem}$ = flow below parker minus Palo Verde Irrigation District and Colorado River Indian Reserve diversions
$Q_{Diversions}$ = sum of Palo Verde Irrigation District and Colorado River Indian Reserve diversions
dC/dt = change in Hoover salinity from the previous timestep

Table A-28
Estimated numerical model coefficients for the Parker Dam to Imperial Dam model and for the Hoover Dam to Imperial Dam model

Coefficient	Estimated value for the Parker Dam to Imperial Dam model	Estimated value for the Hoover Dam to Imperial Dam model	Units
c1	0.95	0.95	Dimensionless
c2	0.7	0.7	Dimensionless
c3	1.187	1.187	Dimensionless
c4	16,860	16,860	ft^3/s
c5	0.088	0.088	Dimensionless
c6	1,140	1,140	mg/L
c7	0	0	inches
c8	0	0	(ft^3/s)/inch
c9	0	0	mg/L
c10	0.5	0.55	Months
c11	5 through April 2008, and 0 thereafter	20 through April 2008, and 0 thereafter	mg/L
c12	NA	1.019	Dimensionless
c13[24]	NA	0.81	Dimensionless

Salinity concentration at the NIB is projected as a function of simulated salinity at Imperial Dam and base flows accruing to the river between Imperial Dam and the NIB. This logic does not simulate operations by Reclamation's Yuma Area Office to ensure compliance with the Minute No. 242 salinity differential. Rather, this logic assumes constant monthly base flows accruing to the Colorado River between Imperial Dam and the NIB to estimate the salinity at the NIB.

[24] If discharge from Bill Williams River is <1,000 ft^3/s, c_{13} = 1.0.

The salinity at the NIB is a function of the estimated volume of Colorado River water originating upstream from Imperial Dam, which is delivered to the NIB. This NIB volume is estimated as the total delivery to Mexico determined by CRSS, minus estimated deliveries to Mexico from sources downstream from Imperial Dam. These include deliveries from pumped groundwater and irrigation return flows to the Southerly International Boundary with Mexico; and pumped groundwater, base flow, irrigation return flows, and canal wasteway flows which accrue to the Colorado River between Imperial Dam and the NIB. Base flow and salinity concentration from these sources are represented between Imperial Dam and NIB as other measured flows, unmeasured flows, and pumped groundwater returned to the river. Flow and concentration values from these sources were estimated using available historical data from the period of 2018 through 2022. The salinity at the NIB is calculated via a simple monthly mass balance using the volume of Colorado River water delivered to Mexico through Imperial Dam (with the associated Imperial Dam salinity value) plus the base flows and their associated salinity values. These base flow values and salinity concentrations vary for each month but do not vary each year or across traces or alternatives.

Salinity concentration below Hoover Dam and at 17 locations represented in CRSS above Hoover Dam are determined with a basin-wide salinity modeling framework described in Prairie and Rajagopalan (2007), which is implemented within RiverWare™ model's water quality module. Natural flow and salt mass data for an observed period is first developed using Reclamation's RiverWare™ Natural Flow & Salt model (NFSM). Future salinity concentrations throughout the Colorado River watershed are generated using Reclamation's nonparametric natural salt model. This model relies on annual total flow–salt mass (Upper Basin) and intervening flow–salt mass (Lower Basin) regressions presently developed from 1991–2020 natural flow and salt mass data. The natural salt model provides salt mass estimates based on flows, from which salt concentrations are then calculated that align with natural hydrologic inflows input into CRSS. Present level agricultural salt loading is assumed to remain constant throughout the simulation period while projected increases in agricultural consumptive use are assigned a salinity pickup concentration that determines salt loading as a function of agricultural return flows. Variations in salt mass driven by extreme flow conditions are not explicitly represented; as a result, negative natural salt values can arise during computation.

To maintain realistic behavior at modeled stream gage locations, salt concentrations on river reaches are constrained within their historical minimum and maximum ranges, with any excess stored for later release when concentrations return to historical concentration ranges.

CRSS Lower Division States Water User Priorities

This page intentionally left blank.

Attachment A2. CRSS Lower Division State Water User Priorities

Water user names in the table reflect the water user names in the Colorado River Simulation System (CRSS) and will differ from the Shortage Allocation Model. There are several CRSS "water users" that aggregate multiple real-world users. In those cases, the assumed priority used in CRSS may not match the priority of all users; instead, the assumed priority is chosen as a modeling simplification. The shortage allocation model provides more detail on the distribution of shortages (see **Appendix C**).

Appendix B. Modeling Assumptions: Lake Powell and Lake Mead Storage and Delivery of Conserved Water

B.1 Introduction

This appendix describes the Colorado River Simulation System (CRSS) modeling assumptions for the storage and delivery of conserved Colorado River system and non-system water in Lake Mead and Lake Powell pursuant to applicable federal Law, to increase flexibility in meeting water use needs while maintaining reservoir storage above critical elevations.

Extended drought, low reservoirs, and hydrologic variability from year to year create challenges when trying to plan for water supply and protect critical elevations. Conservation mechanisms that offer water users flexibility to conserve and/or augment water supplies can increase stability of the reservoirs, thereby reducing the need for and mitigating the impacts of large shortages. The alternatives represent a wide range of approaches to this element, ranging from no new conservation mechanism, to moderately sized pools in Lake Powell and Lake Mead open to users within the Upper and Lower Basins, respectively, to large, inclusive pools that may be flexibly stored in either reservoir to maximize their benefit to the system.

At this time, it is unknown which entities might participate in a Lake Mead or Lake Powell mechanism that allows the storage and delivery of conserved system and non-system water. Furthermore, the timing and magnitude of the storage and delivery of conserved water is unknown. These assumptions were developed to include the maximum amount of storage credits that may be created during any year, the maximum amount of storage credits that may be recovered during any year, and the maximum total amount of storage credits that may be available at any one time. Specific entities in CRSS had to be selected to model the storage and delivery mechanisms, including developing assumptions for their respective level of participation, to enable the evaluation of the mechanism and its potential effects on environmental resources. These assumptions are a reasonable and appropriate representation of potential conservation activities and the storage and delivery of water under the alternatives for purposes of environmental analyses, reflecting both the historical use of conservation programs and the need to bound the analysis by evaluating maximum potential impacts. The Bureau of Reclamation's (Reclamation) modeling assumptions are not intended to constitute a position on the use of the storage mechanisms by any specific water user nor are they an interpretation of the law, contracts or a legal position. Reclamation chose these modeling assumptions for a number of reasons, including the following: (1) a larger volume of potential storage in Lake Powell and Lake Mead is identified; (2) the maximum potential impacts on river flows downstream of Hoover Dam are identified; (3) concepts for the potential future use of a

storage mechanism are represented; and (4) the modeling impacts of a program of potential future cooperation between the United States (U.S.) and the United Mexican States (Mexico) are identified.

The following sections of this appendix discuss general modeling assumptions, then individual conservation creation, storage, and delivery assumptions for each alternative and the comparative baseline evaluated in this Final Environmental Impact Statement (EIS). These mechanisms may be in either Lake Powell, Lake Mead, or both reservoirs, and cover a range of possible conservation structures, maximum accumulations, and delivery rules.

B.2 General Modeling Assumptions

Three alternatives (Enhanced Coordination, Maximum Operational Flexibilities, and Supply Driven [both Lower Basin Priority (LB Priority) and Lower Basin Pro Rata (LB Pro Rata) approaches]) include assumptions for new storage and delivery mechanisms for conserved water in Lake Powell and Lake Mead. The Continued Current Strategies (CCS) Comparative Baseline assumes that existing agreements, including the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead (2007 Interim Guidelines), 2017 Minute 323, and 2019 Drought Contingency Plan (DCP) continue through the analysis period (2027-2060), which includes an assumed continuation of the storage and delivery mechanism in Lake Mead. The No Action and Basic Coordination Alternatives only include assumptions for the delivery of Intentionally Created Surplus (ICS) created and stored before January 1, 2027.

The following sections explain the general modeling assumptions for the Lake Powell and Lake Mead mechanisms regarding how storage credits are generated and delivered within the CRSS model. Examples of the accounting of storage credits within the model are also presented below.

B.2.1 Lake Powell Mechanism

When storage credits are created, the conserved water is modeled by injecting as a lumped volume above Lake Powell on a water year basis. As such, the Lake Powell mechanism does not account for state or water-user specific balances. It is assumed that all water users in the Upper Basin, including tribal and non-tribal entities, would be able to contribute to the conservation pool; no assumptions are made with respect to where contributions of conserved water are generated or what specific activities generated the water for the Enhanced Coordination, Maximum Operational Flexibility, and Supply Driven (both LB Priority and LB Pro Rata approaches) Alternatives. The Enhanced Coordination Alternative includes an assumption that in addition to conservation, a portion of the Upper Basin Tribes' unused water could be contributed to the Lake Powell storage mechanism (see **Section B.6**).

The model assumes that the accounting of storage credits occurs annually, at the end of the water year. The initial balance (January 1, 2027) of the Lake Powell conservation mechanism is 0 acre-feet (af). Storage credits in Lake Powell are assumed to be subject to the following rules:

- If the Lake Powell conservation pool reaches full capacity, annual conservation continues; however, the conserved volumes are assumed to be system water rather than being stored in the Lake Powell storage mechanism.
- If Lake Powell releases additional water to maintain safe operating capacity, Lake Powell storage credits are assumed to be released first. Except for the Maximum Operational Flexibility Alternative, the conservation pool is reduced by the volume equal to the safe operating capacity release. In the Maximum Operational Flexibility Alternative, it is assumed that the safe operating capacity release moves water from the pool in Lake Powell to the pool in Lake Mead (see **Section B.7** for more information). Safe operating capacity releases are calculated as the difference between the actual water year release and the annual target release, adjusted for applicable releases constraints.
- At low lake levels, the storage credits in Lake Powell may exceed the total available storage.

B.2.2 Lake Mead Mechanism

B.2.2.1 Pre-2027 ICS, Mexico's Water Reserve, Mexico's Recoverable Water Savings, and Interstate Banking Initial Balances

The Interim Guidelines incorporate a conservation mechanism called ICS. The ICS mechanism has been in place since the 2007 Interim Guidelines operations were implemented. Each alternative, except the CCS Comparative Baseline, assumes the 2007 Interim Guidelines expire at the end of December 2026, and have their own assumptions on how to handle storage credits in Lake Mead at the end of 2026.

In addition to ICS conservation, Nevada has water stored in Arizona and California stored via the Interstate Water Banking mechanism. Agreements on the storage and withdrawal of this water are independent of ICS and any new conservation mechanism, and interstate banked water may be delivered through 2057. It is modeled as a delivery to Nevada from Lake Mead with a subsequent decrease in delivery from the state in which the water was pulled from. Interstate banking is assumed to be available in all alternatives and assumed to continue through 2060 as a source of conserved water Nevada can use. The interstate banked water is included in these assumptions as it is one source of water Nevada can use, and as such it is a component of the assumed delivery logic for Nevada.

Initial balances for all ICS types, as well as Mexico's Water Reserve (MWR), Mexico's Recoverable Water Savings, created as a contribution to Mexico's Binational Water Scarcity Contingency Plan (BWSCP), and Nevada's interstate banked water are included in **Table B-1**. **Table B-1** provides the end of calendar year 2026 balances as simulated by the November 2024 Colorado River Midterm Modeling System simulated with Ensemble Streamflow Prediction forecasts. The end of calendar year 2026 volumes were used to initialize conservation balances in all alternatives and are the same for all three sets of initial conditions.

Table B-1
Initial Balances (af)

State/Country - Water User - ICS Type	End of calendar year 2026
Arizona	
Central Arizona Water Conservation District (CAWCD)	
Binational ICS (BICS)	51,024
Extraordinary Conservation ICS (EC-ICS)	165,539
DCP-ICS	87,720
System Efficiency – Warren H. Brock (Brock)	100,000
System Efficiency – Yuma Desalting Plant (YDP) Pilot Run	3,050
Colorado River Indian Tribe (CRIT-AZ)

System Efficiency – Brock	65,000
System Efficiency – YDP	24,397
Total of EC-ICS, BICS, and DCP-ICS	**1,650,000**
Nevada	
Southern Nevada Water Authority (SNWA)	
BICS	51,024
EC-ICS	398,976
DCP-ICS	-
System Efficiency – Brock	400,000
System Efficiency – YDP	3,050
Tributary Conservation[1]	-
Nevada-Arizona Interstate Bank[2]	613,846
Nevada-California Interstate Bank[3]	330,225
Total of EC-ICS, BICS, and DCP-ICS	**450,000**

State/Country - Water User - ICS Type	End of calendar year 2026
Mexico	
Mexico's Recoverable Water Savings	175,500
MWR	150,000
Total of Mexico's Recoverable Water Savings + MWR	**325,500**

[1] The modeled tributary conservation initial balance is zero because it is assumed that any remaining Tributary Conservation at the end of the year is converted and stored as EC-ICS, subject to maximum accumulation limits.
[2] Water stored in Arizona by the Arizona WBA for the benefit of SNWA, Nevada. Not a type of ICS; listed in this table as it is a component of the assumed delivery logic for Nevada in CRSS.
[3] Water stored in California by the MWD for the benefit of SNWA, Nevada. Not a type of ICS; listed in this table as it is a component of the assumed delivery logic for Nevada in CRSS.

B.2.2.2 Generation of Storage Credits

When storage credits are created, the model assumes either a delivery from Lake Mead is decreased or a new gain to the system is introduced, resulting in an increase to Lake Mead storage. If the reduced delivery is located downstream of Lake Mead, creation of the storage credit results in a reduction in the release from Lake Mead and river flow downstream.

At the beginning of each year, the model assumes that storage credits will be generated based on model logic that varies by state/water user and alternative; the amount does not change throughout the year unless Lake Mead declines below critical elevations. The ability to generate storage credits varies by alternative; for alternatives with an assumed new storage mechanism, conservation credits in Lake Mead are assumed to be generated for the entire model simulation period of 2027 to 2060.

A one-time system assessment is assumed to be dedicated to the system upon the creation of storage credits. The system assessment varies among alternatives and is described in the subsequent alternative specific sections. For example, if an entity wishes to receive credit for 100 thousand acre-feet (kaf), then the credits that must be generated become: 100 kaf / (1 - system assessment).

The model assumes that the accounting of storage credits occurs annually, at the end of the calendar year. For alternatives that include assumptions for a new storage mechanism, storage credits in Lake Mead are assumed to be subject to the following rules:

- Storage credits in the Lake Mead mechanism can be created under Surplus, Normal, and Shortage Conditions
- The amount of storage credits that may be generated in a single year is constrained by assumed maximum annual and maximum total limits. If maximum limits are reached, volumes are proportionally reduced until the limit is reached. These assumed limits vary by alternative and are presented in the *General Assumptions* section for each alternative.

- If Lake Mead is at or near dead pool, creation of storage credits is cancelled for the remainder of the year, except the following:
  - Nevada's Tributary Conservation – the full volume of tributary conservation still occurs and is stored or delivered to Southern Nevada Water Authority (SNWA).
- Specific to the CCS Comparative Baseline, DCP-ICS creation and Mexico's Recoverable Water Savings creation is assumed to continue, if occurring.

B.2.2.3 Delivery of Storage Credits

All alternatives include assumptions for the delivery of existing, pre-2027 storage credits and alternatives that include assumptions for a new storage mechanism. When storage credits are delivered from Lake Mead, the model assumes that the delivery from Lake Mead was increased for that year, resulting in a decrease in Lake Mead storage. If the increased delivery is located downstream of Lake Mead, delivery of the storage credits results in an increase in the release from Lake Mead and downstream river flows. To mitigate shortage, a user may take delivery of storage credits or convert storage credits into system water (i.e., the volume of water delivered to the user is the same in either case). If Lake Mead is experiencing dead pool-related reductions, the delivery of storage credits is canceled for the remainder of the year. If Lake Mead is operating in flood control, any spill is first attributed to storage credits in the Lake Mead mechanism. For the CCS Comparative Baseline, the No Action Alternative and the Basic Coordination Alternative, all ICS balances are set to zero. For the Enhanced Coordination Alternative, the Maximum Operational Flexibility Alternatives, and the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches), individual water-user storage credits are reduced proportionally.

B.3 Continued Current Strategies Comparative Baseline

The CCS Comparative Baseline assumes that existing agreements, including the 2007 Interim Guidelines, 2017 Minute 323, and 2019 DCP continue through the analysis period (2027-2060). As part of this assumption, all types of ICS, MWR, and Mexico's Recoverable Water Savings are assumed to continue (creation and delivery) through the end of the analysis period.

B.3.1 Lake Powell Mechanism

No Lake Powell mechanism is modeled in the CCS Comparative Baseline.

B.3.2 Lake Mead Mechanism (ICS)

Storage credits can be delivered for objectives such as tribal firming obligations, augmenting water supplies during dry years, satisfy demands exceeding apportionment, or to satisfy DCP contributions (domestic water users) and BWSCP savings (Mexico) (see **Appendix A**, CRSS Model Documentation).

B.3.2.1 Treatment of Pre-2027 ICS

Pre-2027 ICS remains in their current ICS accounts and is immediately available for use, subject to existing rules, constraints, and assumptions.

B.3.2.2 General Assumptions

The maximum capacity of the ICS mechanism is 4.2 million acre-feet (maf), split between the Lower Division States and Mexico per the existing agreements. Each state/country has its own capacity and delivery limits, shown in **Table B-2**. Water users within a state may have agreed upon accumulation limits and/or modeling assumptions for the split of the state's accumulation limit, however, no creation or delivery limit exists for individual water users. For individual water user creation and delivery assumptions, see **Sections B.3.2.3 – B.3.2.6**.

Table B-2
Accumulation, Creation, and Delivery Limits by Entity in the Continued Current Strategies Comparative Baseline

State/Country	Arizona			California			Nevada	Mexico
Entity	CAWCD	Tribal	Total	IID	MWD	Total	Total	Total
Capacity (kaf)	250	250	**500**	50	1,650	**1,700**	**500**	**1,500**
Creation Limit (kaf)	-	-	**100**	-	-	**400**	**125**	**250**
Delivery Limit (kaf)	-	-	**300**	-	-	**400**	**300**	**200**

Assumptions for the creation and delivery of stored ICS water are designed to reflect the historical range of use of the ICS mechanism. ICS may be created through various mechanisms, including extraordinary conservation (EC-ICS), DCP contributions (DCP-ICS), Binational ICS (BICS), Tributary Conservation, system efficiency projects, and importation of non-Colorado River Water. Mexico has its own mechanism which can create conservation via MWR and Mexico's Recoverable Water Savings mechanism created as a contribution to Mexico's BWSCP. The following assumptions exist for the creation and delivery of the different ICS types, and are as follows:

- **EC-ICS/MWR**: Creation can occur at any pool elevation at Lake Mead. Delivery can occur when Lake Mead's pool elevation is above 1,025 feet at the start of the calendar year for all water users who are signatories to the DCP, while water users who are not signatories to the DCP can take delivery when Lake Mead's pool elevation is above 1,075 feet at the start of the calendar year.
- **DCP-ICS/BWSCP:** DCP-ICS can be created to satisfy required DCP contributions. It can be created by either (1) converting existing EC-ICS or (2) creating new EC-ICS and immediately converting to DCP-ICS. Delivery can occur when Lake Mead's pool elevation is greater than 1,110 feet at the start of the calendar year. The same assumptions are applied to Mexico's BWSCP contributions.
- **BICS:** BICS is credited to water users pursuant to agreements executed under Minutes 319 and 323. It is assumed that it can be delivered when Lake Mead's pool elevation is above 1,025 feet.
- **Tributary Conservation:** Creation from conservation on the Virgin and Muddy Rivers. Occurs annually and is converted and stored as EC-ICS if not used in the year it is created.

- **System Efficiency:** System Efficiency ICS creation occurs due to the implementation of system efficiency projects, such as building the Warren H. Brock Reservoir (Brock), and pilot operation of the Yuma Desalting Plant (YDP). No new creation of system efficiency ICS is modeled. Delivery is modeled to occur when Lake Mead's pool elevation is above 1,025 feet. Deliveries of Brock ICS are further constrained with maximum annual delivery volumes by water user, with a maximum of 25 kaf and 40 kaf for the Metropolitan Water District of Southern California (MWD) and Nevada, respectively, and a maximum of 65 kaf minus current year MWD and Nevada Brock ICS deliveries for Central Arizona Water Conservation District (CAWCD).
- **Imported ICS:** No imported ICS is modeled.

Accumulated ICS stored in Lake Mead is included in all operational determinations. The individual entities, or water users, assumed to use the storage and delivery mechanism are:

Table B-3
Existing ICS Water Users in the Continued Current Strategies Comparative Baseline

Water User	State
CAWCD	Arizona
CRIT-AZ	Arizona
GRIC	Arizona
IID	California
MWD	California
SNWA	Nevada
Mexico	Mexico

For all water users except Imperial Irrigation District (IID), in the year that EC-ICS, DCP-ICS, and Tributary Conservation is created and stored, a one-time system assessment of 10 percent is applied. For IID, because they are not a signatory to the DCP, in the year that ICS is created and stored, a one-time system assessment of 5 percent is applied, and a 3 percent evaporation assessment is applied to the stored volume (excluding current year's ICS creation) in every subsequent year.

B.3.2.3 Arizona Creation and Delivery Assumptions

In general, Arizona's creation and delivery logic was developed in coordination with Arizona Department of Water Resources and Central Arizona Project (CAP). Arizona is assumed to create ICS to help meet DCP contributions and take delivery of ICS to meet state and federal tribal firming obligations, mitigate shortages, and to recover all ICS by the end of the simulation horizon in most simulations.

Creation

Arizona is assumed to create and simultaneously convert 100 kaf of EC-ICS to DCP-ICS to contribute towards Arizona's DCP contribution, when required. The remaining required DCP contribution is assumed to be met through system water. There is no assumed additional creation of EC-ICS for any Arizona users.

Delivery

Generally, CAWCD is assumed to take delivery of conserved water when Arizona is experiencing shortage to mitigate shortages and to meet state and federal tribal firming obligations. The delivery volume is dependent on shortage volume.

CAWCD is assumed to take delivery of their EC-ICS, BICS, Brock and YDP ICS during Shortage Conditions to mitigate shortages. ICS is assumed to be delivered from CAWCD's stored EC-ICS credits first, followed by BICS, Brock, then YDP. ICS credits of one type will be completely withdrawn before moving to the next ICS type. Delivery volumes are dependent on the shortage volume and are shown in **Table B-4** below.

EC-ICS in the Arizona accumulation space is also assumed to be delivered to assist with satisfying state and federal tribal firming obligations. It is assumed that, of the Gila River Indian Community's (GRIC's) EC-ICS, (**Table B-1**) 16 kaf is modeled to be delivered for Arizona's firming obligations, while 160,708 af is modeled to be delivered for federal tribal firming obligations. This water is modeled to be delivered when the Lower Basin is in shortage and Lake Mead's pool elevation is less than or equal to 1,050 feet and greater than 1,025 feet. The firming volumes will be delivered from GRIC EC-ICS consistent with applicable agreements until the applicable GRIC EC-ICS runs out, after which deliveries will be made from remaining GRIC EC-ICS. The assumed delivery volumes are shown in **Table B-4**.[1]

Table B-4
Summary of CAWCD Delivery Volume Assumptions in the Continued Current Strategies Comparative Baseline

Lake Mead Pool Elevation (feet)	Arizona Shortage (kaf)	CAWCD (kaf)	GRIC EC-ICS for Arizona Firming (kaf)	GRIC EC-ICS for Federal Firming (kaf)	GRIC EC-ICS
<1,075 to ≥ 1,050	320	60	0	0	0
<1,050 to ≥ 1,025	400	100	15	10	15

Note: The non-Arizona non-federal government GRIC EC-ICS is only delivered after Arizona and the Federal Government's portion of GRIC's EC-ICS has been fully depleted.

If Lake Mead begins the calendar year above pool elevation 1,110 feet and DCP-ICS exists, CAWCD is assumed to take delivery of DCP-ICS up to the maximum annual ICS delivery limit (300 kaf; **Table B-2**) to recover DCP-ICS as quickly as possible.

There is no assumed delivery of Colorado River Indian Tribes' (CRIT's) EC-ICS.

[1] Please see the Arizona Water Settlements Act, Public Law (Pub. L.) 108-451, 118 Stat. 3478 (Dec. 10, 2004), section 105, for a general description of the firming program. All firming deliveries in any given year would be made in accordance with applicable law. This appendix is not a legal interpretation of the firming program or of federal obligations. Actual firming deliveries may vary from the modeling approximations contained in this appendix, and Reclamation retains discretion to include legally-required tribal deliveries in this priority mechanism.

B.3.2.4 California Creation and Delivery Assumptions

The ICS mechanism is assumed to be used by MWD and IID in California. MWD's ICS creation and delivery is based on the Sacramento River Water Year Type (SRWYT), while IID strives to maintain maximum ICS accumulation.

Creation

IID is assumed to maintain their maximum accumulation limit of 50 kaf. Approximately 1.5 kaf of EC-ICS is created when Lake Mead's pool elevation is above 1,075 feet (normal, ICS surplus, and domestic surplus years). This creation volume is the volume required to offset the annual 3 percent evaporation assessment applied annually, thus keeping their ICS at its maximum accumulation limit. If IID's ICS balance goes to 0 due to flood control conditions, IID is assumed to create up to 25 kaf of EC-ICS annually until the maximum accumulation limit is achieved. The following formula is used to determine IID's total EC-ICS creation:

$$IID\ EC-ICS\ Creaion\ (kaf) = Minimum(CA\ ICS\ Creation\ Limit\ (kaf) - \text{MWD ICS Creation}\ (kaf), 25\ kaf)$$

MWD's EC-ICS creation volumes are based on the annual Sacramento River Water Year Classification (SRWYC) index,[2,3] and are shown in **Table B-5** below.

Table B-5
MWD EC-ICS Creation Volumes by SRWYC in the Continued Current Strategies Comparative Baseline

SRWYC	Creation (kaf)
Critical (C)	0
Dry (D)	50
Below Normal (BN)	275
Above Normal (AN)	400
Wet (W)	400

DCP contributions for California are assumed to be contributed by MWD (93 percent) and Coachella Valley Water District (CVWD) (7 percent). MWD's portion of the DCP contribution volume is assumed to be made by converting existing EC-ICS, if available. If existing EC-ICS is insufficient to meet required DCP contributions, MWD will create EC-ICS and convert it to DCP-ICS to satisfy their contributions. If MWD's EC-ICS creation as per **Table B-5** is less than MWD's required DCP contribution volume, then additional EC-ICS will need to be created and converted to DCP-ICS to fully satisfy MWD's DCP contribution. CVWD's portion of the DCP contribution volume is supplied as an EC-ICS creation that is added to MWD's EC-ICS accumulation and converted to DCP-ICS. If MWD's maximum accumulation limit has been reached and there is

[2] Obtained at https://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST

[3] Historical SRWYC is resampled using the index sequential method for hydrologic traces developed from resampling the Natural Flow record. For paleo data, the index is created from the Sacramento Valley 4 river index volume as reconstructed in Meko et al. (2014). For all other hydrology sequences, annual SRWYC values are generated using a trained decision tree model that was developed from the historical relationship between intervening natural flows and observed SRWYC, applied year-by-year to each sequence.

insufficient EC-ICS to convert to meet the DCP contribution, system water will be created to satisfy the outstanding DCP contribution volume.

Delivery

IID is not assumed to take delivery of their BICS or EC-ICS.

MWD's delivery volumes are based on the SRWYC index and are shown in **Table B-6** below. ICS deliveries will first be satisfied from DCP-ICS (if allowed, i.e., Lake Mead above 1,110 feet), then from EC-ICS, BICS, Brock, and YDP, respectively. Deliveries will completely recover stored ICS from one ICS category before moving on to the next.

Table B-6
MWD EC-ICS Creation Volumes by SRWYC in the Continued Current Strategies Comparative Baseline

SRWYC	Creation (kaf)
C	150
D	0
BN	0
AN	0
W	0

Additional ICS deliveries will be made to offset deliveries reductions due to Nevada's withdrawal from the California portion of the Interstate Water Bank. See **Section B.3.2.5**, Nevada Creation and Delivery Assumptions below for further information.

B.3.2.5 Nevada Creation and Delivery Assumptions

In Nevada, ICS is assumed to be created and delivered by SNWA. SNWA is assumed to try to fully satisfy their annual depletion schedule plus any demands that exceed apportionment.

Creation

There are two ICS types with modeled creation by SNWA: EC-ICS and Tributary Conservation. SNWA is assumed to create EC-ICS from conserved water under SNWA's exhibit for EC-ICS as long as Nevada has not achieved their total accumulation limit (**Table B-2**).

SNWA's annual EC-ICS creation is calculated using the following equation:

$$Annual\ Creation = Maximum(\ 300{,}000\ af - \ Annual\ Shortage_{NV} - Annual\ Demand_{NV}, 0\ af)$$

Based on the assumed depletion schedules, SNWA attempts to create ICS until 2047, at which point demands equal full apportionment (see **Appendix M**, Lower Division States Depletion Schedules).

Tributary conservation occurs annually and represents conservation on the Virgin and Muddy Rivers, generating an assumed 35 kaf per year, which is converted to EC-ICS if not delivered in the year it is created. If Nevada is at their maximum total accumulation limit, or Lake Mead is

experiencing dead pool-related reductions, Tributary Conservation will still be created and will be delivered to SNWA the same year.

If there is a required DCP contribution, SNWA is assumed to convert EC-ICS to DCP-ICS to satisfy their DCP contribution. If there is not enough EC-ICS available to meet the full DCP contribution, SNWA will create additional EC-ICS and convert it to DCP-ICS to satisfy the DCP contribution. If Nevada has reached their maximum accumulation limit, SNWA will make the DCP contribution via system water.

Delivery
SNWA is assumed to take delivery of ICS and/or Interstate Banked Water to satisfy demands exceeding apportionment and/or offset Nevada's annual shortage and DCP contributions, and can be calculated using the following equation, subject to the maximum delivery constraint of 300 kaf (**Table B-2)**:

$$\textit{Annual Delivery} = \textit{Maximum}\left(\begin{matrix}\textit{Annual Depletion Schedule}_{NV} + \textit{Demands Exceeding Apportionment}_{NV} \\ -(300{,}000\ af - \textit{Annual Shortage}_{NV} - \textit{ECICS or System Water creation for DCP contribution}_{NV}), \\ 0\ af\end{matrix}\right)$$

The modeled demands do not exceed apportionment until 2047, after which they increase through 2060 as shown in **Table B-7**.

Table B-7
Nevada Demands Above Apportionment

Year	Demands Above Apportionment (af)
2027-2046	0
2047	2,339
2048	5,460
2049	8,554
2050	11,410
2051	14,447
2052	17,455
2053	20,433
2054	23,381
2055	26,310
2056	29,194
2057	32,047
2058	34,979
2059	37,764
2060	40,415

If available, surplus water is used first to meet the calculated annual delivery during surplus years. Then, different categories of ICS and Interstate Banked Water are used to meet the calculated annual delivery. Nevada is assumed to take delivery of ICS and Interstate Banked Water in the

following order, with one ICS category being completely exhausted or delivered to its annual delivery limit before progressing to the next:

1. DCP-ICS
2. Tributary Conservation
3. Brock ICS
4. YDP ICS
5. BICS
6. Nevada-Arizona Interstate Water Bank
7. Nevada-California Interstate Water Bank
8. EC-ICS

If Lake Mead starts the year with a pool elevation below 1,025 feet, EC-ICS, BICS, and System Efficiency ICS (Brock and YDP) are assumed to not be delivered; however, current year Tributary Conservation ICS and Interstate Water Bank deliveries can be made. In this case, the model would skip all EC-ICS, BICS, and System Efficiency ICS categories and try to satisfy the annual delivery from Tributary Conservation and Interstate Water Banking balances.

The Interstate Water Bank represents water stored in California and Arizona for the benefit of SNWA. Deliveries from the Interstate Water Bank are modeled by increasing SNWA's delivery and reducing CAP and/or MWD's delivery by the same volume, depending on whether it is a delivery from the Arizona or California Interstate Water Bank, respectively.

Deliveries from the Interstate Water Bank include assumed constraints on the maximum delivery that can be withdrawn from the bank each year. Specifically, in the first-year water from the Arizona bank is needed, SNWA can withdraw up to 20 kaf, followed by 30 kaf in the following consecutive year, and 40 kaf in the remaining consecutive years. Delivery from the Nevada-Arizona bank is further constrained if it is a shortage year. The maximum delivery from the Nevada-Arizona bank is reduced proportional to the reduction in CAP's municipal and industrial delivery due to shortages.

The maximum SNWA can withdraw from the Nevada-California Interstate Water Bank is assumed to 30 kaf per year. In years when SNWA withdraws from the Nevada-California bank, MWD first tries to offset their delivery reduction by taking delivery of their ICS. In years when MWD is unable to offset the bank delivery with ICS, their delivery is reduced by a like amount delivered to SNWA.

B.3.2.6 Mexico Creation and Delivery Assumptions[4]

Mexico is assumed to create and deliver MWR on a three-year cycle. Mexico is assumed to satisfy their BWSCP savings via creating Mexico's Recoverable Water Savings (BWSCP).

4 Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Creation
Mexico is assumed to create 60 kaf of MWR every three years starting in 2027.

Mexico is assumed to create Recoverable Water Savings to satisfy their BWSCP savings if Mexico has not reached their total accumulation limit (**Table B-2**). If no space is available, BWSCP savings are met as system water.

Delivery
Mexico is assumed to take delivery of up to 27 kaf in years that they are not creating MWR.

Mexico is assumed to take delivery of 25 kaf of Recoverable Water Savings when allowed, i.e., Lake Mead is above 1,110 feet.

The total annual delivery of MWR and Recoverable Water Savings is assumed to not exceed 27 kaf, with Recoverable Water Savings deliveries taking precedence over MWR deliveries.

B.4 No Action Alternative

The No Action Alternative assumes that there is no new conservation mechanism to proactively conserve and store water in Lake Powell or Lake Mead, therefore the existing conservation mechanism will operate as per the current agreements, which expire at the end of 2026. Water users have through the end of 2036 to remove all ICS types except DCP-ICS, which can be delivered through the end of 2057. All ICS remaining in Lake Mead after the respective expiration dates is assumed to become system water.

B.4.1 Lake Powell Mechanism
No Lake Powell mechanism is modeled in the No Action Alternative.

B.4.2 Lake Mead Mechanism
The No Action Alternative assumes that the ICS mechanism expires at the end of 2026, and water users may take delivery of existing ICS in accordance with the dates specified in the respective agreements, but no new creation and storage is allowed, with one exception described in the following sections. Water users can take delivery of EC-ICS and System Efficiency ICS through 2036 and DCP-ICS through 2057; if ICS storage credits remain in Lake Mead on January 1, 2037 (or 2057 for DCP-ICS), they are assumed to become system water. As a result, the No Action Alternative assumptions reflect water users' efforts to take delivery of ICS storage credits prior to this deadline.

Exceptions to this include Tributary Conservation ICS and Interstate Water Banking, which are assumed to continue through 2057.

B.4.2.1 Treatment of Pre-2027 ICS
Pre-2027 ICS is modeled based on the existing ICS types and respective rules for delivery beyond 2026.

B.4.2.2 General Assumptions

The No Action Alternative utilizes the same Lake Mead ICS mechanism as is described in **Section B.3**, Continued Current Strategies Comparative Baseline, with the additional assumption that Interim Guidelines ICS and 2019 DCP conservation agreements have expired, and the creation of EC-ICS, DCP-ICS, BICS and System Efficiency ICS may no longer occur after the end of calendar year 2026.

Tributary Conservation and Imported ICS can be created and delivered through the end of calendar year 2057, but cannot be stored, i.e., they are assumed to be created and delivered in the same year. Any creation of these ICS types is modeled to incur a 5 percent assessment upon creation. Because the 2019 DCP has expired, all ICS balances are assessed a 3 percent evaporation assessment.

For further modeling assumptions, please see **Section B.3.2.2**, General Assumptions from the CCS Comparative Baseline.

B.4.2.3 Arizona Delivery Assumptions

Arizona is assumed to try and take delivery of all conserved ICS water before it expires at the end of 2036 for EC-ICS, BICS, and System Efficiency ICS, and at the end of 2057 for DCP-ICS.

Delivery

CAWCD is modeled to take delivery of their remaining EC, Binational, Brock, and YDP ICS by 2036 by taking delivery of 150 kaf per year through 2029, then by taking delivery up to Arizona's maximum annual delivery of 300 kaf from 2030-2036, until all CAWCD ICS has been delivered. CAWCD's EC-ICS credits are delivered first, followed by BICS, Brock, then YDP.

CRIT is assumed to take delivery of all their EC-ICS the first year they are able to do so.

It is assumed that of GRIC's EC-ICS (**Table B-1**) 16 kaf is modeled to be delivered for Arizona's firming obligations, while 160,708 af is modeled to be delivered for federal tribal firming obligations. The firming volumes will be delivered from GRIC EC-ICS consistent with applicable agreements until the applicable GRIC EC-ICS runs out. The portion of GRIC's EC-ICS that is modeled for federal firming is assumed to be delivered during Shortage Conditions to meet federal firming obligations, with the modeled delivery volumes shown in **Table B-8**.[5] In 2036, if there is still GRIC EC-ICS for federal firming, the entire available volume is assumed to be delivered, if possible, based on other constraints.

[5] Please see the Arizona Water Settlements Act, Pub. L. 108-451, 118 Stat. 3478 (Dec. 10, 2004), section 105, for a general description of the firming program. All firming deliveries in any given year would be made in accordance with applicable law. This appendix is not a legal interpretation of the firming program or of federal obligations. Actual firming deliveries may vary from the modeling approximations contained in this appendix, and Reclamation retains discretion to include legally-required tribal deliveries in this priority mechanism.

Table B-8
GRIC EC-ICS for Federal Firming - Assumed ICS Delivery by Lake Mead Pool Elevation in the No Action Alternative

Pool Elevation	Delivery Volume (af)
<1,075 to ≥ 1,050	24,325
<1,050 to ≥ 1,025	36,924

15 kaf/year of the GRIC EC-ICS that is for Arizona firming is assumed to be delivered during Shortage Conditions when Lake Mead's pool elevation is less than 1,050 feet and greater than or equal to 1,025 feet until supplies are depleted.

GRIC is assumed to attempt to take delivery of their remaining EC-ICS that is not for Arizona or federal firming by 2036. The modeled annual delivery volume is computed as the GRIC EC-ICS balance divided by the number of years remaining through the end of 2036.

DCP-ICS is assumed to be recovered as fast as possible when Lake Mead's pool elevation is above 1,110 feet. (i.e., all existing DCP-ICS is recovered up to the maximum annual ICS delivery limit).

B.4.2.4 California Delivery Assumptions

The ICS mechanism is assumed to be used by MWD and IID in California as they are the users in California with existing ICS.

Delivery

IID is modeled to take delivery of as much of their EC-ICS as possible when Lake Mead's pool elevation is greater than 1,075 feet. MWD's ICS delivery is prioritized above IID's ICS delivery. IID's ICS delivery can be calculated using the equation:

$$IID\ ICS\ Delivery\ (kaf) = Maximum(CA\ ICS\ Delivery\ Limit\ (kaf) - \text{MWD ICS Delivery}\ (kaf), 0\ kaf)$$

MWD's ICS delivery volumes are based on the annual Sacramento River Water Year Classification (SRWYC) (see **Section B.3.2.4**, *California Creation and Delivery Assumptions*). ICS deliveries will first be satisfied from DCP-ICS (if allowed), then from EC-ICS, BICS, Brock, and YDP, respectively. Deliveries will completely recover ICS from one ICS type before moving on to the next. **Table B-9** below shows MWD's assumed delivery volume by SRWYC.

Table B-9
MWD ICS Assumed Delivery Volumes by SRWYC in the No Action Alternative

SRWYC	Delivery (af)
W	25,000
AN	25,000
BN	100,000
D	225,000
C	400,000

Additional ICS deliveries may also occur to offset delivery reductions due to Nevada's withdrawal from the California portion of the Interstate Water Bank. See **Section B.4.2.5**, *Nevada Creation and Delivery Assumptions* below for further information.

B.4.2.5 Nevada Creation and Delivery Assumptions

In Nevada, ICS is assumed to be created and delivered by SNWA. SNWA is assumed to try to fully satisfy their annual depletion schedule plus any demands that exceed apportionment.

Creation

At the start of 2027, SNWA is still able to create Tributary Conservation water, and is assumed to do so to a volume of 35 kaf per year until 2057 when the Tributary Conservation agreements expire. Based on the No Action Alternative assumption of no new storage and delivery mechanism, Tributary Conservation is no longer able to be converted to EC-ICS and stored in the Lake Mead ICS mechanism. A 5 percent assessment is applied to the Tributary Conservation ICS, and the remaining volume is delivered to SNWA.

Delivery

It is assumed that SNWA will attempt to recover their ICS that expires in 2036 using the following equation:

$$Full\ ICS\ Recovery_{year} = \frac{\sum Expiring\ ICS\ Type\ balances}{nYears\ until\ 2036 + 1}$$

where:

$\sum$*Expiring ICS Categories balances* = sum of balance of all ICS types that are set to expire at the end of 2036 (EC-ICS, BICS, Brock, YDP)

nYears until 2036 = number of years until 2036 including the current year; 1 is added because recovery can occur through the end of 2036

year = current year

"Full ICS Recovery" is modeled to be recovered in the following order, with one ICS category being completely recovered before progressing to the next:

1. Brock ICS
2. YDP ICS
3. BICS ICS
4. EC-ICS

Additional ICS can be used to satisfy Nevada's scheduled demand if the above computed delivery is not enough. This additional delivery is calculated as:

$$\begin{aligned} &Additional\ ICS\ Delivery \\ &\quad = Maximum(\ 300{,}000\ af - \ Annual\ Shortage_{NV} - Annual\ Depletion\ Schedule_{NV} \\ &\quad + \ Annual\ ICS\ Delivery_{Full\ ICS\ Recovery}, 0\ af) \end{aligned}$$

If an additional ICS delivery is required, ICS will be delivered from different categories of ICS in the order laid out in **Section B.3.2.5**, *Nevada Creation and Delivery Assumptions*, recovering one type either completely or to its annual delivery limit before progressing to the next.

Tributary conservation will be delivered in the same year as it was created.

After 2037, SNWA is assumed to take delivery of interstate bank water to satisfy demands exceeding apportionment or when Nevada's shortage reduces Nevada's use below their scheduled use by more than SNWA's annual tributary conservation, and is calculated using the following equation:

$$\begin{aligned} &Interstate\ Water\ Bank\ Requested\ Delivery \\ &= Maximum\begin{pmatrix} Annual\ Depletion\ Schedule_{NV} + \ Demands\ Exceeding\ Apportionment_{NV} \\ -(\ 300{,}000\ af - \ Annual\ Shortage_{NV}) - 35\ kaf_{Tributary\ Conservation} \\ 0\ af \end{pmatrix} \end{aligned}$$

Interstate banked water is recovered from the water stored in Arizona first, followed by the water stored in California. Assumed delivery limits for each Interstate Water Bank are the same as the limits in the CCS Comparative Baseline and can be found in **Section B.3.2.5**, *Nevada Creation and Delivery Assumptions*.

B.4.2.6 Mexico Delivery Assumptions[6]

Mexico is assumed to try and take delivery of all MWR and Recoverable Water Savings through the end of 2060.

Delivery

Mexico is assumed to take delivery of 25 kaf of MWR water in years where Lake Mead's pool elevation is greater than 1,075 feet at the start of the calendar year. MWR deliveries are assumed to be able to occur through the end of 2060.

Mexico is assumed to take delivery of 25 kaf of its Recoverable Water Savings when Lake Mead's pool elevation is above 1,110 feet at the start of the calendar year. Recoverable Water Savings are assumed to be able to be delivered through the end of 2057.

6 Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

In years when the delivery of both MWR and Recoverable Water Savings is possible, the total delivery is assumed to be constrained to a maximum of 25 kaf and priority will be given to the delivery of Recoverable Water Savings.

B.5 Basic Coordination Alternative

The Basic Coordination Alternative assumes that there is no new conservation mechanism to proactively conserve and store water in Lake Powell or Lake Mead, therefore the existing conservation mechanism will operate as per the current agreements, which expire at the end of 2026. Water users have through the end of 2036 to remove all ICS types except DCP-ICS, which can be delivered through the end of 2057. All ICS remaining in Lake Mead after the respective expiration dates is assumed to become system water.

The Basic Coordination Alternative uses the same conservation logic as the No Action Alternative. For details on the modeling assumptions, refer to **Section B.4**, No Action Alternative.

B.6 Enhanced Coordination Alternative

The Enhanced Coordination Alternative includes three pools to store, convert and deliver water for the benefit of water users and the system: the Lake Powell mechanism, the water user-controlled Lake Mead mechanism, and the Lake Mead Protection Pool, which was informed by a group of Basin Tribes and would be controlled by Reclamation for Lower Basin-wide benefits. The design of these mechanisms supports proactive conservation and water user flexibility while the relatively lower accumulation limits represent a goal of ensuring that system storage is not overtaken by user-controlled conservation.

Details on modeling assumptions for each mechanism including creation, delivery, and associated constraints are provided below.

B.6.1 Lake Powell Mechanism

As described in **Appendix S,** water conserved by Upper Basin users would be stored in a pool in Lake Powell that can reach a maximum volume of 2.0 maf. Upper Division States and Upper Basin Tribes would have equal access to contribute to the conservation pool and to use their conserved water in intra- and interstate transactions with other Upper Basin users; however, no modeling assumptions were developed to model those specific transactions in the Enhanced Coordination Alternative. Additionally, water held in the Lake Powell conservation pool would be converted to system water and combined with Lower Basin shortages to provide system benefits based on the shortages specified in the Enhanced Coordination Alternative; assumptions regarding this conversion are detailed below.

B.6.1.1 General Assumptions

The volume of water in the Lake Powell conservation pool affects the determination of Lake Powell's water year release, as the calculation for the release accounts for the physical storage in

Lake Powell and Lake Mead, but it does not affect the Lower Basin/Lake Mead operations as they are determined using a combination of the effective storage[7] at Lake Powell coupled with the physical storage at Lake Mead. There is a maximum capacity of 2.0 maf. There are no assumed state-specific limitations on the maximum accumulation, nor are there state-specific annual creation and delivery limits, as conservation creation for the Lake Powell mechanism is modeled as a total Upper Basin volume.

There is an annual deduction for evaporation equal to the conservation pool's proportional share of total evaporation from Lake Powell. The evaporation deduction is applied annually in October based on the previous year's evaporation computed using the RiverWare™ Periodic Net Evaporation method and the total volume in the conservation pool at the end of the previous water year. Additionally, it is assumed a one-time system assessment of 7 percent is applied in the year the water is conserved and stored.

B.6.1.2 Creation

Storage credits are assumed to be created and stored in the Lake Powell conservation pool in two different ways: Upper Basin conservation and storage of a portion of unused Upper Basin tribal water. While the conservation is modeled as a single lumped gain to Lake Powell and no assumptions are made with respect to contributions from different entities, or via specific activities, it is contemplated that both the Upper Division States and Upper Basin Tribes would have equal access to contribute to the conservation pool.

For modeling purposes, unused Upper Basin tribal water is calculated as the difference between each tribe's depletion entitlement (or depletion equivalent) and its corresponding annual baseline depletion demand. Between 5 to 15 percent of the unused Upper Basin tribal water is assumed to be available for storage in the Lake Powell mechanism. The specific percentage, which varies with hydrologic conditions, is determined by comparing the modeled water year Lees Ferry natural flow to the 1991–2020 historical average (**Table B-10**). Linear interpolation is used to determine the specific percentage when the modeled (water year) Lees Ferry natural flow falls between 13.49 and 20.24 maf—with contributions increasing proportionally from 5 percent to 15 percent as natural flow increases across this range. The volume computed based on this relationship is assumed to be stored in the Lake Powell pool, without changing the inflow to Lake Powell.

Appendix H, Sensitivity Analysis - Modeled Unused Tribal Water Available for Storage in the Enhanced Coordination Alternative, provides information on the methodology used to estimate the Upper Basin unused tribal water, which was needed to model this concept and documents other relevant assumptions and caveats related to these assumptions.

[7] "Effective" elevation or storage is calculated as physical elevation (storage) minus any conserved volume that is held in the respective reservoir(s).

Table B-10
Upper Basin Tribal Water Available for Storage in the Lake Powell Conservation Pool (Enhanced Coordination Alternative) Relative to Historical Lees Ferry Natural Flow Thresholds

Current Water Year Lees Ferry Natural Flow (maf)	Annual Upper Basin Unused Tribal Contribution (%)
≥ 20.24[8]	15
Between 20.24 and 13.49[9]	5 to 15 (linear interpolation)
= 13.49	5
< 13.49	0

Exact volumes of Upper Basin conservation over time are uncertain, but for modeling purposes, conservation volumes up to a specified annual maximum may be added in any given year, depending on hydrologic conditions. The modeled conservation volume is determined by comparing the modeled water year Lees Ferry natural flow to the historical 1991–2020 25th and 75th percentile thresholds shown in **Table B-11**. Linear interpolation is used when the modeled Lees Ferry natural flow falls between 10.6 and 16.5 maf—with conservation increasing from 0 to the maximum volume as natural flow increases across this range.

Table B-11
Upper Basin Modeled Annual Conservation Volumes in the Enhanced Coordination Alternative

Current Water Year Lees Ferry Natural Flow (maf)	Annual (Water Year) Upper Basin Conservation (kaf)		
	2027-2031	2032-2036	2037-2060
> 16.50[10]	200	275	350
Between 16.50 and 10.60[11]	200 to 0 (linear interpolation)	275 to 0 (linear interpolation)	350 to 0 (linear interpolation)
≤ 10.60	0	0	0

Annual conservation volumes are disaggregated to the monthly scale using the average monthly Upper Basin agricultural demand distribution shown in **Table B-12**. These monthly volumes are then modeled as an inflow above Lake Powell.

[8] 150 percent of the historical average Lees Ferry natural flow from 1991-2020.
[9] Historical average Lees Ferry natural flow from 1991-2020.
[10] Historical 1991–2020 75th percentile Lees Ferry natural flow value.
[11] Historical 1991–2020 25th percentile Lees Ferry natural flow value.

Table B-12
Average Monthly Upper Basin Agricultural Demand Distribution

Month	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sept	Oct	Nov	Dec	Total
Percent	0%	0%	1%	4%	15%	25%	27%	17%	8%	3%	0%	0%	100%

B.6.1.3 Delivery/Conversion

Storage credits in the Lake Powell conservation pool are assumed to be converted to system water and combined with Lower Basin shortages to provide system benefits based on the shortage. When Lower Basin calendar year shortages are greater than 1.5 maf, a volume equal to one-third of the volume above 1.5 maf would be converted from the Lake Powell pool into system water such that the total of Lower Basin shortages and conversion of Upper Basin water equals the required total shortage volume (i.e., above 1.5 maf, there is a 2-to-1 Lower Basin shortage-to-Upper Basin conversion ratio). If the prescribed 2-to-1 volume is not available in the Lake Powell conservation pool, 100 percent of the available volume would be converted, and the Lower Basin would take the balance of shortages.

Water created for storage in the Lake Powell mechanism is not available for conversion in the year in which it is created.

B.6.2 Lake Mead Mechanism

As described in **Appendix S**, this pool represents the water user-controlled Lake Mead mechanism. Lower Colorado River entitlement holders, including Lower Basin Tribes, consistent with applicable implementation agreements, would be able to contribute to the conservation pool and to use their conserved water for delivery and/or in intra- and interstate transactions with other Lower Basin users. Water conserved by Lower Basin users would be stored in a pool in Lake Mead that can reach a maximum volume of 5.0 maf, which includes the storage of pre-2027 ICS. Water users could contribute and convert or deliver water previously stored under this new mechanism at their discretion within the annual volume constraints related to the pool. All conserved storage credits in Lake Mead would be included in determinations of Lake Powell releases and shortage volumes.

The subsequent sections provide a detailed description of the modeling assumptions and associated constraints.

B.6.2.1 Treatment of Pre-2027 ICS

For modeling purposes only, ICS created under the 2007 Interim Guidelines and 2019 DCP that remains in Lake Mead in 2027 is converted to the Post-2026 Lake Mead water user-controlled mechanism on January 1, 2027.[12]

B.6.2.2 General Assumptions

The maximum capacity of the Lake Mead mechanism, along with individual annual creation and delivery limits, is provided in **Table B-13** below. The Lake Mead mechanism operates on a calendar

[12] The modeling erroneously excludes the conversion of system efficiency ICS to the Lake Mead mechanism.

year to align with reservoir operations. Delivery/conversion from the Lake Mead mechanism is prohibited if Lake Mead starts the year with a physical pool elevation below 1,025 feet.[13]

Table B-13
Lake Mead Mechanism Limitations of Storage of Conserved Water in the Enhanced Coordination Alternative

Entity	Maximum Annual Contribution (kaf)	Maximum Cumulative Storage (kaf)	Maximum Annual Conversion or Delivery (kaf)
Arizona	466.667	700	620
California	733.333	1,900	980
Nevada	50	700	70
Mexico[1]	250	1,700	330[2]
Total	**1,500**	**5,000**	**2,000**

1) Volumes include modeling assumptions for Mexico's storage and delivery limits. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 United States-Mexico Treaty on Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande (1944 Water Treaty) or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the International Boundary and Water Commission (IBWC) in consultation with the Department of State.

2) According to the modeling assumption for Mexico, storage credits in the bank may only be used to mitigate Mexico's reductions exceeding 250 kaf. This activity is considered a "delivery" (i.e., conversion) from the bank. As a result, banking activity will not cause Mexico's delivery to exceed 1.7 maf. The 1944 Water Treaty authorizes scheduled delivery of up to 200 kaf in excess of the 1.5 maf annual allotment to Mexico.

The conservation activity is modeled using the following water users:

Table B-14
Lake Mead Mechanism Water Users in the Enhanced Coordination Alternative

Water User	Entity
CAP	Arizona
Colorado River Indian Tribe (CRIT-AZ)	Arizona
MWD	California
IID	California
Colorado River Indian Tribe (CRIT-CA)	California
SNWA	Nevada
Mexico	Mexico

It is assumed that a one-time system assessment of 7 percent is applied in the year the water is conserved and stored. This volume of water is assumed to be stored in the Protection Pool as "System Assessment" storage credits, subject to the Protection Pool's constraints and associated modeling assumptions (**See Section B.6.3.3**, *System Assessment Creation*). Additionally, there is an

[13] The logic included in CRSS erroneously did not apply this constraint to the delivery/conversion of California's storage credits.

annual deduction for evaporation equal to the conservation pool's proportional share of total evaporation from Lake Mead. The evaporation deduction is applied annually in January based on the previous year's evaporation computed using the RiverWare™ Input Evaporation method and the total volume in the conservation pool at the end of the previous calendar year.

B.6.2.3 Arizona Creation and Conversion/Delivery Assumptions

In general, Arizona's creation and delivery of conserved water is inversely related to the combined storage of Lake Mead (physical) and Lake Powell (effective) and the state shortage volume.

For modeling purposes, Arizona's conservation activity is modeled using CAP and CRIT-Arizona (AZ).

Creation

Arizona can create up to 466.667 kaf per year, depending on the state's total shortage volume. An overview of the logic is provided below, followed by a summary in **Table B-15**.

- If the combined storage of Lake Mead (physical) and Lake Powell (effective) exceeds 85 percent, both Arizona's shortage and creation volume are 0 kaf.
- If the combined storage of Lake Mead (physical) and Lake Powell (effective) is between 85 percent and 60 percent, Arizona's shortage is 0 kaf and its creation volume is 466.667 kaf.
- If the combined storage of Lake Mead (physical) and Lake Powell (effective) is between 60 percent and 39.83 percent, Arizona's shortage increases from 466.667 kaf to 760 kaf. As the shortage increases, Arizona's creation decreases from 293.333 kaf to 0 kaf. As a result, the sum of Arizona's shortage and creation equals 760 kaf.
- If the combined storage of Lake Mead (physical) and Lake Powell (effective) is less than 39.83 percent, Arizona's shortage is greater than 760 kaf and their creation is 0 kaf.

Table B-15
Summary of Arizona's Assumed Creation Volumes Relative to Shortage in the Enhanced Coordination Alternative

Lake Mead (physical) & Lake Powell (effective) Combined Storage (%)	Arizona Shortage (kaf)	Arizona Annual Creation(kaf)
> 85%	0	0
≤ 85% to > 60%	0	466.667
≤ 60% to ≥ 39.83%	466.667 to 760.000	293.333 to 0
< 39.83%	> 760.000	0

For modeling purposes, CAP and CRIT-AZ create storage credits in the Lake Mead mechanism. The creation volume for each water user is proportional to their annual depletion schedule minus their annual shortage. The following equation is used to calculate each water user's portion of Arizona's total annual creation volume:

$$\begin{aligned} Creation\ Volume_A &= AZ\ Total\ Creation\ Volume\ (af) \\ &\times \frac{(Annual\ Depletion\ Schedule_A - Annual\ Shortage_A)}{\sum Annual\ Depletion\ Schedule_{CAP+CRIT\ AZ} - \sum Annual\ Shortage_{CAP+CRIT\ AZ}} \end{aligned}$$

where "A" is either the CAP or CRIT-AZ water-user. For both water users, an initial portion of the creation volume is first stored in the Protection Pool, subject to the constraints of the Protection Pool and the associated modeling assumptions (see **Section B.6.3.4**), and the remaining volume is stored in the Lake Mead mechanism.

Delivery/Conversion

Arizona is assumed to take delivery of storage credits in the Lake Mead mechanism to mitigate shortages greater than 760 kaf. The following formula is used to determine Arizona's total delivery volume from the Lake Mead mechanism, subject to available storage credits:

$$\begin{aligned} &AZ\ Total\ Delivery\ Volume\ (af) \\ &= Maximum(AZ\ Total\ Annual\ Policy\ Shortage\ (af) - 760{,}000\ (af), 0\ (af)) \end{aligned}$$

The total Arizona delivery is then distributed to CAP and CRIT-AZ, proportional to each water user's annual shortage:

$$Delivery\ Volume_A = AZ\ Total\ Delivery\ Volume\ (af) \times \frac{Annual\ Shortage_A}{\sum Annual\ Shortage_{CAP+CRIT\ AZ}}$$

where "A" is either the CAP or CRIT-AZ water-user.

For modeling purposes only, if CAP is unable to mitigate their portion of the statewide shortage exceeding 760 kaf using their own storage credits, then it is assumed that CRIT-AZ storage credits, followed by IID's storage credits (see **Section B.6.2.4**, *Delivery/Conversion*) are delivered to CAP. The volume of the CRIT-AZ's storage credits that are modeled as deliveries to CAP is limited to the lesser of the storage credits available in CRIT-AZ's account and CAP's remaining unmitigated shortage.

For GRIC's Pre-2027 ICS that is converted to the Lake Mead mechanism on January 1, 2027, the delivery of this water—subject to availability—is modeled using the following logic. While the water is physically delivered to CAP in the model, this approach ensures that the delivery is properly accounted for using GRIC's existing storage credits:

$$\left(AZ\ Total\ Delivery\ Volume \times \frac{Annual\ Shortage_{CAP}}{\sum Annual\ Shortage_{CAP+CRIT\ AZ}}\right) X \left(\frac{200{,}760\ af}{Annual\ Depletion\ Schedule_{CAP}}\right)$$

B.6.2.4 California Creation and Conversion/Delivery Assumptions

For modeling purposes, California's conservation activity is modeled using IID, MWD, and CRIT-California (CA).

Creation

Both MWD and IID's annual conservation volumes are based on the SRWYT, described in **Section B.3.2.4**, California Creation and Delivery Assumptions. **Table B-16** below shows the assumed conservation for MWD and IID:

Table B-16
Summary of MWD and IID Assumed Conservation Volumes in the Enhanced Coordination Alternative

SRWYT	MWD (kaf)	IID (kaf)	Total (kaf)
C	0.000	0.000	0
D	41.667	0.000	41.667
BN	229.167	125.000	354.167
AN	416.666	166.667	583.333
W	483.333	250.000	733.333

Conservation first goes towards meeting any shortages in the same year it occurs. Any remaining conserved water is stored in the Lake Mead mechanism.

Every three years, CRIT-CA is assumed to store 10 percent of its depletion schedule. The creation volume is reduced by any annual shortage, which depends on the shortage distribution method and the total shortage volume.

Delivery/Conversion

MWD and IID are assumed to convert storage credits in the Lake Mead mechanism to meet shortages that are not met by same-year conservation. They also are assumed to take additional deliveries from their pools, independent of shortage, as shown in the **Table B-17**; both subject to the maximum annual delivery/conversion limit.

Table B-17
Summary of MWD and IID Assumed Delivery Volumes in the Enhanced Coordination Alternative

SRWYT	MWD (kaf)	IID (kaf)	Total (kaf)
C	125.000	125.000	250.000
D	0.000	62.500	62.500
BN	0.000	0.000	0.000
AN	0.000	0.000	0.000
W	0.000	0.000	0.000

Additionally, for modeling purposes only, it is assumed IID storage credits are delivered to MWD, CAP and/or SNWA if the total Lower Basin shortage exceeds 1.5 maf and there is at least 150 kaf in IID's account after accounting for current-year deliveries/conversions (as described above). These storage credits are assumed to only be used to mitigate each water user's respective shortage attributable to total Lower Basin shortages greater than 1.5 maf. It is assumed that MWD may take delivery of all IID storage credits, if needed, to fully mitigate their portion of the Lower Basin shortage above 1.5 maf. Any remaining IID storage credits are assumed to be distributed between CAP (90 percent) and SNWA (10 percent). Deliveries of IID's storage credits to MWD, CAP, and/or SNWA are modeled to occur after the following assumed, respective, operations are insufficient to mitigate this portion of each water user's shortage:

- MWD storage credits;
- CAP storage credits and the delivery of CRIT-AZ storage credits to CAP; and
- SNWA storage credits and Interstate Water Banking.

CRIT-CA does not take direct delivery of their storage credits in the Lake Mead mechanism. Rather, this water is transferred to CRIT-AZ when CRIT-AZ is unable to mitigate its shortage usings its own storage credits, subject to the following constraints:

- The water may be used only to mitigate CRIT-AZ's shortage; however, mitigation is limited to the portion of CRIT-AZ's shortage associated with total Lower Basin shortages exceeding 1.5 maf.
- Arizona's total shortage exceeds 760 kaf (i.e., total Lower Basin shortage exceeds 1.5 maf)
- Maximum delivery volume is limited to 25 kaf/year.

B.6.2.5 Nevada Creation and Conversion/Delivery Assumptions

Creation

SNWA is modeled to store two types of water in the Lake Mead mechanism: conserved water and Tributary Conservation. With respect to Tributary Conservation, which represents conservation on the Virgin and Muddy Rivers, 35 kaf per year is created. This water is stored in the Lake Mead mechanism if space is available, after the applicable system assessment is applied. In CRSS, this is modeled as a gain to Lake Mead.

For conserved water, SNWA's annual creation is calculated using the following equation:

$$Annual\ Creation = Maximum(\ 300{,}000\ af - Annual\ Shortage_{NV} - Annual\ Demand_{NV}, 0\ af)$$

Based on the assumed depletion schedules, SNWA creates conservation water until 2047, at which point demands equal full apportionment (see **Appendix M**, Lower Division States Depletion Schedules).

Delivery
Water stored in the Lake Mead mechanism is assumed to first mitigate shortages and, if available, then delivered to meet Nevada's demands exceeding apportionment, which starts in 2047. These additional demands range from 2,339 af in 2047 to 40,415 af in 2060 (**Table B-7**).

If there are insufficient storage credits in the Lake Mead mechanism to fully mitigate SNWA's shortages or to satisfy demands exceeding apportionment, SNWA is modeled to take delivery of water stored in the Interstate Water Banks, located in Arizona and California. This mechanism is independent of the Lake Mead mechanism; however, the model contains logic to account for this delivery (**see Section B.3.2.2**). As part of these modeling assumptions, SNWA withdraws from the Arizona bank followed by the California bank subject to the constraints described in **Section B.3.2.2**.

Additionally, if Nevada's account in the mechanism is full or dead pool related reductions occur, SNWA is assumed to take full delivery of its Tributary Conservation.

B.6.2.6 Mexico Creation and Conversion/Delivery Assumptions
Reclamation developed modeling assumptions for the storage and delivery of deferred water by Mexico to evaluate possible impacts of this activity on flow and other resources for this Final EIS.[14] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 U.S.-Mexico Treaty on Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande (1944 Water Treaty) or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the International Boundary and Water Commission (IBWC) in consultation with the Department of State.

Creation
Mexico is assumed to create up to 250 kaf per year, depending on its total reduction volume. An overview of the general creation logic is provided below, followed by a summary in **Table B-18**.

- If the combined storage of Lake Mead (physical) and Lake Powell (effective) exceeds 85 percent, both Mexico's reduction and creation volumes are 0 kaf.
- If the combined storage of Lake Mead (physical) and Lake Powell (effective) is between 85 percent and 60 percent, Mexico's reduction is 0 kaf and their creation volume is 250 kaf.
- If the combined storage of Lake Mead (physical) and Lake Powell (effective) is less than 60 percent, Mexico's reduction is greater than or equal to 250 kaf and their creation is 0 kaf.

[14] Assuming activity in Mexico is beneficial for National Environmental Policy Act purposes because it maximizes the effects on river flows as it occurs at the most downstream point in CRSS.

Table B-18
Summary of Mexico's Assumed Creation Volume Relative to Reductions in the Enhanced Coordination Alternative

Lake Mead (physical) & Lake Powell (effective) Combined Storage (%)	Mexico Reduction[A] (kaf)	Mexico Annual Contribution [A] (kaf)
> 85%	0	0
≤ 85% to > 60%	0	250
≤ 60%	≥ 250	0

[A] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico

Delivery/Conversion
Mexico is assumed to convert storage credits to meet assumed delivery reductions that exceed 250 kaf, which occur when the combined storage of Lake Mead (physical) and Lake Powell (effective) is less than or equal to 60 percent. The conversion volume is limited by the available stored credits, the maximum annual delivery/conversion, and are assumed to only occur when Lake Mead's physical elevation is above 1,025 feet.

B.6.3 Lake Mead Mechanism (Protection Pool)

As described in **Appendix S**, the Protection Pool—designed with significant input from representatives of Basin Tribes—would be a pool of water controlled by Reclamation that can reach a maximum volume of 2.0 maf. It would acquire water through multiple mechanisms, including but not limited to system assessments on water user-created conservation, potentially compensated Lower Basin tribal water (conserved consumptive use and unused), system efficiency projects and potentially compensated nontribal conservation. Contents of the Protection Pool would be included in determinations of Lake Powell releases and shortage volumes.

The Protection Pool could be used for a range of purposes, including, but not limited to, meeting federal firming obligations,[15] other federal delivery obligations, protecting Lower Basin water supplies, protecting infrastructure, and providing environmental benefits.

The subsequent sections provide a detailed description of the modeling assumptions and associated constraints.

B.6.3.1 Treatment of Pre-2027 ICS

For modeling purposes, it was intended that GRIC's pre-2027 EC-ICS that was assumed to exist on December 31, 2026 (**Table B-1**) would be converted to the Protection Pool on January 1, 2027. In the Enhanced Coordination Alternative, the existing GRIC EC-ICS (286,708 af) and CRIT-AZ EC-ICS (9,009 af) were erroneously transferred to the Lake Mead mechanism.

[15] The Secretary is obligated to firm certain volumes of CAP non-Indian agricultural water provided as part of Indian water rights settlements to specific tribes in Arizona, under Section 105(a) of the Arizona Water Settlements Act of 2004, Pub. L. 108-451, 118 Stat. 3478.

B.6.3.2 General Assumptions

The maximum capacity of the Protection Pool is 2.0 maf. Annual limits on creation and delivery are not explicitly modeled. The Protection Pool operates on a calendar year to align with reservoir operations. Delivery/conversion from the Lake Mead mechanism – Protection Pool is prohibited if Lake Mead starts the year with a physical pool elevation below 1,025 feet.

Protection Pool conservation activity is modeled using water generated from the following, prioritized, mechanisms:

1. Unused Water from the Lower Division Tribes with Mainstream Entitlements;
2. Lower Basin Tribal Conserved Consumptive Use;
3. System Efficiency;
4. System Assessment; and
5. Non-Tribal Conservation.

It is assumed that when the total conservation volume exceeds the Protection Pool capacity, higher-priority creation mechanisms generate conservation until the Protection Pool reaches full capacity. Additional details on each mechanism and the associated model assumptions are provided in the subsequent sections below.

For all mechanisms, except for water created via System Assessment, it is assumed a one-time system assessment of 7 percent is applied in the year the water is conserved and stored in the Protection Pool. Additionally, there is an annual deduction for evaporation equal to the Protection Pool's proportional share of total evaporation from Lake Mead. The evaporation deduction is applied annually in January based on the previous year's evaporation computed using the RiverWare™ Input Evaporation method and the total volume in the conservation pool at the end of the previous calendar year.

Similarly, conversion/delivery from the Protection Pool is modeled using the following, prioritized, mechanisms:

1. Federal Tribal Firming
2. Lower Basin Shortage Mitigation
3. Deliveries to benefit Lower Colorado River Multi-Species Conservation Program (LCR MSCP) sites

Additional details on the modeling assumptions for the creation and delivery/conversion of storage credits from the Protection Pool are provided below.

B.6.3.3 Contribution

Unused Water from the Lower Division Tribes with Mainstream Entitlements - Creation Assumptions

As noted above, Protection Pool conservation activity is modeled using water generated from five prioritized mechanisms. It is assumed that storing unused water associated with the Lower Division Tribes is the top priority, i.e., if there is limited available space, this water is stored first. Such storage would be voluntary. A table of the explicitly modeled Lower Division Tribes that are assumed to be able to create unused tribal water for storage in the Protection Pool is shown below (**Table B-19**):

These tribes hold diversion entitlements; therefore, for modeling purposes, unused water is calculated as the difference between the depletion equivalent of each of the tribe's entitlement and the assumed depletion schedule for the current year (see **Appendix M**, Lower Division State Depletion Schedules). Additionally, for modeling purposes, it is assumed 10 percent of the unused Lower Basin tribal water can be stored in the Protection Pool. As a result, this water would not be available for diversion and use by lower priority water users—specifically, MWD, CAP and SNWA—and the corresponding volumes are deducted from their modeled demands. **Appendix H**, Sensitivity Analysis - Modeled Unused Tribal Water Available for Storage in the Enhanced Coordination Alternative, provides information on the methodology used to estimate the Lower Division States unused tribal water, which was needed to model this concept.

Table B-19
Explicitly Modeled Lower Division Tribes that are Assumed to Create Unused Tribal Water for Storage in the Protection Pool – Enhanced Coordination Alternative.

CRSS Water User	State
Chemehuevi Indian Reservation	California
Cocopah Indian Reservation	Arizona
Colorado River Indian Reservation	Arizona
Colorado River Indian Reservation	California
Fort Mojave Indian Reservation	Arizona
Fort Mojave Indian Reservation	California
Fort Mojave Indian Reservation	Nevada
Fort Yuma Indian Reservation	Arizona
Fort Yuma Indian Reservation	California
Indian Water Rights Settlements[16]	Arizona

Pending available capacity in the Protection Pool, the assumed annual volume of unused tribal water available for storage in the Protection Pool ranges from 7.66 kaf in 2027 to 0 kaf per year in 2040-2060.[17]

[16] Please see **Appendix H** for a description of this line item.
[17] This modeling erroneously includes unused tribal water associated with the Hopi Tribe. As such, the range here does not match 10 percent of the total shown in **Appendix H, Table H-4**. The maximum magnitude of the discrepancy is 868 af in 2039-2060.

Tribal Conserved Consumptive Use Creation

For modeling purposes, tribal conserved consumptive use storage credits are assumed to be generated by the CAP Tribes and CRIT-AZ. In CRSS, CAP's entire Colorado River diversion, with the exception of the Salt River Pima-Maricopa Indian Community and Ak-Chin Indian Community portion of the diversion that is Arizona Priority 3, is represented as a single diversion. As such, this diversion is reduced to model the storage credits that are assumed to be generated by CAP Tribes. Such conservation would be voluntary.

For modeling purposes, it is assumed CAP and CRIT-AZ's tribal conserved consumptive use is an initial portion of each water user's creation volume described in **Section B.6.2.3**, *Creation*. Specifically**,** given the pro rata shortage distribution[18] included in the Enhanced Coordination Alternative, it is assumed CRIT-AZ can create up to 50 kaf per year of tribal conserved consumptive use, and the CAP Tribes can create up to 100 kaf per year of tribal conserved consumptive use. Note, in the modeling, this water was added to the Lake Mead mechanisms but was not properly subtracted from the respective water user's requested depletion schedule. Additionally, a discrepancy in the modeling exists in the calculation of each water user's Tribal Conserved Consumptive Use contribution when the Protection Pool is at capacity. Rather than proportionally reducing contributions based on each user's calculated desired contribution, the model calculates the actual contribution based on each user's proportional creation for the Lake Mead mechanism.

System Efficiency Creation

For modeling purposes, it is assumed that voluntary system efficiency projects generate the System Efficiency storage credits. The creation of this mechanism is phased-in over a three-year period, with 25 kaf in 2027, 50 kaf in 2028, and 75 kaf per year for the remainder of the simulation period (2030-2060). The conservation for this mechanism is modeled by reducing the scheduled demands on the water user that represents the water bypassed pursuant to IBWC Minute 242.

System Assessment Creation

It is assumed a one-time system assessment of 7 percent is applied in the year water is conserved and stored in the Lake Mead mechanism and the Protection Pool. The assessed volume is stored in the Protection Pool as a contribution generated through "System Assessment" activity. Water generated via this activity is not subject to a subsequent system assessment. Any assessed volume that cannot be stored in the Protection Pool becomes system water.

Non-Tribal Creation

It is assumed non-tribal contributions are generated when the Lake Mead water user-controlled pools are at capacity and the respective water users cannot store their full desired annual contribution volume (**see Section B.6.2.2**). Subject to availability in the Protection Pool, a maximum of 300 kaf of non-tribal contributions may be stored in the Protection Pool annually. Each state's share of the 300 kaf annual contribution limit is assumed to be proportional to the

[18] It is assumed these maximum creation limits could change under a priority-based shortage distribution, which is not modeled in the Enhanced Coordination Alternative.

assumed cumulative storage limits modeled for the Lake Mead mechanism and are shown below in **Table B-20**.

Table B-20
Constraints for the Non-Tribal Annual Contributions in the Enhanced Coordination Alternative

Entity	Maximum Annual Contribution (kaf)
Arizona	42
California	114
Nevada	42
Mexico	102
Total	**300**

B.6.3.4 Delivery/Conversion

Federal Tribal Firming Delivery/Conversion Assumptions

As noted above, taking delivery/conversion of storage credits from the Protection Pool is modeled using three prioritized mechanisms. For modeling purposes, it is assumed the highest priority mechanism is the delivery/conversion of storage credits to meet federal tribal firming obligations.

For modeling purposes only, CAP is assumed to take delivery of storage credits in the Protection Pool when shortages exceed specified thresholds as a modeling approximation of federal tribal firming obligations.[19] The modeled maximum annual delivery/conversion volume relative to these shortage thresholds are provided below in **Table B-21**.

Table B-21
CAP Shortage Thresholds Relative to Delivery/Conversion of Storage Credits in the Enhanced Coordination Alternative

Current Year Shortage for CAP (kaf)	Maximum Annual Delivery/Conversion Volume (kaf)
≥ 592	36.924
< 592 to ≥ 512	24.325

[19] Please see the Arizona Water Settlements Act, Pub. L. 108-451, 118 Stat. 3478 (Dec. 10, 2004), section 105, for a general description of the firming program. All firming deliveries in any given year would be made in accordance with applicable law. This appendix is not a legal interpretation of the firming program or of federal obligations. Actual firming deliveries may vary from the modeling approximations contained in this appendix, and Reclamation retains discretion to include legally-required tribal deliveries in this priority mechanism.

Lower Basin Shortage Mitigation Delivery/Conversion Assumptions

Following federal tribal firming, storage credits in the Protection Pool are assumed to be delivered/converted to mitigate Lower Basin shortage. For modeling purposes, this delivery/conversion is assumed to occur, subject to availability, when the annual Lower Basin shortage exceeds 1.8 maf for three consecutive years, at which point up to 300 kaf of storage credits in the Protection Pool are delivered/converted to mitigate Lower Basin shortage. This shortage mitigation is modeled by reducing the annual Lower Basin shortage volume by a quantity equal to the volume delivered/conserved under this mechanism resulting in all Lower Basin users receiving a proportional benefit of the reduced shortage.

LCR MSCP Delivery/Conversion Assumptions

One of the stated uses of the Protection Pool is to provide environmental benefits. As a modeling simplification to represent this in CRSS, storage credits are assumed to be delivered to the Cibola National Wildlife Refuge (NWR). Cibola NWR was chosen as a modeling simplification and approximation as a representative LCR MSCP site. Subject to available storage credits in the Protection Pool, this delivery is modeled as a 40 kaf delivery to the Cibola NWR water user every three years.

B.7 Maximum Operational Flexibility Alternative

The Maximum Operational Flexibility Alternative includes a conservation mechanism that operates differently from those in the other alternatives. The conservation mechanism – referred to as the Conservation Reserve – is a pool that would store water conserved by Colorado River water users in either Basin (including Mexico) and would be distributed strategically across Lake Powell and Lake Mead to protect infrastructure and benefit a range of resources including the Colorado River Delta, LCR MSCP, and Grand Canyon. Reclamation would determine how to allocate the Conservation Reserve volume between reservoirs and could increase or decrease Lake Powell's basic water year release volume to meet infrastructure needs or resource goals. Operation of the Conservation Reserve would not affect tracking of Lee Ferry flows.

B.7.1 Lake Powell and Lake Mead Mechanism

B.7.1.1 General Assumptions

The Conservation Reserve volume in Lake Powell and Lake Mead does not affect the determination of Lake Powell's water year release or Lower Basin/Lake Mead operations, as they are based on effective storage and three-year preceding average natural flow at Lees Ferry. The Conservation Reserve has a maximum volume of 8.0 maf split between Upper and Lower Basin users, with 3.0 maf of space allocated to Upper Basin users and 5.0 maf allocated to Lower Basin users, which includes the storage of pre-2027 ICS. There is no maximum volume in Lake Powell or Lake Mead nor a maximum total storage for any single user or state, though there are Basin-specific total annual creation and delivery limits described in the following sections.

For modeling purposes, the storage credits are stored in Lake Powell or Lake Mead and are exchanged between the two reservoirs. Upper Basin and Lower Basin storage credits are tracked

separately as described in the following sections. Each Basin's storage credits do not sit in one reservoir and are allowed to be exchanged between Lake Powell and Lake Mead. The location of storage credits does not impact any individual water user's ability to take delivery of their conserved water. The following objectives are assumed to govern the exchange of storage credits between Lake Powell and Lake Mead, listed in order of priority, and define how exchange volumes are calculated to achieve each objective:

1. **Protection of critical elevations at Lake Powell (3,510 feet) and Lake Mead (1,000 feet).**

   In January, if Lake Powell or Lake Mead are projected to end the water year below their respective critical elevations, storage credits may be exchanged between the two reservoirs by adjusting the Lake Powell release to protect critical elevations.

2. **Delivery of storage credits to users, including Upper and Lower Basin users, LCR MSCP sites, and the Colorado River Delta.**

   If Lower Basin storage credits are requested for delivery but exceed the Conservation Reserve volume available in Lake Mead, additional storage credits are added to the Lake Powell release to meet the shortfall.

3. **Protection of Grand Canyon resources to support native fish populations, mitigate invasive species, and improve opportunities for high-flow experiments by maintaining Lake Powell elevations between 3,530 and 3,600 feet.**

   In January, the exchange volume is calculated as the difference between the projected end of water year Lake Powell storage and the equivalent storage at elevation 3,570 feet (the modeling target elevation). This exchange volume is then added to the Lake Powell release. Due to uncertainty in projected end of water year storage, the target elevation range may not be fully achieved.

If objectives conflict, the highest-priority objective governs adjustments to the Lake Powell release. Exchanges are assumed to be subject to the following conditions:

- Exchanges from Lake Mead to Lake Powell are constrained to ensure that Lake Powell's minimum daily release does not drop below 6,150 cubic feet per second (cfs)[20] and the basic water year release remains at or above 5.0 maf.
- No exchanges occur if beginning-of-year reservoir elevations are below their respective critical elevations.
- If Lake Powell declines below 3,510 feet any time during the water year, run-of-river operations will govern the Lake Powell release. If this occurs, Conservation Reserve activities affecting the Lake Powell release are suspended for the remainder of the year, and Conservation Reserve balances are reset to their prior end of calendar year values.

[20] A minimum daily release of approximately 7,000 cfs was preferred to support recreation resources; however, the minimum daily release was set at 6,150 cfs in CRSS to avoid conflict with the minimum basic water year release of 5 maf.

B.7.1.2 Upper Basin Mechanism

General Assumptions

The maximum capacity of Upper Basin's Conservation Reserve is 3.0 maf. The conservation creation for the Lake Powell mechanism is modeled as a total Upper Basin volume and not specific to any state or user. At the time of creation, a one-time 10-percent assessment is deducted from the volume.

Creation

Exact volumes of Upper Basin conservation over time are uncertain, but for the purposes of modeling, conservation up to 500 kaf per year is included, with variable annual volumes based on hydrologic conditions. The specific conservation volume is determined by comparing the modeled water year Lees Ferry natural flow to the historical 1991–2020 10th, 40th, and 80th percentile thresholds (**Table B-22**). Linear interpolation is used when the modeled Lees Ferry natural flow falls between percentile thresholds.

Table B-22
Upper Basin Modeled Annual Conservation Volumes in the Maximum Operational Flexibility Alternative

Current Water Year Natural Flow Relative to Historical Flows (1991-2020)	Annual (Water Year) Upper Basin Conservation (kaf)
Current Yr Natural Flow > 80th percentile	500
80th percentile ≥ Current Yr Natural Flow > 40th percentile	300
40th percentile ≥ Current Yr Natural Flow > 10th percentile	200
10th percentile ≥ Current Yr Natural Flow	0

Annual conservation volumes are disaggregated to the monthly scale using the average monthly Upper Basin agricultural demand distribution shown in **Table B-12** (**Section B.6.1.2**). These monthly volumes are then modeled as an inflow above Lake Powell.

Delivery/Conversion

Upper Basin users' conserved water is assumed to be converted to system water based on the shortage curve described in **Appendix S**. When Lower Basin shortages are greater than 2.0 maf, the volume above 2.0 maf is assumed to be converted from Upper Basin users' Conservation Reserve water to system water, subject to availability in the Conservation Reserve. The required Lower Basin shortage volume would be reduced by whatever volume of previously conserved Upper Basin water is converted. Conservation is assumed to not be available for conversion in the year in which it is created.

B.7.1.3 Lower Basin Mechanism

Treatment of Pre-2027 ICS

As described in **Appendix S**, ICS created under the 2007 Interim Guidelines and 2019 DCP that remains in Lake Mead in 2027 would be used or converted to the Post-2026 mechanism using a phased approach over 5 years.[21] Once transferred to the new mechanism, it is modeled as being subject to all provisions described herein.

As a modeling simplification, ICS created under the 2007 Interim Guidelines and 2019 DCP that remains in Lake Mead in 2027 (Pre-2027 ICS; **Table B-1**) is converted to the Post-2026 Lower Basin mechanism on January 1, 2027, and phased into the exclusion of operational determinations (i.e., operational neutrality) over 5 years. Other than the immediate exclusion from operational determinations, the new mechanism provisions—described herein—are modeled as immediately applying to Pre-2027 ICS. Additionally, the Pre-2027 ICS included in operational determinations (i.e., non-operationally neutral), is assumed to be delivered/used before the Pre-2027 ICS that is excluded from operational determinations (i.e., operationally neutral). This may result in the Pre-2027 ICS being fully exhausted before the end of the 5-year transition period.

General Assumptions

The maximum capacity of the Lower Basin mechanism is 5.0 maf,[22] with an annual maximum creation calculated as 3.0 maf minus the total Lower Basin shortage for the year. The maximum delivery is 3.0 maf. The Lower Basin mechanism operates on a calendaryear to align with reservoir operations. There is no delivery of storage credits modeled if Lake Powell or Lake Mead starts the water year below critical elevations, 3,510 feet and 1,000 feet, respectively. Creation volumes are assumed to not be exchanged between Lake Powell and Lake Mead in the year of creation. It is assumed a one-time system assessment of 10-percent is applied in the year the water is conserved and stored.

For modeling purposes, the conservation activity is modeled using the water users in **Table B-23.**

Table B-23
Lower Basin Mechanism Water Users in the Maximum Operational Flexibility Alternative

Water User	Entity
CAP	Arizona
Cibola NWR	Arizona
CRIT-AZ	Arizona
Yuma County Water Users Association (Yuma County WUA)	Arizona
MWD	California
IID	California

[21] The modeling erroneously excludes the conversion of system efficiency ICS to the Lake Mead mechanism.
[22] The 5.4 maf maximum capacity shown in **Table TA 4-13** for the Critically Dry flow category appears to be a modeling error.

Water User	Entity
CRIT-CA	California
SNWA	Nevada
Mexico	Mexico

Arizona Creation and Conversion/Delivery Assumptions

In general, Arizona's creation and delivery of conserved water is inversely related to the state's shortage volume.

Creation

Arizona is assumed to create up to 880 kaf per year, depending on the state's total shortage volume. An overview of the logic is provided below.

- If Arizona's shortage is zero, the creation volume is 0 kaf.
- If Arizona's shortage is 0 to 880 kaf, Arizona's creation linearly decreases from 880 kaf to 0 kaf as Arizona's shortage increases from 0 kaf to 880 kaf.
- If Arizona's shortage is greater than 880 kaf, the creation volume is 0 kaf.

The computed state creation volume is then split to the CAP and CRIT-AZ water-users using the methodology described in the Enhanced Coordination Alternative (see **Section B.6.2.3**, *Creation*). The computed state creation volume is then split to the CAP and CRIT-AZ water-users using the methodology described in the Enhanced Coordination Alternative (see **Section B.6.2.3**, *Creation*).

Delivery/Conversion

Arizona is assumed to take delivery of storage credits to mitigate shortages greater than 880 kaf, subject to delivery constraints. The water-user delivery logic is identical to the methodology described in Enhanced Coordination Alternative (see **Section B.6.2.3**, *Delivery/Conversion*). Additionally, if CAP is unable to mitigate the portion of shortage that may be offset with storage credits, it is assumed that CAP takes delivery of CRIT-AZ storage credits, followed by an assumed delivery from IID using the methodology described in Enhanced Coordination Alternative (see **Section B.6.2.4**, *Delivery/Conversion*).

California Creation and Conversion/Delivery Assumptions

For modeling purposes, California's conservation activity is modeled using IID, MWD, and CRIT-CA.

Creation

Both MWD and IID's annual conservation volumes are based on the SRWYT, described in **Section B.3.2.4**. **Table B-24** shows the assumed conservation for MWD and IID. **Table B-24** shows the assumed conservation for MWD and IID.

Table B-24
Summary of MWD and IID Assumed Conservation Volumes in the Maximum Operational Flexibility Alternative

SRWYT	MWD (kaf)	IID (kaf)	Total (kaf)
C	0	0	0
D	50	0	50
BN	275	150	425
AN	500	200	700
W	580	300	880

Conservation is assumed to first go towards meeting any shortages in the same year it occurs. Any remaining conserved water is stored in the Lower Basin mechanism.

Every three years, CRIT-CA is assumed to store 10 percent of its depletion schedule. The creation volume is reduced by any annual shortage.

Delivery/Conversion
MWD and IID are assumed to convert storage credits in the Lake Mead mechanism to meet shortages that are not met by same-year conservation. They also are assumed to take additional deliveries from their pools, independent of shortage, as shown in **Table B-25**; both subject to the maximum annual delivery/conversion limit.

Table B-25
Summary of MWD and IID Assumed Delivery Volumes in the Maximum Operational Flexibility Alternative

SRWYT	MWD (kaf)	IID (kaf)	Total (kaf)
C	150	150	300
D	0	75	75
BN	0	0	0
AN	0	0	0
W	0	0	0

CRIT-CA's delivery assumptions are identical to those described in the Enhanced Coordination Alternative (see **Section B.6.2.4**, *Delivery/Creation*). Additionally, it is assumed IID storage credits are delivered to MWD, CAP and SNWA using the same methodology as those described in the Enhanced Coordination Alternative (see **Section B.6.2.4**, *Delivery/Conversion*).

Nevada Creation and Conversion/Delivery Assumptions
Nevada's creation and delivery logic is identical to the methodology described in the Enhanced Coordination Alternative (see **Section B.6.2.5**).

Mexico Creation and Conversion/Delivery Assumptions

Reclamation developed modeling assumptions for the storage and delivery of deferred water by Mexico to evaluate possible impacts of this activity on flow and other resources for this Final EIS.[23] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

Creation

Mexico is assumed to create up to 275 kaf per year, depending on its total reduction volume. An overview of the general creation logic is provided below.

- If Mexico's reduction is zero, the creation volume is 0 kaf.
- If Mexico's reduction is 0 to 275 kaf, Mexico's creation linearly decreases from 275 kaf to 0 kaf as Mexico's reduction increases from 0 kaf to 275 kaf.
- If Mexico's reduction is greater than 275 kaf, the creation volume is 0 kaf.

Delivery/Conversion

Mexico is assumed to convert storage credits to meet assumed delivery reductions that exceed 275 kaf. The conversion volume is limited by the available stored credits and the maximum annual total delivery/conversion and other delivery constraints.

LCR MSCP Creation and Conversion/Delivery Assumptions

One of the stated goals of the Conservation Reserve is to benefit a range of resources including the LCR MSCP. As a modeling simplification to represent this in CRSS, it is assumed that one user in each state creates storage credits in the Conservation Reserve, and then these storage credits are delivered to the Cibola NWR. Cibola NWR was chosen as a modeling simplification and approximation as a representative LCR MSCP site. Conservation Reserve water is assumed to be created and delivered on a three-year creation and delivery cycle, with Conservation Reserve water being created in years one and two and delivered in year three. For modeling purposes, storage credits are generated by the Yuma County Water Users Association (Yuma County WUA) in Arizona, CVWD in California, and SNWA in Nevada.

Creation

Participating water users are assumed to create 22.22 kaf annually for 2 years. Creation will not occur on year three of the creation and delivery cycle, when deliveries are assumed to be made to support the MSCP sites. This creation will allow the delivery of 40 kaf of Conservation Reserve storage credits to be made in year three and accounts for the system assessment applied to the creation of Conservation Reserve storage credits in years one and two.

[23] Assuming activity in Mexico is beneficial for National Environmental Policy Act purposes because it maximizes the effects on river flows as it occurs at the most downstream point in CRSS.

Creation by each water user (Yuma County WUA, CVWD, or SNWA) is proportional to their use in the current year, adjusted for the water user's shortage. It can be computed using the equation:

$$Creation_A = \frac{SDepl_A - Shortage_{Water\ User\ A}}{\sum SDepl_{Yuma\ County\ WUA\ ,Coachella,SNWA} - \sum Shortage_{Yuma\ County\ WUA,Coachella,SNWA}}$$

where:

$Creation_A$ = water user's creation volume

$SDepl_A$ = water user's depletion schedule for the current year

$Shortage_{Water\ User\ A}$ = The water user's shortage for the current year

$\sum SDepl_{Yuma\ County\ WUA,\ CVWD,\ SNWA}$ = sum of Yuma County WUA, CVWD, and SNWA's depletion schedules for the current year

$\sum Shortage_{Yuma\ County\ WUA,\ CVWD,\ SNWA}$ = sum of Yuma County WUA, CVWD, and SNWA's shortage for the current year

Delivery/Conversion

On year three of the three-year creation and delivery cycle, 40 kaf of Conservation Reserve storage credits are assumed to be delivered to the Cibola NWR.

Colorado River Delta Creation and Conversion/Delivery Assumptions

One of the stated goals of the Conservation Reserve is to benefit a range of resources including the Colorado River Delta. For modeling purposes, the conservation activity to benefit the Colorado River Delta is modeled using Mexico.[24] The creation and deliveries to benefit the Colorado River Delta are modeled on a three-year cycle, with creation occurring every year and deliveries occurring every third year.

Creation/Conversion

Mexico is assumed to create 48,214.3 af annually to support a 135 kaf delivery to the delta every three years. On year three of the three-year creation and delivery cycle, Mexico creates water for the delta but is not charged the system assessment as the volumes is taken as a delivery in the same year. The annual creation volume is 1/3 of the desired Conservation Reserve delivery to the delta, adjusted for the system assessment in 2 out of 3 years.

[24] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussion regarding the proposed federal action and implementation of the 1944 Treaty with Mexico through the IBWC in consultation with the Department of State.

Delivery
Delivery of 135 kaf is assumed to occur every three years. This delivery is distributed equally over the months of June and July, with 67.5 kaf being delivered each month.

B.8 Supply Driven Alternative

The Supply Driven Alternative (both LB Priority and LB Pro Rata approaches) includes a Lake Powell mechanism and a Lake Mead mechanism. Details on each mechanism including creation, delivery, and constraints are provided below.

B.8.1 Lake Powell Mechanism

As described in **Appendix S**, water conserved by Upper Basin users would be stored in a pool in Lake Powell that could reach a maximum volume of 3.0 maf. Upper Division States and Upper Basin Tribes would be able to contribute to the conservation pool and could use their conserved water in intra- and interstate transactions with other Upper Basin users. Water in the Lake Powell conservation pool could be released if needed to meet the determined water year volume. No modeling assumptions were developed to represent these specific uses of water in the Lake Powell conservation pool in the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches).

B.8.1.1 General Assumptions

The volume of water in the Lake Powell conservation pool does not affect the determination of Lake Powell's water year release, as the release is computed solely based on the preceding three-year average natural flow at Lees Ferry, nor does it affect Lower Basin/Lake Mead operations as they are based on Lake Mead elevation. There is a maximum capacity of 3.0 maf. There are no assumed state-specific limitations on the maximum accumulation, nor are there state-specific annual creation or delivery limits, as conservation creation for the Lake Powell mechanism is modeled as a total Upper Basin volume.

There is an annual deduction for evaporation equal to the conservation pool's proportional share of total evaporation from Lake Powell. The evaporation deduction is modeled annually in October based on the previous year's evaporation computed using the RiverWare™ Periodic Net Evaporation method and the total volume in the conservation pool at the end of the previous water year.

B.8.1.2 Creation

Exact volumes of Upper Basin conservation over time are uncertain, but for the modeling purposes, conservation volumes up to 200 kaf may be added in any given year, depending on hydrologic conditions. The modeled conservation volume is determined by comparing the modeled water year Lees Ferry natural flow to the historical 1991–2020 25th and 75th percentile thresholds (**Table B-26**). Linear interpolation is used when the modeled Lees Ferry natural flow falls between 10.60 and 16.5 maf—with conservation increasing from 0 to 200 kaf as natural flow increases across this range.

Table B-26
Upper Basin Modeled Annual Conservation Volumes in the Supply Driven Alternative

Current Water Year Lees Ferry Natural Flow (maf)	Annual (Water Year) Upper Basin Conservation (kaf)
> 16.50[25]	200
Between 16.50 and 10.60[26]	200 to 0 (linear interpolation)
≤ 10.60	0

Annual conservation volumes are disaggregated to the monthly scale using the average monthly Upper Basin agricultural demand distribution shown in **Table B-12** (**Section B.6.1.2**). These monthly volumes are then modeled as inflow above Lake Powell.

If the Lake Powell mechanism reaches full capacity, annual conservation continues; however, the conserved volumes are assumed to be system water rather than being accounted for within the Lake Powell mechanism.

B.8.1.3 Delivery/Conversion

There is no assumed conversion or delivery of storage credits in the Lake Powell mechanism, but water in the Lake Powell conservation pool can be released if needed to meet the determined water year volume.

B.8.2 Lake Mead Mechanism

Water conserved by Lower Basin users would be stored in Lake Mead in a pool that could reach a maximum volume of 8.0 maf (including Pre-2027 ICS). Water users could contribute, convert or deliver water previously stored under this new mechanism at their discretion, within the mechanism's applicable constraints. All storage credits in the Lake Mead conservation mechanism would be excluded from determinations of shortage volumes. The subsequent sections provide a detailed description of the modeling assumptions and associated constraints.

B.8.2.1 Treatment of Pre-2027 ICS

The conversion of pre-2027 ICS to the Post-2026 Lake Mead mechanism is identical to the methodology described in the Maximum Operational Flexibility Alternative except the pre-2027 ICS is phased to the new mechanism over 10 years (see **Section B.7.1.3**, *Treatment of Pre-2027 ICS*).[27]

B.8.2.2 General Assumptions

The maximum capacity of the Lake Mead mechanism, along with individual annual creation and delivery limits, is provided in **Table B-27** below. The Lake Mead mechanism operates on a calendar year to align with reservoir operations. Delivery/conversion from the Lake Mead mechanism is

[25] Historical 1991–2020 75th percentile Lees Ferry natural flow value.
[26] Historical 1991–2020 25th percentile Lees Ferry natural flow value.
[27] The modeling erroneously excludes the conversion of system efficiency ICS to the Lake Mead mechanism.

assumed to be prohibited if Lake Mead starts the year with a physical pool elevation below 1,025 feet.[28]

Table B-27
Lake Mead Mechanism Modeled Limitations of Storage of Conserved Water in Supply Driven Alternative

Entity	Maximum Annual Contribution (kaf)	Maximum Cumulative Storage (kaf)	Maximum Annual Conversion or Delivery (kaf)
Arizona	880	3,000	465
California	880	3,000	745
Nevada	225	1,000	90
Mexico[1]	500	1,000	100
TOTAL	**2,485**	**8,000**	**1,400**

[1] Volumes include modeling assumptions for Mexico's storage and delivery limits. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

The conservation activity is modeled using the water users in **Table B-28**.

Table B-28
Lake Mead Mechanism Water Users in the Supply Driven Alternative

Water User	Entity
CAP	Arizona
CRIT-AZ	Arizona
MWD	California
IID	California
CRIT-CA	California
SNWA	Nevada
Mexico	Mexico

It is assumed a one-time system assessment of 5 percent is applied in the year the water is conserved and stored. In every subsequent year, the evaporation assessment is assumed to be 3 percent of the stored volume. If water is created and delivered in the same calendar year, no assessments are applied.

[28] The logic included in CRSS erroneously did not apply this constraint to the delivery/conversion of California's storage credits.

B.8.2.3 Arizona Creation and Conversion/Delivery Assumptions

In general, Arizona's delivery of conserved water is inversely related to the effective elevation at Lake Mead and the state shortage volume.

For modeling purposes, Arizona's conservation activity is modeled using CAP and CRIT-AZ.

Creation

Arizona is modeled to create up to 880 kaf per year, depending on the state's total shortage volume. An overview of the logic is provided below, followed by a summary in **Table B-29**.

- If Lake Mead effective elevation is greater than or equal to 1,165 feet, both Arizona's shortage and creation volume are 0 kaf.
- If the Lake Mead effective elevation is between 1,165 feet and 1,145 feet (inclusive), Arizona's shortage is 0 kaf. However, their creation volume increases from 0 kaf to 880 kaf as the effective elevation decreases within this range.
- If the Lake Mead effective elevation is between 1,145 feet and 1,125 feet (inclusive), Arizona's shortage increases from 0 kaf to 760 kaf. As the shortage increases, Arizona's creation decreases from 880 kaf to 440 kaf. As a result, the sum of Arizona's shortage and creation increases linearly from 880 kaf to 1,200 kaf.
- If the Lake Mead effective elevation is between 1,125 feet and 1,050 feet (inclusive), Arizona's creation remains static at 440 kaf. As a result, the sum of Arizona's shortage (760 kaf) and creation (440 kaf) equals 1,200 kaf.
- If the Lake Mead effective elevation is less than 1,050 feet, Arizona's creation decreases from 440 kaf to 0 kaf as shortages increase.

Table B-29
Summary of Arizona's Assumed Creation Volumes Relative to Shortage in the Supply Driven Alternative

Lake Mead Effective Elevation (feet)	Arizona Shortage (kaf)	Arizona Annual Creation (kaf)
≥ 1,165	0	0
< 1,165 to ≥ 1,145	0	0 to 880
< 1,145 to ≥ 1,125	0 to 760	880 to 440
< 1,125 to ≥ 1,050	760	440
< 1,050	> 760	440 to 0

The computed state creation volume is then split to the CAP and CRIT-AZ water users using the methodology described in the Enhanced Coordination Alternative (see **Section B.6.2.3**, *Creation*).

Delivery/Conversion

Arizona is assumed to take delivery of storage credits to mitigate shortages greater than 760 kaf, subject to delivery constraints. The water-user delivery logic is identical to the methodology described in the Enhanced Coordination Alternative (see **Section B.6.2.3**, *Delivery/Conversion*).

B.8.2.4 California Creation and Conversion/Delivery Assumptions

For modeling purposes, California's conservation activity is modeled using IID, MWD, and CRIT CA.

Creation

Both MWD and IID's annual conservation volumes are based on the SRWYT, described in **Section B.3.2.4**. The assumed conservation for MWD and IID is the same as the Maximum Operational Flexibility Alternative (**Table B-24**). Conservation is assumed to first go towards meeting any shortages in the same year it occurs. Any remaining conserved water is stored in the Lake Mead pool.

Every three years, CRIT-CA is assumed to store 10 percent of its depletion schedule. The creation volume is reduced by any annual shortage, which depends on the shortage distribution method and Lake Mead elevation.

Delivery/Conversion

MWD and IID are assumed to convert storage credits in the Lake Mead mechanism to meet shortages that are not met by same-year conservation. They are also assumed to take additional deliveries from their pools, independent of shortage; both are subject to the maximum annual delivery/conversion limit. Delivery volumes are the same as the Maximum Operational Flexibility Alternative (**Table B-25**).

CRIT-CA's delivery assumptions are identical to those described in Enhanced Coordination Alternative (see **Section B.6.2.4**, *Delivery/Conversion*).

B.8.2.5 Nevada Creation and Conversion/Delivery Assumptions

Nevada's creation and delivery logic is identical to the methodology described in Enhanced Coordination Alternative (see **Section B.6.2.5**, *Delivery*).

B.8.2.6 Mexico Creation and Conversion/Delivery Assumptions

Reclamation developed modeling assumptions for the storage and delivery of deferred water by Mexico to evaluate possible impacts of this activity on flow and other resources for this Final EIS.[29] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

In general, the volumes of creation and delivery depend on the assumed annual delivery reductions to Mexico, and the storage credits are used to mitigate these delivery reductions.

[29] Assuming activity in Mexico maximizes the effects on river flows as it occurs at the most downstream point in CRSS.

Creation

Mexico is assumed to create up to 500 kaf per year, depending on its total reduction volume. An overview of the general creation logic is provided below, followed by a summary in **Table B-30**.

- If Lake Mead effective elevation is greater than or equal to 1,145 feet, both Mexico's reductions and creation volume are 0 kaf.
- If the Lake Mead effective elevation is between 1,145 feet and 1,125 feet, Mexico's reductions increase from 0 kaf to 250 kaf. As the reductions increase, Mexico's creation decreases from 250 kaf to 0 kaf. As a result, the sum of Mexico's reductions and creation equals 250 kaf.
- If the Lake Mead effective elevation is less than 1,125 feet, Mexico's creation is 0 kaf.

Table B-30
Summary of Mexico's Assumed Creation Volume Relative to Reductions in the Supply Driven Alternative

Lake Mead Effective Elevation (feet)	Mexico Reduction[B] (kaf)	Mexico Annual Contribution[B] (kaf)
≥ 1,145[A]	0	0
< 1,145 to ≥ 1,125	0 to 250	250 to 0
< 1,125	> 250	0

[A] Mexico is assumed to create 500 kaf in the first year following flood control, and this can occur only once per trace.
[B] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico.

Additionally, Mexico is assumed to create 500 kaf in the first year following flood control surplus, and this can occur only once per trace.

Delivery/Conversion

Mexico is assumed to convert storage credits to meet assumed delivery reductions that exceed 250 kaf (which occur when Lake Mead's effective elevation is below 1,050 feet). The conversion volume is limited by the available stored credits, the maximum annual delivery/conversion, and are assumed to only occur when Lake Mead's physical elevation is above 1,025 feet.

B.9 Representative Preferred Alternative

The Representative Preferred Alternative includes three pools to store, convert and deliver water for the benefit of water users and the system: the Lake Powell mechanism, the water user-controlled Lake Mead mechanism, and the Lake Mead Federally Managed Water Resources Pool, which was informed by a group of Basin Tribes and would be controlled by Reclamation for Lower Basin-wide benefits. The design of these mechanisms supports proactive conservation and water user flexibility.

Details on modeling assumptions for each mechanism including contribution, delivery, and associated constraints are provided below.

B.9.1 Lake Powell Mechanism

As described in **Chapter 2**, water conserved by Upper Basin users would be stored in a pool in Lake Powell that could reach a maximum volume of 3.0 maf. Upper Division States and Upper Basin Tribes would have equal access to contribute to the conservation pool and to use their conserved water in intra- and interstate transactions with other Upper Basin users; however, no modeling assumptions were developed to model those specific transactions in the Representative Preferred Alternative. Additionally, no modeling assumptions were developed to represent specific uses of water in the Lake Powell conservation pool in the Representative Preferred Alternative.

B.9.1.1 General Assumptions

The volume of water in the Lake Powell conservation pool is included in the determination of Lake Powell's water year release, which is based on the physical pool elevation at Lake Powell. There is a maximum capacity of 3.0 maf. There are no assumed state-specific limitations on the maximum accumulation, nor are there state-specific annual contribution or delivery limits, as conservation contribution for the Lake Powell mechanism is modeled as a total Upper Basin volume.

An annual evaporation assessment of 3 percent is applied to the volume of water remaining in the conservation pool at the end of each water year. The assessment is deducted in October based on the total volume stored at the end of the preceding water year. Additionally, a one-time assessment of 10 percent is applied in the year the water is initially conserved and stored.

B.9.1.2 Contribution

Exact volumes of Upper Basin conservation over time are uncertain, but for the modeling purposes, conservation volumes up to 200 kaf may be added in any given year, depending on hydrologic conditions. The modeled conservation volume is determined by comparing the modeled water year Lees Ferry natural flow to the historical 1991–2020 25th and 75th percentile thresholds (**Table B-31**). Linear interpolation is used when the modeled Lees Ferry natural flow falls between 10.6 and 16.5 maf—with conservation increasing from 0 to 200 kaf as natural flow increases across this range.

Table B-31
Upper Basin Modeled Annual Conservation Volumes in the Representative Preferred Alternative

Current Water Year Lees Ferry Natural Flow (maf)	Annual (Water Year) Upper Basin Conservation (kaf)
> 16.50[30]	200
Between 16.50 and 10.60[31]	200 to 0 (linear interpolation)
≤ 10.60	0

[30] Historical 1991–2020 75th percentile Lees Ferry natural flow value.
[31] Historical 1991–2020 25th percentile Lees Ferry natural flow value.

Annual conservation volumes are disaggregated to the monthly scale using the average monthly Upper Basin agricultural demand distribution shown in **Table B-12** (**Section B.6.1.2**). These monthly volumes are then modeled as inflow above Lake Powell.

If the Lake Powell mechanism reaches full capacity, annual conservation continues; however, the conserved volumes are assumed to be system water rather than being accounted for within the Lake Powell mechanism.

Note, this is the same approach implemented in the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches).

B.9.1.3 Delivery/Conversion

The same approach is implemented as the Supply Driven Alternative (both LB Priority and LB Pro Rata approaches): there is no assumed conversion or delivery of storage credits from the Lake Powell mechanism, but water in the Lake Powell conservation pool can be released if needed to meet the determined water year volume.

B.9.2 Lake Mead Mechanism

As described in **Chapter 2**, this pool represents the water user-controlled Lake Mead mechanism. Lower Colorado River entitlement holders, including Lower Basin Tribes, consistent with applicable implementation agreements, would be able to contribute to the conservation pool and to use their conserved water for delivery and/or in intra- and interstate transactions with other Lower Basin users. Water conserved by Lower Basin users would be stored in a pool in Lake Mead that can reach a maximum volume of 7.0 maf, which includes the storage of pre-2027 ICS. Water users could contribute and convert or deliver water previously stored under this new mechanism at their discretion within the annual volume constraints related to the pool. All conserved storage credits in Lake Mead would be included in determination of Lower Basin surplus and shortage volumes and equalization releases from Lake Powell.

The subsequent sections provide a detailed description of the modeling assumptions and associated constraints.

B.9.2.1 Treatment of Pre-2027 ICS

For modeling purposes only, ICS created under the 2007 Interim Guidelines and 2019 DCP that remains in Lake Mead in 2027 is converted to the Post-2026 Lake Mead water-user controlled mechanism on January 1, 2027.

B.9.2.2 General Assumptions

The Lake Mead mechanism operates on a calendar year to align with reservoir operations. The maximum capacity of the Lake Mead mechanism and the individual annual contribution and delivery limits are provided in **Table B-32** below.

Table B-32
Lake Mead Mechanism Modeled Limitations of Storage of Conserved Water in the Representative Preferred Alternative

Entity	Maximum Annual Contribution (kaf)	Maximum Cumulative Storage (kaf)	Maximum Annual Conversion or Delivery[2] (kaf)
Arizona	880	2,300	430
California	880	2,300	430
Nevada	100	900	140
Mexico[1]	500	1,500	200[3]
TOTAL	**2,360**	**7,000**	**1,200**

1) Volumes include modeling assumptions for Mexico's storage and delivery limits. Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.
2) The Representative Preferred Alternative maintained the total U.S. annual delivery of 1.0 maf from the 2007 Interim Guidelines. For modeling purposes, to maximize reach impacts, and to integrate with other modeling assumptions, e.g., demand schedules, the state specific maximums were modified from those in the 2007 Interim Guidelines; this modeling assumption is not intended to determine any future state maximum delivery constraints.
3) The 1944 Water Treaty authorizes scheduled delivery of up to 200 kaf in excess of the 1.5 annual allotment to Mexico.

For modeling purposes only, additional general delivery/conversion constraints include the following:

- Delivery/conversion from the Lake Mead mechanism is prohibited when Lake Mead begins the year with a physical pool elevation below 1,000 feet and is limited to 50 percent of the maximum annual delivery/conversion volume (**Table B-32**) when Lake Mead begins the year with a physical pool elevation between 1,000 and 1,025 feet.
- Delivery/conversion of stored water from the Lake Mead mechanism is limited such that a state's annual apportionment or Mexico's annual allotment is not exceeded when the Lower Basin shortage is greater than or equal to 1.5 maf (i.e., when Lake Mead's physical pool elevation is less than or equal to 1,125 feet). The delivery/conversion is not subject to those constraints when the Lower Basin shortage is less than 1.5 maf (i.e., when Lake Mead's physical pool elevation exceeds 1,125 feet).
- Delivery/conversion of existing DCP ICS (Arizona) and BWSCP credits (Mexico) is allowed when Lake Mead's physical pool elevation exceeds 1,110 feet.

The conservation activity is modeled using the following water users:

Table B-33
Lake Mead Mechanism Water Users in the Representative Preferred Alternative

Water User	Entity
CAP	Arizona
CRIT-AZ	Arizona
MWD	California
IID	California
CRIT-CA	California
SNWA	Nevada
Mexico	Mexico

At the time the water is conserved, a one-time three percent system assessment, along with a one-time seven percent assessment allocated to the Federally Managed Water Resources Pool, for a total assessment of 10 percent are assumed to be applied. The volume allocated to the Federally Managed Water Resources Pool as "System Assessment" storage credits is subject to the Federally Managed Water Resources Pool's constraints and associated modeling assumptions (**See Section B.9.3.3**). If water is created and delivered in the same calendar year, no system assessment is applied.

Additionally, an annual evaporation deduction of 3 percent is applied in January based on the volume of water remaining in the conservation pool at the end of the preceding calendar year.

B.9.2.3 Arizona Contribution and Conversion/Delivery Assumptions

In general, Arizona's contribution and delivery of conserved water is inversely related to the physical elevation at Lake Mead and the state shortage volume.

For modeling purposes, Arizona's conservation activity is modeled using CAP and CRIT-AZ.

Contribution

Arizona is modeled to create up to 880 kaf per year, depending on the state's total shortage volume. An overview of the logic is provided below, followed by a summary in **Table B-34**.

- If Lake Mead physical pool elevation is greater than or equal to 1,165 feet, both Arizona's shortage and contribution volume are 0 kaf.
- If the Lake Mead physical pool elevation is between 1,165 feet and 1,145 feet (inclusive), Arizona's shortage is 0 kaf. However, their contribution volume linearly increases from 0 kaf to 880 kaf as the physical elevation decreases within this range.
- If the Lake Mead physical pool elevation is less than 1,145 feet, the contribution equals 1,200 kaf minus Arizona's Policy Shortage, resulting in decreasing contribution volumes as the shortage increases from zero. The maximum annual contribution is 880 kaf.

Table B-34
Summary of Arizona's Assumed Contribution Volumes Relative to Shortage in the Representative Preferred Alternative

Lake Mead Physical Elevation (feet)	Arizona Shortage (kaf)	Arizona Annual Contribution (kaf)
≥ 1,165	0	0
< 1,165 to ≥ 1,145	0	0 to 880
< 1,145	> 0	880 to 0

The computed state contribution volume is then split to the CAP and CRIT-AZ water users using the methodology described in the Enhanced Coordination Alternative (see **Section B.6.2.3**, *Creation*). For modeling purposes, it is assumed that the first 50 kaf of conserved water generated by CAP and the first 100 kaf of conserved water generated by CRIT-AZ are stored in the Lake Mead mechanism – Federally Managed Water Resources Pool and accounted for as tribal conserved consumptive use (see **Section B.9.3.3**, *Lower Basin Tribal Conserved Consumptive Use Contribution*).

Delivery/Conversion

Arizona is assumed to take delivery of storage credits in the Lake Mead mechanism to mitigate shortages greater than 760 kaf. The following formula is used to determine Arizona's total delivery volume from the Lake Mead mechanism, subject to available storage credits:

$$AZ\ Total\ Delivery\ Volume\ (af) = Maximum(AZ\ Total\ Annual\ Policy\ Shortage\ (af) - 760{,}000\ (af), 0\ (af))$$

The total Arizona delivery is then distributed to CAP and CRIT-AZ, proportional to each water user's annual shortage:

$$Delivery\ Volume_A = AZ\ Total\ Delivery\ Volume\ (af) \times \frac{Annual\ Shortage_A}{\sum Annual\ Shortage_{CAP+CRIT\ AZ}}$$

where "A" is either the CAP or CRIT-AZ water-user.

For modeling purposes only, if CAP is unable to mitigate their portion of the statewide shortage exceeding 760 kaf using their own storage credits, then it is assumed that CRIT-AZ storage credits, followed IID's storage credits (see **Section B.9.2.4**, *Delivery/Conversion*) are delivered to CAP. The volume of the CRIT-AZ's storage credits that are modeled as deliveries to CAP is limited to the lesser of the storage credits available in CRIT-AZ's account and CAP's remaining unmitigated shortage.

To analyze the maximum impact of the total maximum delivery constraints (**Table B-32**) CAP is assumed to take delivery of 430 kaf of storage credits, if the following conditions are all met:

- The previous year total Lower Basin shortage was 1.5 maf, i.e., Lake Mead was below 1,125 feet
- Lake Mead's elevation is above 1,125 feet at the beginning of the current year

- Arizona, Nevada and Mexico's pools within the Lake Mead mechanism all contain sufficient water to meet their respective maximum annual deliveries (**Table B-32**). Note that California's maximum annual delivery is determined using different logic based on the SRWYT, as described in **Section B.3.2.4**. As such, this logic does not apply to California.
- The maximum delivery has not previously occurred, i.e., this maximum delivery may occur at most once per trace.

B.9.2.4 California Contribution and Conversion/Delivery Assumptions

For modeling purposes, California's conservation activity is modeled using IID, MWD, and CRIT-CA.

Contribution

Both MWD and IID's annual conservation volumes are based on the SRWYT, described in **Section B.3.2.4**. **Table B-35** shows the assumed conservation for MWD and IID.

Table B-35
Summary of MWD and IID Assumed Conservation Volumes in the Representative Preferred Alternative

SRWYT	MWD (kaf)	IID (kaf)	Total (kaf)
C	0	0	0
D	50	0	50
BN	275	150	425
AN	500	200	700
W	580	300	880

Conservation is assumed to first go towards meeting any shortages in the same year it occurs. Any remaining conserved water is stored in the Lake Mead mechanism.

Every three years, CRIT-CA is assumed to store 10 percent of its depletion schedule. The contribution volume is reduced by any annual shortage.

Delivery/Conversion

MWD and IID are assumed to convert storage credits in the Lake Mead mechanism to meet shortages that are not met by same-year conservation. They also are assumed to take additional deliveries from their pools, independent of shortage, as shown in **Table B-36**; both subject to the maximum annual delivery/conversion limit.

Table B-36
Summary of MWD and IID Assumed Delivery Volumes in the Representative Preferred Alternative

SRWYT	MWD (kaf)	IID (kaf)	Total (kaf)
C	215	215	430
D	0	75	75
BN	0	0	0
AN	0	0	0
W	0	0	0

Additionally, for modeling purposes only, it is assumed IID storage credits are delivered to MWD, CAP and/or SNWA if the total Lower Basin shortage exceeds 1.5 maf and there is at least 150 kaf in IID's pool after accounting for current-year deliveries/conversions (as described above). These deliveries are assumed to only be used to mitigate each water user's respective shortage attributable to total Lower Basin shortages greater than 1.5 maf. It is assumed that MWD may take delivery of all IID storage credits, if needed, to fully mitigate their portion of the Lower Basin shortage above 1.5 maf. Any remaining IID storage credits are assumed to be distributed between CAP (90 percent) and SNWA (10 percent). Deliveries of IID's storage credits to MWD, CAP, and/or SNWA are modeled to occur after the following assumed, respective, deliveries are insufficient to mitigate this portion of each water user's shortage:

- MWD storage credits;
- CAP storage credits and the delivery of CRIT-AZ storage credits to CAP; and
- SNWA storage credits and Interstate Water Banking.

CRIT-CA's is assumed to not take direct delivery of their storage credits from the Lake Mead mechanism. Rather, this water is delivered to CRIT-AZ when CRIT-AZ is unable to mitigate its shortage usings its own storage credits, subject to the following constraints:

- The water may be used only to mitigate CRIT-AZ's shortage; however, mitigation is limited to the portion of CRIT-AZ's shortage associated with total Lower Basin shortages exceeding 1.5 maf.
- Maximum delivery volume is limited to 25 kaf/year.

B.9.2.5 Nevada Contribution and Conversion/Delivery Assumptions

Contribution

SNWA is modeled to store two types of water in the Lake Mead mechanism: conserved water and Tributary Conservation. With respect to Tributary Conservation, which represents conservation on the Virgin and Muddy Rivers, 35 kaf per year is created. This water is stored in the Lake Mead mechanism if space is available, after the applicable system assessment is applied. In CRSS, this is modeled as a gain to Lake Mead.

For conserved water, SNWA's annual contribution is calculated using the following equation:

$$Annual\ Creation = Maximum(\ 300{,}000\ af - Annual\ Shortage_{NV} - Annual\ Demand_{NV}, 0\ af)$$

Based on the assumed depletion schedules, SNWA may create conservation water until 2047 depending on the annual shortage volume, at which point demands equal full apportionment (see **Appendix M**, Lower Division States Depletion Schedules).

Delivery

In general, water stored in the Lake Mead mechanism is assumed to first mitigate shortages and, if available, then delivered to meet Nevada's demands exceeding apportionment, which starts in 2047. These additional demands range from 2,339 af in 2047 to 40,415 af in 2060 (**Table B-7**).

If there are insufficient storage credits in the Lake Mead mechanism to fully mitigate SNWA's shortages or to satisfy demands exceeding apportionment, SNWA is modeled to take delivery of water stored in the Interstate Water Banks, located in Arizona and California. This mechanism is independent of the Lake Mead mechanism; however, the model contains logic to account for this delivery (**see Section B.3.2.2**). As part of these modeling assumptions, SNWA withdraws from the Arizona bank followed by the California bank subject to the constraints described in **Section B.3.2.2**.

Additionally, if Nevada's account in the mechanism is full or dead pool related reductions occur, SNWA is assumed to take full delivery of its Tributary Conservation.

To analyze the maximum impact of the total maximum delivery constraints (**Table B-32**) SNWA is assumed to take delivery of 140 kaf of storage credits, if the following conditions are all met:

- The previous year total Lower Basin shortage was 1.5 maf, i.e., Lake Mead was below 1,125 feet
- Lake Mead's elevation is above 1,125 feet at the beginning of the current year
- Arizona, Nevada and Mexico's pools within the Lake Mead mechanism all contain sufficient water to meet their respective maximum annual deliveries (**Table B-32**). Note that California's maximum annual delivery is determined using different logic based on the SRWYT, as described in **Section B.3.2.4.** As such, this logic does not apply to California.
- The maximum delivery has not previously occurred, i.e., this maximum delivery may occur at most once per trace.

B.9.2.6 Mexico Contribution and Conversion/Delivery Assumptions

Reclamation developed modeling assumptions for the storage and delivery of deferred water by Mexico to evaluate possible impacts of this activity on flow and other resources for this EIS.[32] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico. The U.S. will conduct all necessary and appropriate discussions

[32] Assuming activity in Mexico maximizes the effects on river flows as it occurs at the most downstream point in CRSS.

regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the IBWC in consultation with the Department of State.

In general, the volumes of contribution and delivery depend on the assumed annual delivery reductions to Mexico, and the storage credits are used to mitigate these delivery reductions.

Contribution

Mexico is assumed to create up to 500 kaf per year, depending on its total reduction volume. An overview of the general contribution logic is provided below, followed by a summary in **Table B-37**.

- If the Lake Mead physical pool elevation is greater than 1,165 feet, Mexico's reduction and contribution volume are 0 kaf.
- If the Lake Mead physical pool elevation is between 1,165 feet and 1,145 feet (inclusive), Mexico's reduction is 0 kaf and their contribution volume is 250 kaf.
- If the Lake Mead physical pool elevation is less than 1,145 feet, the contribution equals 250 kaf minus Mexico's reduction, resulting in decreasing contribution volumes as the reduction increases from zero.

Table B-37
Summary of Mexico's Assumed Contribution Volume Relative to Reductions in the Representative Preferred Alternative

Lake Mead Physical Elevation (feet)	Mexico Reduction[B] (kaf)	Mexico Annual Contribution[B] (kaf)
> 1,165[A]	0	0
≤ 1,165 to ≥ 1,145	0	250
< 1,145	0 to 250	250 to 0

[A] Mexico is assumed to create 500 kaf in the first year following flood control, and this can occur only once per trace.
[B] Reclamation's modeling assumptions are not intended to constitute an interpretation or application of the 1944 Water Treaty or to represent current U.S. policy or a determination of future U.S. policy regarding deliveries to Mexico.

Additionally, Mexico is assumed to create 500 kaf in the first year following flood control surplus, and this can occur only once per trace.

Delivery/Conversion

In general, Mexico is assumed to take delivery of storage credits from the Lake Mead mechanism to mitigate assumed delivery reductions greater than 250 kaf.

To analyze the maximum impact of the total maximum delivery constraints (**Table B-32**) Mexico is assumed to take delivery of 200 kaf of storage credits, if the following conditions are all met:

- The previous year total Lower Basin shortage was 1.5 maf, i.e., Lake Mead was below 1,125 feet
- Lake Mead's elevation is above 1,125 feet at the beginning of the current year

- Arizona, Nevada and Mexico's pools within the Lake Mead mechanism all contain sufficient water to meet their respective maximum annual deliveries (**Table B-32**). Note that California's maximum annual delivery is determined using different logic based on the SRWYT, as described in **Section B.3.2.4.** As such, this logic does not apply to California.
- The maximum delivery has not previously occurred, i.e., this maximum delivery may occur at most once per trace.

B.9.3 Lake Mead Mechanism (Federally Managed Water Resources Pool)

As described in **Chapter 2**, the Federally Managed Water Resources Pool is a pool of water in Lake Mead established by Reclamation that is anticipated to be around 450 kaf, but could reach a maximum volume of 1.0 maf[33]; for modeling purposes it was assumed the maximum capacity was 1.0 maf. It could acquire water through multiple mechanisms involving acquisition of conserved consumptive use water including but not limited to ICS. Contents of the Pool would be included in determinations of Lake Powell equalization releases and Lower Basin surplus and shortage volumes.

Chapter 2 provides a description of the range of purposes contemplated for the Federally Managed Water Resources Pool. The subsequent sections provide a detailed description of the modeling assumptions and associated constraints used to represent the Federally Managed Water Resources Pool in the Representative Preferred Alternative.

B.9.3.1 Treatment of Pre-2027 ICS

For modeling purposes, GRIC's and CRIT-AZ's pre-2027 EC-ICS that were assumed to exist on December 31, 2026 (**Table B-1**) was converted to the Federally Managed Water Resources Pool on January 1, 2027.

B.9.3.2 General Assumptions

The maximum capacity of the Federally Managed Water Resources Pool is 1.0 maf. Annual limits on contribution and delivery are not explicitly modeled. The Federally Managed Water Resources Pool operates on a calendar year to align with reservoir operations. Delivery/conversion from the Lake Mead mechanism – Federally Managed Water Resources Pool are prohibited if Lake Mead starts the year with a physical pool elevation below 1,000 feet.

Federally Managed Water Resources Pool conservation activity is modeled using water generated from the following, prioritized, mechanisms:

1. Lower Basin Tribal Conserved Consumptive Use;
2. System Efficiency;
3. System Assessment; and
4. Non-Tribal Conserved Consumptive Use.

It is assumed that when the total conservation volume exceeds the Federally Managed Water Resources Pool capacity, conservation generated through higher-priority contribution mechanisms is

[33] This volume has been proposed to accommodate future water use arrangements, which could include but would not be limited to conservation programs, contracts, and potential Indian water rights settlements.

stored in the Federally Managed Water Resources Pool until it reaches full capacity. Additional details on each mechanism and the associated modeling assumptions are provided in the subsequent sections below.

For all mechanisms, except for water created via System Assessment, it is assumed a one-time system assessment of 10 percent is applied in the year the water is conserved and stored in the Federally Managed Water Resources Pool. Additionally, an annual evaporation deduction of 3 percent is applied in January based on the volume of water remaining in the conservation pool at the end of the preceding calendar year.

Similarly, conversion/delivery from the Federally Managed Water Resources Pool is modeled using the following, prioritized, mechanisms:

1. Federal Tribal Firming
2. Lower Basin Shortage Mitigation
3. Deliveries to benefit LCR MSCP sites

Additional details on the modeling assumptions for the contribution and delivery/conversion of storage credits from the Federally Managed Water Resources Pool are provided below.

B.9.3.3 Contribution

Lower Basin Tribal Conserved Consumptive Use Contribution
For modeling purposes, tribal conserved consumptive use storage credits are assumed to be generated by the CAP Tribes and CRIT-AZ. In CRSS, CAP's entire Colorado River diversion, with the exception of the Salt River Pima-Maricopa Indian Community and Ak-Chin Indian Community portion of the diversion that is Arizona Priority 3, is represented as a single diversion. As such, this diversion is reduced to model the storage credits that are assumed to be generated by CAP Tribes. Such conservation would be voluntary.

For modeling purposes, it is assumed CAP and CRIT-AZ's tribal conserved consumptive use is an initial portion of each water user's contribution volume described in **Section B.9.2.3**, *Contribution*. Specifically**,** given the priority shortage distribution included in the Representative Preferred Alternative, it is assumed CRIT-AZ can create up to 100 kaf per year of tribal conserved consumptive use, and the CAP Tribes can create up to 50 kaf per year of tribal conserved consumptive use.

System Efficiency Contribution
For modeling purposes, it is assumed that voluntary system efficiency projects generate the System Efficiency storage credits. The contribution of this mechanism is phased-in over a three-year period, with 25 kaf in 2027, 50 kaf in 2028, and 75 kaf per year for the remainder of the simulation period (2029-2060). The conservation for this mechanism is modeled by reducing the scheduled demands on the water user that represents the water bypassed pursuant to IBWC Minute 242.

System Assessment Contribution

It is assumed that at the time water is conserved and stored in the Lake Mead mechanism (water user-controlled pools or Federally Managed Water Resources Pool), a one-time three percent system assessment would be applied, along with a one-time seven percent assessment allocated to the Federally Managed Water Resources Pool, for a total assessment of 10 percent. The portion of the assessment allocated to the Federally Managed Water Resources Pool is this "System Assessment Contribution." Water generated via this activity is not subject to a subsequent system assessment. Any assessed volume that cannot be stored in the Federally Managed Water Resources Pool becomes system water.

Non-Tribal Contribution

It is assumed non-tribal contributions are generated when the Lake Mead water user-controlled pools are at capacity, and the respective water users cannot store their full desired annual contribution volume (see **Section B.9.2.2**). Subject to availability in the Federally Managed Water Resources Pool, a maximum of 300 kaf of non-tribal contributions may be stored in the Federally Managed Water Resources Pool annually. Each state's share of the 300 kaf annual contribution limit is assumed to be proportional to the assumed cumulative storage limits modeled for the Lake Mead mechanism and is shown below in **Table B-38**.

Table B-38
Constraints for the Non-Tribal Annual Contributions in the Representative Preferred Alternative

Entity	Maximum Annual Contribution (kaf)
Arizona	42
California	114
Nevada	42
Mexico	102
Total	**300**

B.9.3.4 Delivery/Conversion

Federal Tribal Firming Delivery/Conversion

As noted above, taking delivery/conversion of storage credits from the Federally Managed Water Resources Pool is modeled using three prioritized mechanisms. For modeling purposes, it is assumed the highest priority mechanism is the delivery/conversion of storage credits to meet federal tribal firming obligations.

For modeling purposes only, CAP is assumed to take delivery of storage credits in the Federally Managed Water Resources Pool when shortages exceed specified thresholds as a modeling

approximation of federal tribal firming obligations.[34] The modeled maximum annual delivery/conversion volume relative to these shortage thresholds is provided below in **Table B-39**.

Table B-39
CAP Shortage Thresholds Relative to Delivery/Conversion of Storage Credits in the Representative Preferred Alternative

Current Year Shortage for CAP (kaf)	Maximum Annual Delivery/Conversion Volume (kaf)
≥ 592	36.924
< 592 to ≥ 512	24.325

Lower Basin Shortage Mitigation Delivery/Conversion

Following federal tribal firming, storage credits in the Federally Managed Water Resources Pool are assumed to be delivered/converted to mitigate Lower Basin shortage. For modeling purposes, this delivery/conversion is assumed to occur, subject to availability, when the annual Lower Basin shortage exceeds 1.8 maf for three consecutive years, at which point up to 300 kaf of storage credits in the Federally Managed Water Resources Pool are delivered/converted to mitigate Lower Basin shortage. This shortage mitigation is modeled by reducing the annual Lower Basin shortage volume by a quantity equal to the volume delivered under this mechanism.

LCR MSCP Delivery/Conversion

One of the stated uses of the Federally Managed Water Resources Pool is to provide environmental benefits. As a modeling simplification to represent this in CRSS, storage credits are assumed to be delivered to the Cibola NWR. Cibola NWR was chosen as a modeling simplification and approximation as a representative LCR MSCP site. Subject to available storage credits in the Federally Managed Water Resources Pool, this delivery is modeled as a 40 kaf delivery to the Cibola NWR water user every three years.

[34] Please see the Arizona Water Settlements Act, Pub. L. 108-451, 118 Stat. 3478 (Dec. 10, 2004), section 105, for a general description of the firming program. All firming deliveries in any given year would be made in accordance with applicable law. This appendix is not a legal interpretation of the firming program or of federal obligations. Actual firming deliveries may vary from the modeling approximations contained in this appendix, and Reclamation retains discretion to include legally-required tribal deliveries in this priority mechanism.

Appendix C. Shortage Allocation Model and Alternative Distribution Model Documentation

This appendix describes the Shortage Allocation Models and Alternative Distribution Models that were used to estimate the results of different concepts or sets of assumptions for the distribution of water during shortages to water users in the States of Arizona, California, and Nevada (Lower Division States) as part of the analysis of alternatives in this Environmental Impact Statement (EIS). Similar material was contained within the following documents:

- Appendix G, Shortage Allocation Model Documentation, to the 2007 Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead - Final Environmental Impact Statement (2007 FEIS).
- Appendix E, Shortage Allocation Model Documentation, to the 2024 Near-term Colorado River Operations - Final Supplemental Environmental Impact Statement (2024 FSEIS).

C.1 Introduction

To help assess the general effects of changes in the quantity of Colorado River water supplies available to water users in the Lower Division States[1] under alternatives analyzed in this EIS and proposals requested to be evaluated as a sensitivity analysis, the Bureau of Reclamation developed Shortage Allocation Models and Alternative Distribution Models and documented the specific modeling assumptions in this appendix. The results inform analyses described in the Water Deliveries, Socioeconomics, Land Use, and Indian Trust Assets sections of **Chapter 3** of the Final EIS.

C.2 Background and Purpose

The Shortage Allocation Model was created in 2007 to estimate the quantity of Colorado River water that would be available to water entitlement holders or water users under Shortage Conditions on the mainstream lower Colorado River over a specified range of shortage volumes. A Shortage Condition exists during a year when the Secretary of the Department of the Interior (Secretary), as documented in the Annual Operating Plan, determines that there is less than 7.5 million acre-feet (maf) of lower Colorado River water available for consumptive use within the Lower Division States.

[1] The U.S. will conduct all necessary and appropriate discussions regarding the proposed federal action and implementation of the 1944 Water Treaty with Mexico through the International Boundary and Water Commission in consultation with the Department of State. Total shortage volumes portrayed in Shortage Allocation Models and Alternative Distribution Models include an assumed component for Mexico, as described for each model.

For this EIS, Reclamation further developed what are referred to as Shortage Allocation Models or Alternative Distribution Models. The Shortage Allocation Models and Alternative Distribution Models were developed in parallel with the alternatives development phase of the EIS, in advance of having certainty about formulation of the alternatives and the depths of shortage resulting from their reservoir operating parameters. Stakeholders requested that Reclamation prepare a wide range of models demonstrating the effects of different assumptions for the distribution of water, which could support analyses of alternatives or potential agreements arising among water users in response to reservoir operating guidelines proposed by this EIS.

While this appendix uses the word shortage loosely to mean any modeled reduction to the ability of an entitlement holder[2] to exercise an entitlement as described in the assumptions of the model, reductions arising from voluntary arrangements may not be a Shortage Condition as defined in Article II.B.3 of the Consolidated Decree in *Arizona v. California*, 547 U.S. 150 (2006). The models themselves are not intended to achieve environmental compliance for the depths of shortage the models are capable of calculating, and the models do not themselves imply Federal action at any specific modeled volume; please see **Chapter 3** of the Final EIS for the resource analysis associated with the alternatives. Additionally, these models are not, and are not intended to be, used by Reclamation as implementation tools. The models should only be used for decision support as part of this EIS.

There are eight models documented in this appendix, described briefly in the following paragraphs; the following crosswalk table illustrates the relationship between the alternatives, which are described in **Chapter 2**, and the Shortage Allocation and Alternative Distribution Models.

Table C-1
Crosswalk Between Alternatives and Shortage Allocation and Alternative Distribution Models

Alternative	Shortage Model
Continuing Current Strategies (CCS) Comparative Baseline	CCS Shortage Allocation Model
No Action	Priority Shortage Allocation Model
Representative Preferred (2027-2028)[3]	LB Priority Shortage Allocation Model
Representative Preferred (2029 and later)	Priority Shortage Allocation Model
Basic Coordination	Priority Shortage Allocation Model

[2] Entitlement holders are all persons or entities authorized to beneficially use Colorado River water pursuant to: 1) a right decreed by the United States (U.S) Supreme Court, 2) a contract for the delivery of Colorado River water through the Secretary, or 3) a Secretarial reservation. For a current list of each Lower Division State's Colorado River water entitlement holders, please see: https://www.usbr.gov/lc/region/g4000/contracts/entitlements.html.

[3] The distribution of shortages up to 1.5 maf in 2027-2028 in the Representative Preferred Alternative reflects the May 1 proposal by the Lower Division States. Although not specified in their proposal, the Representative Preferred assumes shortages and their distribution above 1.5 maf in 2028 as necessary to avoid critically low elevations in Lake Mead. (See Chapter 2 for more details on the sideboards under the Preferred Alternative and their representation in the Representative Preferred Alternative).

Alternative	Shortage Model
Enhanced Coordination	Pro Rata Alternative Distribution Model
Maximum Operational Flexibility	LB Priority Shortage Allocation Model
Supply Driven – LB Priority Approach	LB Priority Shortage Allocation Model
Supply Driven – LB Pro Rata Approach	LB Pro Rata Alternative Distribution Model
N/A (Sensitivity)	Priority No Tribal Alternative Distribution Model
N/A (Sensitivity)	Pro Rata No PPR Tribal Alternative Distribution Model
N/A (Sensitivity)	Pro Rata No Tribal Alternative Distribution Model

The Priority Shortage Allocation Model simulates shortage allocations and adjusts deliveries of Colorado River water in accordance with the priority of entitlements within each of the Lower Division States' apportionments.

The Continuing Current Strategies Shortage Allocation Model is an adaptation of the Priority Shortage Allocation Model; it distributes available water first among the Lower Division States based on the 2007 Record of Decision for the adoption of Colorado River Interim Guidelines for Lower Basin Shortages and Coordinated Operations for Lake Powell and Lake Mead (2007 ROD) and the 2019 Lower Basin Drought Contingency Plan (2019 DCP) and then among the entitlement holders within each Lower Division State based on priority or as otherwise provided by the 2019 DCP.

The Lower Basin Priority Shortage Allocation Model is an adaptation of the Priority Shortage Allocation Model that uses a different state-level shortage distribution, as specified in the Lower Division States proposal submitted on March 6, 2024.

The other models are referred to as Alternative Distribution Models. These present variations on ways to distribute shortage outside the priority system, which would involve modifications to certain laws, contracts, agreements, and other authorities that are part of the Colorado River legal and contractual framework referred to as Law of the River. The Alternative Distribution Models include distributing shortages in a fully pro rata approach, a pro rata approach using the March 6, 2024, Lower Division States proposed state distribution, variations of the priority and pro rata approaches without shortage to tribes, and a variation of the pro rata approach without shortage to tribal PPR entitlements.

This appendix does not describe possible modifications to Law of the River, as any modifications may be informed by potential agreements arising among water users and would reflect the shortage distribution variation pursued. Certain Shortage Allocation Model and Alternative Distribution Model assumptions analyze distributions of water in ways that diverge from provisions in the Consolidated Decree and other applicable Federal law. Reclamation has determined that, based on public input received during the scoping and alternative development phases of the NEPA process, analysis of these distributions will present a broader range of impacts for agency and stakeholder consideration, review, and input, and will foster meaningful and informed decision-making among Reclamation and Colorado River Basin stakeholders. Such proposals may ultimately not be

implementable. Input from stakeholders on distribution variations, including from Colorado River Basin Tribes, is being identified and considered in the EIS and will help inform any final decision. Reclamation also recognizes that the Supreme Court retains jurisdiction in *Arizona v. California* for the purpose of any order, direction, or modification of the Consolidated Decree, or any supplementary Decree, that may at any time be deemed proper in relation to the subject matter in controversy, or for further amendment or relief. As in the 2001 and 2007 Guidelines, the Secretary anticipates retaining all applicable authority including to respond to emergency conditions in any decision.

Table C-2 presents a comparison of the results of each Shortage Allocation Model and Alternative Distribution Model at certain volumes of total shortage, all in acre-feet per year. The table is presented in three panels, Tribal, Domestic, and Irrigation, consistent with the summary tables for each model that appear at the end of each section of this appendix. Shading indicates the severity of shortage relative to the entitlements associated with each general category of entitlement holder, and is provided for the purpose of enabling a comparison of the effects of different proposals for the distribution of shortage. The following sections explain the assumptions associated with each Shortage Allocation Model and Alternative Distribution Model, which are a combination of universally applied assumptions and those unique to different models.

As described in the following **Section C.3**, model results are presented in this appendix for the levels of total shortage shown on **Table C-2**, all in acre-feet per year, only for the purpose of comparing the effects of the modeled distributions; these volumes were chosen based on points of interest in one or more models, or to provide granularity in the results over a range of volumes of interest. Total shortage volumes include an assumed component for Mexico, as described in the sections of this appendix pertaining to each model, and will not sum across panels.

Table C-2

Pro Rata w/No Tribal Shortage	372	620	929	1,115	1,239	1,301	1,425	1,859	2,168	2,478	3,098

*Continuing Current Strategies results are of limited comparability due to their fixed shortage volumes; shortages shown for 600 kafy and 1.0 mafy in total shortage are associated with 613 kafy and 1,013 kafy of total shortage in the Continuing Current Strategies Shortage Allocation Model.

Notes:

Total shortage volumes include an assumed component for Mexico and will not sum across panels.

The Tribal results panel is shaded on a gradient with zero in white and 1,103.88 kaf in orange. The Domestic results panel is shaded on a gradient with zero in white and 1,606.33 kaf in orange. The Irrigation results panel is shaded on a gradient with zero in white and 4,749.94 kaf in orange. The maximum values are a total of the Consumptive Use or equivalent entitlements assigned to each category.

The color gradient indicates the percentage reduction, with the darkest orange representing 100 percent reduction:

C.3 Assumptions Common to All Shortage Allocation Models and Alternative Distribution Models

Shortage Allocation Models and Alternative Distribution Models are Excel workbooks. Model results are presented in this appendix for the following levels of total shortage, all in acre-feet per year, only for the purpose of comparing the effects of the modeled distributions; these volumes were chosen based on points of interest in one or more models, or to provide granularity in the results over a range of volumes of interest:

- 600,000 (613,000 for the Continuing Current Strategies Shortage Allocation Model)
- 1,000,000 (1,013,000 for the Continuing Current Strategies Shortage Allocation Model)
- 1,500,000
- 1,800,000
- 2,000,000

- 2,100,000
- 2,300,000
- 3,000,000
- 3,500,000
- 4,000,000
- 5,000,000

In all models, volumes of shortage are distributed according to the assumptions of the model without regard to any proposed events causing those volumes of shortage, which are described as part of the alternatives analyzed in this EIS, or the frequency with which certain operational conditions may occur.

For the purpose of consistency with hydrologic modeling results and for comparison across models, total shortage volumes are presented in terms of the Lower Basin as a whole, including Mexico. No opinion on binational negotiations or potential shortages to Mexico under the 1944 Water Treaty or any future minutes is expressed or should be implied, and no attempt is made to further characterize the distribution of shortage within Mexico.

The Shortage Allocation Models and Alternative Distribution Models require certain modeling assumptions with regard to how shortages may be allocated. Reclamation acknowledges there may be other variations of how shortages could be distributed. These modeling assumptions are not intended to represent current or future policy with respect to shortage sharing or to limit Secretarial discretion to distribute shortages. A Shortage Allocation Model or Alternative Distribution Model is not a substitute for the annual process of reviewing water orders and determining annual water availability for each water entitlement holder on the lower Colorado River and, as such, cannot replicate the precision required for that process. While individual entitlement holders may find the results informative, these models are not intended to analyze and do not reflect any entitlement holder's individual drought preparedness or mitigation plans and may thereby overstate impacts.

The Shortage Allocation Models and Alternative Distribution Models developed for this EIS cannot represent the effects of any physical limitations on water access due to low river stage. The models thus assume there are no physical limitations on access to the distributed volume.

Central Arizona Project (CAP) excess water contracts and mainstream unused apportionment or surplus entitlements are subject to availability of water, and under the assumptions of the Shortage Allocation Models and Alternative Distribution Models, water is not available to fulfill them; therefore, they are not itemized in modeling results.

Each state is assumed to be using its entire apportionment each year, and each entitlement holder is assumed to be using its entire entitlement each year. Entitlements are used as the basis for distributing the available water supply to individual users. These assumptions facilitate measuring shortage impacts as a loss of water supply relative to entitlements (estimated or otherwise), or how shortage affects the ability of a water user to exercise an entitlement. The results can be characterized economically as an opportunity cost. Shortage to an entitlement may involve loss of a

wet water supply that is currently in use, loss of a supply currently being used for system conservation or intentionally created surplus (ICS), and/or loss of a future use. For long-range planning, losses to future uses have a cost through foregone opportunities. Accordingly, the Shortage Allocation Models and Alternative Distribution Models do not reflect contractual provisions that provide for unordered water to be made available to other contractors or subcontractors within a priority, or unordered water from one priority to be made available to another. These assumptions are consistent with a reasonably foreseeable long-term steady state for lower Colorado River water use, but in the near term through annual operations, unordered water may be made available to junior priority entitlement holders which would reduce the impacts of shortage.

Shortage to individual entitlements is estimated in terms of consumptive use for a common basis of comparison to state apportionments and volumes of total shortage. Unquantified and diversionary entitlements were estimated in terms of an equivalent consumptive use. Historical water accounting data were used to estimate average consumptive use/diversion ratios as part of development of the Colorado River Simulation System (CRSS) hydrologic modeling dataset for this EIS[4]. For purposes of modeling, these values are assumed to be generally representative of future return flow conditions for the specified users, and are used in the Shortage Allocation Models, Alternative Distribution Models, and CRSS. Those ratios were used to estimate the consumptive use equivalent of diversion entitlements, and the dataset was also used to estimate unquantified entitlements on the basis of maximum recent historical use; these estimates should not be taken as a limit on the future exercise of those entitlements. Shortages quantified in terms of consumptive use may equate to greater reductions on a diversion basis, depending on a user's CU/diversion ratio.

Mechanisms similar to current and/or future paybacks of overruns or underruns under the Inadvertent Overrun and Payback Policy, creation or use of ICS, or storage and interstate release agreements under 43 CFR Part 414 are not modeled.

Individual entitlements are assigned to one of three categories (domestic, irrigation, or tribal) by their primary use or intended benefit, for the purpose of generalizing shortage impacts. No attempt is made to pro-rate shared irrigation and domestic entitlements by actual use. The historical proportions of irrigation and domestic use of these entitlements may change in a Shortage Condition due to contract-specific terms and conditions and/or the discretion of the entitlement holder.

C.3.1 Relationship Between CRSS and the Shortage Allocation Models and Alternative Distribution Models

CRSS was used to model a variety of river and reservoir parameters in the Colorado River Basin, including reservoir elevations and river flows, primarily for use in decision support related to the physical sciences (see **Appendix A**, CRSS Model Documentation). The Shortage Allocation Models and Alternative Distribution Models provide a more detailed allocation of shortages to entitlement

[4] See the section below entitled Relationship Between CRSS and the Shortage Allocation Models and Alternative Distribution Models; where an entitlement is specified by the Consolidated Decree or other authority in terms of both diversion and CU, the Shortage Allocation Models and Alternative Distribution Models use those specified values, regardless of any other historic relationship between diversion and CU for that user.

holders in the Lower Division States, particularly small users and Central Arizona Project (CAP) contractors and subcontractors, for the purpose of decision support related to the social sciences. This section acknowledges known differences between the models that arise from their different modeling platforms, purposes, and assumptions.

A Shortage Allocation Model or Alternative Distribution Model:

- Does not attempt to represent the effect of any physical limitations on access to water due to low river stage
- Does not distinguish between any reasons for reduced deliveries to users (for example by policy, by mutual agreement, or due to operational constraints) but merely emulates an allocation of a shortfall in deliveries from Lake Mead
- Does not account for the creation, delivery, or conversion of ICS
- Has no temporal component and no annual delivery schedules, instead representing a full-use steady state
- Uses most of the same CU equivalent entitlements developed for CRSS, except for the following:
    - CRSS models the Hopi Tribe P4(i) entitlement as fully consumptive by 2040, while the Shortage Allocation Models and Alternative Distribution Models retain the initial assumption of a 3,037 af consumptive use equivalent entitlement based on a CU/diversion ratio of 0.71.
    - Unallocated P4(i) water is shown as 9,870 af in CRSS and 10,230 af in the Shortage Allocation Models and Alternative Distribution Models.
    - Town of Queen Creek's 2,033.01 af entitlement is identified by name in the Shortage Allocation Models and Alternative Distribution Models, while CRSS models it as part of the CAP diversion.
    - For Imperial and Havasu National Wildlife Refuges, the Shortage Allocation Models and Alternative Distribution Models use the decreed CU entitlements, while CRSS uses a constrained CU based on past water accounting data.
    - The California P2 entitlement for Bard Water District is shown as 7,294 af in the Shortage Allocation Models and Alternative Distribution Models versus 2,294 af in CRSS, where demand was adjusted by 5.0 kaf to represent the effect of the Bard seasonal fallowing program.
    - The Shortage Allocation Models and Alternative Distribution Models reflect the decreed CU entitlement for the Lake Mead National Recreation Area PPR of 300 af, while CRSS assumes full consumption of the decreed diversionary entitlement of 500 af.
- Distributes water by priority similarly to CRSS, except for the following:
    - In the Arizona P4(i) pool, the priority-based Shortage Allocation Models and Alternative Distribution Models distribute shortage in proportion to entitlements, which are quantified on a diversion basis. CRSS distributes shortage in proportion to the CU equivalent of the entitlements, resulting in slightly different ratios between the models.

- An Arizona entitlement in the name of Desert Lawn, for 248.40 afy, is modeled in the P4(i) pool in CRSS and the P3 pool in the Shortage Allocation Models and Alternative Distribution Models. Its priority and status were being re-evaluated at the time modeling assumptions were developed.
- Arizona P2 and P3 are modeled as co-equal in the Shortage Allocation Models and Alternative Distribution Models, while CRSS fills them sequentially.
- California P3a and P3b are modeled as co-equal in the Shortage Allocation Models and Alternative Distribution Models, while CRSS first reduces P3b before shortage is applied to P3a.
- Comments received on California's modeled P4 demands in CRSS for the Draft EIS identified an inconsistency in modeling assumptions for P3 use. Please see **Appendix M** - Lower Division State Depletion Schedules.
- CRSS models California's Quantification Settlement Agreements (QSA) related transfers as demand for the receiving entity (for example as use by The Metropolitan Water District of Southern California [MWD]) while maintaining the priority of the water in priority-based model runs. As described for the Priority Shortage Allocation Model, QSA transfers and exchanges were not modeled independent of the underlying entitlements in the Shortage Allocation Models or Alternative Distribution Models.
- The Shortage Allocation Models and Alternative Distribution Models treat Nevada's P8 "Balance and Surplus" as a separate priority category that is reduced to zero before Laughlin and the quantified Robert B. Griffith Project P8 allocations are shorted, and reduces P8 in full before shortage begins to P7. CRSS sets all Nevada P8 use as co-equal, and models P3, P4, P5, and P6 with P8.
- The Shortage Allocation Models' and Alternative Distribution Models' PPR fill order shorts each PPR entitlement individually and sequentially, according to an assumed fill order, while CRSS models similarly-situated PPR entitlements together.
- Minor differences in shortage attributed to Mexico result from different applications of rounding.

Table C-3 and **Table C-4** below present a comparison of results between the Priority Shortage Allocation Model and CRSS, and the Pro Rata Alternative Distribution Model and CRSS, at the 1.5 mafy volume of shortage. The CRSS results are taken from the 2040 timestep where full-use assumptions are most comparable to the Shortage Allocation Models and Alternative Distribution Models.

Table C-3
Comparison of Shortage Volume Results Between CRSS in 2040 and the Priority Shortage Allocation Model at the 1.5 mafy Volume of Shortage

C.4 Priority Shortage Allocation Model Assumptions

The Priority Shortage Allocation Model, similar to the Shortage Allocation Model developed for the 2007 FEIS, represents an interpretation of the lower Colorado River priority systems among and within the Lower Division States. As discussed in this section, the Priority Shortage Allocation Model, given a volume of total shortage to the Lower Basin, distributes available water first among the states, and subsequently within each state among the entitlement holders based on priority.

For each level of modeled shortage, the Priority Shortage Allocation Model calculates a percentage reduction to the Lower Division States and applies the same percentage reduction to Mexico's 1,500,000 acre-feet per year allotment.

The Excel workbook contains formulas extending into deep shortage levels as a modeling exercise relating to potential capacity constraints on Lake Mead releases, and as a basis for comparison with other distributions of shortage. This deeper shortage level modeling does not represent an effect of the Federal action(s) described in this EIS and is included for informational purposes.

C.4.1 Present Perfected Rights Assumptions for the Priority Shortage Allocation Model

Present Perfected Rights (PPRs), defined to mean perfected rights existing as of June 25, 1929, the effective date of the Boulder Canyon Project Act (see Article I.(H) of the Consolidated Decree in *Arizona v. California*, 547 U.S. 150 (2006)), are an integral part of the priority system in the lower Colorado River Basin.

Article III(a) of the Colorado River Compact of 1922 provides, quoted in pertinent part to PPRs: "There is hereby apportioned from the Colorado River System in perpetuity to… the Lower Basin… 7,500,000 acre feet of water per annum, which shall include all water necessary for the supply of any rights which may now exist." Article VIII further provides that "Present perfected rights to the beneficial use of waters of the Colorado River System are unimpaired by this compact." Section 6 of the Boulder Canyon Project Act also provides that: "the dam and reservoir . . . shall be used: . . . second, for irrigation and domestic uses and satisfaction of present perfected rights in pursuance of Article VIII of said Colorado River compact."

After enumerating and quantifying the PPRs through the *Arizona v. California* litigation (see, e.g., 439 U.S. 419 (1979)), the Supreme Court provides in the Consolidated Decree in *Arizona v. California*, Article II, "The United States, its officers, attorneys, agents and employees be and they are hereby severally enjoined:…

> (B) From releasing water controlled by the United States for irrigation and domestic use in the States of Arizona, California, and Nevada, except as follows:…
>
> (3) If insufficient mainstream water is available for release, as determined by the Secretary of the Interior, to satisfy annual consumptive use of 7,500,000 acre-feet in the aforesaid three States, then the Secretary of the Interior, after providing for satisfaction of present perfected rights in the order of their priority dates without regard to state lines and after consultation with the parties to major delivery contracts and such representatives as the respective States may designate, may apportion the amount remaining available for consumptive use in such manner as is consistent with the Boulder Canyon Project Act as interpreted by the opinion of this Court herein, and with other applicable federal statutes…" (Emphasis added.)

Additionally, Article III of the Consolidated Decree provides that:

> "III. The States of Arizona, California, and Nevada, Palo Verde Irrigation District, Imperial Irrigation District, Coachella Valley Water District, the Metropolitan Water District of Southern California, City of Los Angeles, City of San Diego, and County of San Diego, and all other users of water from the mainstream in said States, their officers, attorneys, agents, and employees, be and they are hereby severally enjoined:…
>
> (B) From interfering with or purporting to authorize the interference with releases and deliveries, in conformity with Article II of this decree, of water controlled by the United States;"

Finally, Paragraph (5) of the Appendix to the Consolidated Decree provides:

> "In the event of a determination of insufficient mainstream water to satisfy present perfected rights pursuant to Article II(B)(3) of this decree, the Secretary of the Interior shall, before providing for the satisfaction of any of the other present perfected rights except for those listed herein as "MISCELLANEOUS PRESENT PERFECTED RIGHTS" (rights numbered 7–21 and 29–80 below) in the order of their priority dates without regard to state lines, first provide for the satisfaction in full of all rights of the Chemehuevi Indian Reservation, Cocopah Indian Reservation, Fort Yuma Indian Reservation, Colorado River Indian Reservation, and the Fort Mojave Indian Reservation as set forth in Article II(D)(1)–(5) of this decree...."

In the Priority Shortage Allocation Model, PPRs are satisfied according to the assumed fill order provided on the following page in **Table C-5** (bottom up), derived from Paragraph 5 of the Appendix to the Consolidated Decree. In order to model this fill order and other elements of the priority system, the Priority Shortage Allocation Model distinguishes PPRs from other priorities of water held by a single entitlement holder. PPRs are assumed to be fully filled before any post-PPR entitlements receive water. Individual PPRs are enumerated in summary tables alongside other entitlements.

The documents cited in this section also underlie the modeled relationship between PPRs and the state-level distribution of shortage (which is further discussed in the next section).

[†]Calculated consumptive use equivalent. Historical Decree Accounting data were used to estimate average CU/Diversion ratios as part of development of the CRSS hydrologic modeling dataset for this EIS. For purposes of modeling, these values are assumed to be generally representative of return flow conditions for the specified users, and match CRSS inputs. Those ratios were used to estimate the consumptive use equivalent of diversion entitlements. In CA, miscellaneous PPRs were assumed to have a CU/Div ratio of .64. For IID, consumptive use was assumed to equal diversion since the CU/diversion ratio based on average historical efficiency was 0.996. In AZ, with limited supporting data about miscellaneous PPRs, they were assumed to be fully consumptive. Where an entitlement was quantified on the basis of CU by the Consolidated Decree, those values are used. The Cumulative Consumptive Use Equivalent column is included as a reference for the estimated amount of water that would need to be available to PPRs to fulfill a given entitlement on this table.

C.4.2 Distribution Among States for the Priority Shortage Allocation Model

With regard to distribution of available water among the Lower Division States, the Priority Shortage Allocation Model assumes their apportionments[5] as coequal, with exceptions relating to PPRs and to the Colorado River Basin Project Act of 1968 (CRBPA).

First, with respect to PPRs, the 1963 Opinion in *Arizona v. California*, 373 U.S. 546, 592-93 in Article III. Apportionment and Contracts in Time of Shortage, provides, in part:

> "There remains the question of what shall be done in time of shortage. The Master, while declining to make any findings as to what future supply might be expected, nevertheless decided that the Project Act and the Secretary's contracts require the Secretary in case of shortage to divide the burden among the three States in this proportion: California 4.4/7.5; Arizona 2.8/7.5; Nevada .3/7.5. While pro rata sharing of water shortages seems equitable on its face, [] more considered judgment may demonstrate quite the contrary. Certainly we should not bind the Secretary to this formula. We have held that the Secretary is vested with considerable control over the apportionment of Colorado River waters. And neither the Project Act nor the water contracts require the use of any particular formula for apportioning shortages. While the Secretary must follow the standards set out in the Act, he nevertheless is free to choose among the recognized methods of apportionment or to devise reasonable methods of his own. This choice, as we see it, is primarily his, not the Master's or even ours. And the Secretary may or may not conclude that a pro rata division is the best solution. . . ." (Footnote omitted.)
>
> None of this is to say that in case of shortage, the Secretary cannot adopt a method of proration or that he may not lay stress upon priority of use, local laws and customs, or any other factors that might be helpful in reaching an informed judgment in harmony with the Act, the best interests of the Basin States, and the welfare of the Nation. It will be time enough for the courts to intervene when and if the Secretary, in making apportionments or contracts, deviates from the standards Congress has set for him to follow, including his obligation to respect "present perfected rights" as of the date the Act was passed. . . . Finally, as the Master pointed out, Congress still has broad powers over this navigable international stream. Congress can undoubtedly reduce or enlarge the Secretary's power if it wishes. Unless and until it does, we leave in the hands of the Secretary, where Congress placed it, full power to control, manage, and operate the Government's Colorado River works and to make contracts for the sale and delivery of water on such terms as are not prohibited by the Project Act."

Consistent with the 1963 Opinion and Article II(B)(3) of the Consolidated Decree, the state distribution for the Priority Shortage Allocation Model provides first for the satisfaction of PPRs in full, before apportioning the amount remaining available for consumptive use among the Lower

[5] 2,800,000 afy to Arizona, 4,400,000 afy to California, and 300,000 afy to Nevada on a consumptive use basis. See Section 4 of the Boulder Canyon Project Act and Article II(B) of the Consolidated Decree in Arizona v. California.

Division States. The ratios used for that apportionment are further described in the following **Section C.4.2.1**, Stage 1 and 2 Shortage Assumptions.

Second, with respect to the CRBPA, Section 301(b) provides, in part:

> "in any year in which, as determined by the Secretary, there is insufficient main stream Colorado River water available for release to satisfy annual consumptive use of seven million five hundred thousand acre-feet in Arizona, California, and Nevada, diversions from the main stream for the Central Arizona Project shall be so limited as to assure the availability of water in quantities sufficient to provide for the aggregate annual consumptive use by holders of present perfected rights, by other users in the State of California served under existing contracts with the United States by diversion works heretofore constructed, and by other existing Federal reservations in that State, of four million four hundred thousand acre-feet of mainstream water, and by users of the same character in Arizona and Nevada. Water users in the State of Nevada shall not be required to bear shortages in any proportion greater than would have been imposed in the absence of this subsection 301(b)."

Additionally, the language of the Arizona priority system as contained in the CAP "Master Repayment Contract"[6] and other Arizona fourth priority Colorado River water delivery contracts provides that CAP and other post-1968 fourth priority contracts in Arizona are coequal in priority. For the purpose of the Priority Shortage Allocation Model, these provisions are assumed to reduce CAP and other Arizona fourth priority Colorado River water uses completely before water available to California is reduced below 4,400,000 acre-feet per year (afy). Mathematically, modeled shortage to Nevada is unaffected by assumptions relating to Section 301(b) of the CRBPA.

The formulation of ratios associated with these assumptions is further described in the subsection immediately below.

C.4.2.1 Stage 1 and 2 Shortage Assumptions

As in the Shortage Allocation Models for the 2007 FEIS and the 2024 FSEIS, the initial shortages to the Lower Division States in this Priority Shortage Allocation Model are characterized by two stages, Stage 1 and Stage 2. In Stage 1, shortages are imposed only upon Arizona and Nevada, continuing until the deliveries to the post-1968 water entitlement holders in Arizona (including the CAP) are reduced to zero. The maximum amount of Stage 1 shortage during the period of analysis is dependent on estimated water availability for the post-1968 water entitlement holders in Arizona.[7]

[6] Contract Between the U.S. and the Central Arizona Water Conservation District for Delivery of Water and Repayment of Costs of the Central Arizona Project, Contract No. 14-06-W-245, Amendment No. 1, dated December 1, 1988, as further amended and supplemented.

[7] The breakpoint between Stage 1 and Stage 2, when California begins to share in shortage, is a precise point at which no Arizona fourth priority Colorado River water is available. In the short run, this breakpoint is non-stationary and varies annually based on use by Arizona priorities one through three. For the Priority Shortage Allocation Model, a shortage volume of 1,404,130 af to the State of Arizona is used as the volume that reduces Arizona fourth priority Colorado River water availability to zero, based on assumed full use of Arizona priority one through three entitlements. The total volume of Stage 1 shortage is dependent on this assumption, as are the state ratios for distribution of Stage 2 shortage.

Stage 1 shortage in this Priority Shortage Allocation Model is consistent with the guiding documents cited in the previous subsections, but the ratios differ from those used in the 2007 FEIS and the 2024 FSEIS because those Shortage Allocation Models deliberately aligned with policy alternatives that did not consider shortages large enough to impact PPRs. At deeper shortages to the Lower Basin, such as 5.0 maf, the distribution of water among the Lower Division States using an unmodified extension of the 2007 methodology (distributing shortage in proportion to state apportionments) could create inconsistencies with obligations cited in **Section C.3.1** above because it may not provide sufficient water to fill all PPRs in every state, resulting in a mix of shortages to PPR entitlements and water available to non-PPR entitlements.[8]

The approach employed in the Priority Shortage Allocation Model for distributing shortage among the Lower Division States ensures that PPRs can be satisfied (or reduced) in the prescribed order as a Basin-wide senior priority group. Instead of setting the entire volume of each state's apportionment as coequal to the others, only state apportionments in excess of PPRs are treated as coequal (but maintaining the assumption that Arizona bears California's share of shortage until the Arizona fourth priority is exhausted). In developing the Stage 1 and Stage 2 percentages for the sharing of shortage among the Lower Division States, the consumptive use (or equivalent) of PPR entitlements was removed from each state's apportionment volumes, as detailed below. The Stage 2 distribution of water among the Lower Division States ends at the volume of total shortage where reductions to PPRs are necessary and all non-PPR entitlements have been fully reduced in each state; at that point, water available to each state equals the consumptive use (or equivalent) of PPR entitlements within the state. The distribution of water among PPRs is characterized as a Stage 3, where water available to each state is an aggregation of the PPR volumes within the state that could be filled at a given level of shortage.

The Stage 1 shortage sharing percentages for the Priority Shortage Allocation Model are computed as follows[9]:

- Nevada bears a reduction of about 7 percent of the total Lower Division States shortage volume, computed as a ratio of Nevada's apportionment less PPR consumptive use (or equivalent) entitlements within Nevada over the sum of the apportionments of the Lower Division States less all PPR consumptive use (or equivalent) entitlements
    - (0.3 maf – NV PPRs) / (7.5 maf -total PPRs) = 7.12 percent, or
        - (0.3 maf – 8,698 af) / (7.5 maf – 3,407,835 af) = 7.12 percent
- Arizona bears the remainder of the total Lower Division States shortage volume (approximately 93 percent), computed as a ratio of Arizona's and California's apportionments less PPR consumptive use (or equivalent) in both states over the sum of the

[8] See pages 306 through 312 of Special Master Simon Rifkind's 1960 Report to the Supreme Court in *Arizona v. California*, 364 U.S. 940 (1961), where the Special Master reaches the same conclusion and describes another potential methodology for responding to it.
[9] Note that these ratios distribute shortage volumes, and the available water is calculated as a remainder.

apportionments of the Lower Division States less all PPR consumptive use (or equivalent) entitlements

- (2.8 maf – AZ PPRs + 4.4 maf – CA PPRs) / (7.5 maf – total PPRs) = 92.88 percent, or
    - (2.8 maf – 597,811 af + 4.4 maf – 2,801,326 af) / (7.5 maf – 3,407,835 af) = 92.88 percent

As in the original Shortage Allocation Model, after deliveries to the fourth priority entitlements within Arizona are expected to be reduced to zero, any additional shortage is shared among Arizona, California, and Nevada. This additional shortage is Stage 2 and is in addition to the Stage 1 shortage volume; the Stage 2 shortage is distributed according to the Stage 2 ratios.

The Stage 2 shortage sharing percentages are computed as follows, with the PPR volumes the same as in the Stage 1 ratios.

- Nevada bears about 7 percent of the Stage 2 shortage in addition to its Stage 1 shortage, computed as a ratio of Nevada's apportionment less PPRs less the amount of shortage applied to Nevada under Stage 1, over the sum of the apportionments of the Lower Division States less PPRs less the total amount shorted to users under Stage 1
    - (0.3 maf – NV PPRs – Nevada Stage 1 shortage) / (7.5 maf – total PPRs – total Stage 1 shortage) = 7.12 percent, or
        - (300,000 - 8,698 - 107,540) / (7,500,000 - 3,407,835 - 1,511,744) = 7.12 percent
- Arizona bears about 31 percent of the Stage 2 shortage in addition to its Stage 1 shortage, computed as a ratio of Arizona's apportionment less PPRs less the amount of shortage applied to Arizona under Stage 1, over the sum of the apportionments of the Lower Division States less PPRs less the total amount shorted to users under Stage 1
    - (2.8 maf – AZ PPRs – Arizona Stage 1 shortage) / (7.5 maf – total PPRs – total Stage 1 shortage) = 30.93 percent, or
        - (2,800,000 - 597,811 - 1,404,130) / (7,500,000 - 3,407,835 - 1,511,744) = 30.93 percent
- California bears about 62 percent of the Stage 2 shortage, computed as a ratio of California's apportionment less PPRs, over the sum of the apportionments of the Lower Division States less PPRs less the total amount shorted to users under Stage 1
    - (4.4 maf – CA PPRs) / (7.5 maf – total PPRs – total Stage 1 shortage) = 61.95 percent, or
        - (4,400,000 - 2,801,326) / (7,500,000 - 3,407,835 - 1,511,744) = 61.95 percent

This method represents one possible way to distribute deep shortages among the Lower Division States in a way that does not reduce PPR water deliveries in one state while fulfilling non-PPR water deliveries in another state. Below Stage 2, water available to each state is calculated as the sum of the PPR volumes within the state that could be filled at a given level of shortage.

Table C-6 below summarizes the distribution of shortage and available water to the Lower Division States under the Priority Shortage Allocation Model. Total shortage volumes include an assumed component for Mexico, as described in the sections that follow, and will not sum across rows.

Table C-6
Summary of Shortage Volumes and Available Water by Lower Division State Under the Priority Shortage Allocation Model (af)

Total Lower Basin Shortage Volumes	Arizona Shortage Volume	Arizona Available Water	California Shortage Volume	California Available Water	Nevada Shortage Volume	Nevada Available Water
0	0	2,800,000	0	4,400,000	0	300,000
(10,000)	(7,740)	2,792,260	0	4,400,000	(593)	299,407

C.4.3 Distribution Within States for the Priority Shortage Allocation Model

C.4.3.1 Introduction

In accordance with Article II(B)(3) of the Consolidated Decree and Section 301(b) of the CRBPA, the Secretary has the authority to declare and allocate shortages to the Lower Division States. Some explicit guidance is given by the Supreme Court and Congress with regard to how shortages would be allocated according to priority, and additional detail is based on intra-state priority systems including as established by law and contract, and federal water delivery contracts executed pursuant to Section 5 of the Boulder Canyon Project Act.

To estimate the impacts of given levels of shortage, assumptions were made with regard to how shortages might be shared. These assumptions are made to facilitate analysis of potential impacts and are not intended to represent current or future policy with respect to shortage allocation. The Shortage Allocation Model is not designed to replicate some of the annual processes that must be undertaken in determining the quantity of water that can be approved for diversion by specific users.

C.4.3.2 General State Assumptions

Entitlement holders with multiple priorities are assumed to divert their highest-priority water first, until it is fully utilized, regardless of whether specific geographic restrictions may exist for the actual use of various priorities.

With the exception of PPRs, entitlement holders within a priority or sub-priority share in a pro rata distribution of available water on the basis of entitlement, unless another distribution is prescribed by contract or other determination. Within priorities other than PPRs, priority dates are not considered except as they pertain to grouping entitlements by priority.

PPRs (on a consumptive use or equivalent basis) are not included in the distribution of shortage within each state; they are subtracted from the water calculated to be available to each state, which water is then distributed in satisfaction of non-PPR entitlements, and the PPRs are accounted for in a separate PPR worksheet. A fill order is assumed for PPRs (see **Section C.4.1**).

C.4.3.3 Nevada Assumptions

Nevada has eight water delivery priorities as established in the Robert B. Griffith Water Project Contract No. 7-07-30-W0004, as amended, for delivery of Colorado River water between the U.S. and the State of Nevada; the contract also provides for the Southern Nevada Water Authority (SNWA) to divert the balance of any remaining un-allocated, unused, and surplus water in Nevada. **Table C-7** on the following page summarizes that priority system, which is also available at https://www.usbr.gov/lc/region/g4000/contracts/entitlements.html.

Deliveries to Nevada are no longer assumed to be constrained by Lake Mead surface elevation as assumed in the 2007 FEIS; however, the Shortage Allocation Model does not reflect the effect of potential system shortages or physical limitations on access to water.

The Shortage Allocation Model does not reflect any arrangements by the SNWA member agencies that may exist regarding the distribution of water amongst themselves during a Shortage Condition.

C.4.3.4 California Assumptions

Entitlements shown on the following page in **Table C-8** for California priorities one through three exclude the full volume of PPR entitlements held by those same parties, which are subject to a separate priority system (see **Section C.4.1**). Reclamation recognizes that the QSA and related agreements help California parties meet the water needs of PPRs by agreeing that certain parties to the Seven Party Agreement would make water available to satisfy the requirements of the PPR holders while keeping the priorities within the Seven Party Agreement[10] intact.

In addition, the Colorado River Water Delivery Agreement (CRWDA) quantifies, for a specific term of years, the deliveries under certain Colorado River water entitlements within shared priorities so that transfers may occur, facilitating California limiting its use to 4.4 mafy. In particular, for the term of the CRWDA, quantification of Priority 3(a) was effected through caps on water deliveries to Imperial Irrigation District (consumptive use of 3.1 million acre-feet per year) and CVWD (consumptive use of 330,000 acre-feet per year). Priorities 1, 2, 3(b), 6(b), 7, and PPRs are not affected, and the CRWDA provides that underlying water delivery contracts with the Secretary remain in full force and effect.

[10] The Seven Party Agreement provides that "The total beneficial consumptive use under priorities stated in Sections 1, 2 and 3 of this article shall not exceed 3,850,000 acre-feet of water per annum."

Table C-7
Framework for Priority-Based Distribution of Available Water Within Nevada

Priority	Entitlement Holder	Contract No.	Priority Date	Use	Entitlements		
					Diversion (afy)	CU or Estimated Equivalent (afy)[1]	Cumulative CU (afy)

2nd	Lake Mead National Recreation Area, Executive Order No. 5339	1964 Decree	4/25/1930	Domestic	Unquantified, estimated ~1,500	1,500	
	TOTAL	-	-	-	**1,500**	1,500	1,500
NEVADA TOTALS	-	-	-	-	381,057	291,302	-

Note: CU means Consumptive Use. All units are in acre-feet per year. The Cumulative CU column is included as a reference for the estimated amount of water that would need to be available to Nevada priorities two through eight to fulfill a given priority on this table.
Subcontracts are displayed below the Entitlement Holder and indented five spaces.
In a shortage, PPRs are delivered water in order of priority date regardless of state lines. PPRs are not included in this table, and they are accounted for in a separate PPR worksheet.
[1]Historical Decree Accounting data were used to estimate average CU/Diversion ratios as part of development of the CRSS hydrologic modeling dataset for this EIS. For purposes of modeling, these values are assumed to be generally representative of return flow conditions for the specified users, and match CRSS inputs; these values were used to estimate the consumptive use equivalent of diversion entitlements.
[2]Boulder City's entitlement is delivered through the Robert B. Griffith Project; historically there have been no return flows from Boulder City, but proposals are under review to begin generating return flows. It will be considered reasonably foreseeable for this to occur over the period of analysis, therefore Boulder City's CU/Div ratio is assumed to be the same as for the Southern Nevada Water Authority as a whole.

Table C-8
Framework for Priority-Based Distribution of Available Water Within California

Priority[1]	Entitlement Holder	Contract No.	Priority Date	Use	Diversion Entitlement (afy)	CU Entitlement (afy)	Estimated Use

Notes: CU means Consumptive Use; all units are in afy (acre feet per year). The Cumulative CU column is included as a reference for the estimated amount of water that would need to be available to California priorities one through four to fulfill a given priority on this table.

[1]Priorities are based on the California Seven Party Agreement, modified for the PPRs identified by the Consolidated Decree (which are accounted for in the PPRs table).

[2]Historical Decree Accounting data were used to estimate average CU/Diversion ratios as part of development of the CRSS hydrologic modeling dataset for this EIS, including estimating the consumptive use equivalent of diversion entitlements. Unless otherwise noted, modeled entitlements match CRSS.

[3]PVID's P3(b) entitlement for the Lower Palo Verde Mesa Lands is unquantified. For modeling purposes, an estimated CU equivalent of 5.0 kaf was assumed based on conversations with PVID.

[4]QSA transfers and exchanges are not modeled in the Shortage Allocation Model, a difference from CRSS. For modeling purposes, CVWD P3(a) was shorted before IID P3(a) based on the 1934 Agreement of Compromise; no interpretation of the agreement is intended by this modeling assumption.

[5]Non-Colorado River water is pumped from the Lower Colorado Water Supply Project wellfield and discharged into the All-American Canal for delivery to IID. IID forbears the consumptive use of an equivalent amount of Colorado River, up to a maximum of 10.0 kaf per year, to make such water available, via exchange, to the Lower Colorado Water Supply Project beneficiaries (includes MWD and the City of Needles and its subcontractors). For purposes of the shortage allocation model, the 10.0 kaf is included in IID's estimated CU equivalent; if the exchange could not be completed in a given year, it is assumed that IID would divert this amount from the Colorado River.

[6]The Yuma Project CU Estimated Equivalent is based on historical consumptive use of the Bard Unit, minus the CU from PPR 28, which is accounted for in the PPRs table. The Yuma Project Reservation Division Indian Unit is not accounted for here since it is covered by PPR 23, also listed in the PPRs table. This estimated CU equivalent differs from CRSS by 5.0 kaf due to CRSS modeling a seasonal fallowing program.

The CRWDA does not limit the Secretary's authority under Article II(B)(3) of the Consolidated Decree in *Arizona v. California* to allocate water in times of shortage. If, however, less than 3,850,000 acre-feet of Colorado River water is made available to entities in California under Priorities 1 through 3 during the year, the Secretary agrees in the CRWDA to deliver any water made available to Imperial Irrigation District and CVWD in the manner provided for in any shortage sharing provisions agreed upon by Imperial Irrigation District, CVWD, MWD, and San Diego County Water Authority prior to or concurrent with the execution of the CRWDA. During development of this EIS in 2024, unresolved issues pertaining to interpretation of the priority language contained within California water delivery agreements resulted in Reclamation retaining the level of detail from Appendix G of the 2007 FEIS, pending additional feedback from the parties. Reclamation also recognizes pre-existing issues raised in connection with the Imperial Irrigation District water delivery agreement with the Secretary, which provided for use of Imperial Irrigation District's entitlement "within the boundaries of the District."

In consequence, Reclamation made the following modeling assumptions, which are intended to facilitate only the comparative analysis of alternatives for this EIS.

- The quantified entitlements in Exhibit B of the CRWDA for Imperial Irrigation District and CVWD were modeled in the Priority Shortage Allocation Model, as this is a pre-requisite to quantifying estimated shortage to any of the parties within California priorities one through three. Without this step, further monetization of estimated socioeconomic impacts on agriculture could not occur, but the model does not limit priorities one through three to the volume stated in the Seven Party Agreement due to the above-described issues regarding transfers.
- Within priority 3a, CVWD's, entitlement is modeled as subordinate to Imperial Irrigation District's entitlement in accordance with the February 14, 1934 Agreement of Compromise; however, no opinion is expressed or implied on the part of the U.S. or the non-Federal parties as to how administration of that agreement during a Shortage Condition may affect the parties' rights pursuant to various arrangements.
- QSA transfers and exchanges were not modeled in the Priority Shortage Allocation Model, as the relevant agreements do not provide sufficient detail to model a system of priority among the transfers. This is also consistent with assumptions for the Priority Shortage Allocation Model as a whole, which models shortage at the (permanent) entitlement level.

Although MWD has a fourth priority Seven Party Agreement entitlement of 550 kaf, MWD's consumptive use equivalent entitlement is calculated (for modeling purposes) to equal the balance of California's apportionment after full use of higher priority entitlements. During a shortage, MWD may acquire water supplies from other sources, and those arrangements are not modeled in the Priority Shortage Allocation Model.

Entitlements associated with each California entitlement holder are available at: https://www.usbr.gov/lc/region/g4000/contracts/entitlements.html.

The San Luis Rey Indian Water Rights Settlement Act, 102 Stat. 4000 (1988), as amended and supplemented by Section 211 of the Act of October 27, 2000, 114 Stat. 1441A-70, directed the

Secretary to permanently furnish annually up to 16,000 acre-feet per year of Colorado River water from the lining of the All-American and Coachella Canals to be made available for purposes of the San Luis Rey Indian water rights settlement. That water is not modeled in the Priority Shortage Allocation Model as being subject to shortage in accordance with the California priority system.

C.4.3.5 Arizona Assumptions

Entitlements associated with each Arizona entitlement holder are available at: https://www.usbr.gov/lc/region/g4000/contracts/entitlements.html.

Water available to entitlement holders in Arizona is distributed through each priority according to the following assumptions. These assumptions do not necessarily reflect operational procedure, but they are necessary to produce a general approximation of the effect of shortages on specific priorities and entitlements for this EIS.

C.4.3.5.1 Arizona Priority Two and Three Assumptions

Arizona priority two is for Secretarial Reservations and Perfected Rights established or effective prior to September 30, 1968. Arizona priority three is for entitlements pursuant to contracts between the U.S. and water users in the State of Arizona executed on or before September 30, 1968. The second and third priorities are coequal.

The available supply to Arizona priorities two and three is calculated as the available supply to Arizona minus the sum (597,811 af) of Arizona's first priority (PPR) entitlements on a consumptive use (or estimated equivalent) basis. That supply is divided between priorities two and three in proportion to the sum of the consumptive use (or equivalent) entitlements within each priority: about 10 percent to priority two and about 90 percent to priority three. The following assumptions for distribution within those priorities consider contract-specific priority language.

Water available to priority two is distributed among its five entitlements in proportion to their consumptive use (or equivalent) entitlement relative to the total for priority two.

Water available to priority three is distributed among its 28 entitlements[11] in six groups according to project and/or division or pertinent contract terms. The alphanumeric sub-priority naming conventions for the six groups (shown in **Table C-9** on the following page) are not operational or contractual designations, and they are only used as an organizational tool specific to this analysis. Five of the six groups are assumed to be coequal within priority three, and they are distributed water in proportion to the sum of the consumptive use (or equivalent) entitlements within each group, relative to the total for all five groups. They are discussed in detail in the sections that follow.

[11] As of February 7, 2025.

Table C-9
Framework for Priority-Based Distribution of Available Water Within Arizona Priorities 2 and 3

Priority	Water Allocation % by Priority	Sub-Priority*	Project	Division	Water Allocation % by Project/Division	Entitlement Holder	Contract No.	Priority Date	Use	Entitlements: Diversion (AFY)	Entitlements: CU or *Estimated Equivalent* (AFY)

The Yuma Mesa Division of the Gila Project

Approximately 33 percent of the available priority three water, up to the limit of the sum of the consumptive use (or equivalent) entitlements within the Division, is distributed among the Division's 11 entitlements. That water is first made available to Yuma Mesa Irrigation and Drainage District, Yuma Irrigation District, and North Gila Valley Irrigation and Drainage District coequally in proportion to their consumptive use entitlements.[12]

Any water remaining for the Division after satisfaction of the district contracts is made available to Union Pacific Railroad, Kaman, Department of the Navy (Marine Corps Air Station), City of Yuma (Cemetery), Yuma Mesa Fruit Growers Association, Desert Lawn Memorial Park Association, Harold Sturges, and Irma Sturges, coequally in proportion to their consumptive use equivalent entitlements.[13]

The Wellton-Mohawk Division of the Gila Project

Approximately 43 percent of the available priority three water, up to the limit of Wellton-Mohawk Irrigation and Drainage District's consumptive use entitlement, is made available to the District.[11]

The Yuma Project

Approximately 11 percent of the available priority three water is first made available to the Yuma County Water Users Association up to the limit of its consumptive use equivalent entitlement. Any water remaining for the Yuma Project after satisfaction of the Association contract is made available to Yuma Union High School District.[12]

The Yuma Auxiliary Project

Approximately 2.0 percent of the available priority three water, up to the limit of the sum of the consumptive use equivalent entitlements within the Yuma Auxiliary Project, is distributed among the Yuma Auxiliary Project's three entitlements. That water is first made available to Unit B Irrigation and Drainage District up to the limit of its consumptive use equivalent entitlement. Any water remaining for the Yuma Auxiliary Project after satisfaction of the District contract is made available to the University of Arizona, the successor to Camille Allec, Jr., and Desert Lawn Memorial Park Association (for Contract No. 14-06-300-2587).[12]

Various Entitlements

A group of 10 entitlements established under various authorities shares approximately 12 percent of the available priority three water, up to the limit of the sum of the consumptive use (or equivalent) entitlements within the group. Water is distributed to the Ak-Chin Indian Community; the Arizona cities of Chandler, Gilbert, Glendale, Mesa, Phoenix, Scottsdale, and Tempe; the Department of the Army (Yuma Proving Ground); and Gila Monster Farms coequally in proportion to their consumptive use (or equivalent) entitlements. The distribution of water is stated in terms of

[12] Domestic use within each district's entitlement is assumed to be subordinated to irrigation use in the district but is not itemized separately.

[13] Water use is subject to availability and is assumed not to be detrimental to water service for the project or prior appropriators.

quantities available at the mainstream point of diversion, and no assumptions are made about the further distribution of priority three water delivered through the CAP.

The City of Yuma

The City of Yuma receives all remaining priority three water, up to the limit of its consumptive use entitlement (minus a portion assumed to be satisfied by PPR No. 21), reflecting that water delivery under its Contract No. 14-06-W-106 is subject to the prior fulfillment of contracts for the diversion of Colorado River water at Imperial Dam and for the delivery of such water through the Gila Gravity Main Canal or the All-American Canal for the irrigation of lands in the State of Arizona.

C.4.3.5.2 Arizona Priority Four Assumptions

For calendar years 2022 through 2026, Reclamation implemented[14] the State of Arizona's August 6, 2009, Arizona Shortage Sharing Recommendation and the "pool" approach described by letter dated January 25, 2021, to inform approval of fourth priority water orders, consistent with Section 301(b) of the CRBPA and the contracts providing that the fourth priority Colorado River water entitlements of the P4(i) or 'mainstream' users and the CAP (P4(ii)) are coequal.

The Priority Shortage Allocation Model uses a simplified version of the fourth priority shortage sharing procedure that is consistent with other assumptions for shortage modeling under long-term steady state conditions. It subtracts the sum of Arizona priority 1 through 3 entitlements (on a consumptive use basis) and the Arizona shortage volume from Arizona's Colorado River water apportionment to derive the fourth priority supply on a consumptive use basis. The P4(i) available supply is calculated as 10 percent[15] of the fourth priority supply on a consumptive use basis, not to exceed the total of the consumptive use equivalents of entitlements in the P4(i) pool (108,958 afy as modeled). The remainder of the fourth priority supply is available for diversion as fourth priority water by the CAP to fulfill CAP contracts and subcontracts.

C.4.3.5.3 P4(i) (Mainstream) Framework and Assumptions

The P4(i) pool is quantified in terms of 164,652 afy of diversions from the Colorado River, which for modeling purposes is converted to a consumptive use total of 108,958 afy with historical Decree Accounting data used to estimate CU/Diversion ratios as part of development of the CRSS hydrologic modeling dataset for this EIS. Shortage to the P4(i) is calculated as the difference between the P4(i) available supply and the total of the consumptive use equivalents of entitlements in the P4(i) pool (108,958 afy as modeled). Shortage to each entitlement within the P4(i) pool is

[14] For example: Reclamation's September 14, 2022, letter notifying interested parties of a Tier 2 Shortage Condition and required DCP contributions in calendar year 2023, and Reclamation's September 28, 2022, letter to the Central Arizona Water Conservation District announcing the calendar year 2023 Available CAP Supply.

[15] Based on the relative volumes of the P4(i) and P4(ii) contracting pools.

borne in proportion to its entitlement[16] relative to the entire pool as quantified by contracts. For purposes of the Priority Shortage Allocation Model, the P4(i) pool includes two outstanding Arizona Department of Water Resources recommendations that have not yet been placed under contract, the 3.5 kafy quantified and reserved for use in a future Navajo-Hopi Indian water rights settlement in accordance with subsection 11.3 of the 2006 Arizona Water Settlement Agreement, and the quantified remainder of the pool which is available for contracting by the Secretary to satisfy current or future tribal and other water needs. (See **Table C-10** below)

Contracts and subcontracts are itemized separately, meaning an entity's total modeled supply may be the sum of multiple distributions.

Table C-10
Framework for Priority-Based Distribution of Available Water Within Arizona P4(i) (Mainstream)

P4(i) Entitlement Holders	Contract Number(s)	Contract Date	Type of Use	Diversion Entitlement in afy	Divided By	Sum of Entitlements in afy (Div. or Equiv.)	Equals	Proportionate Share of P4(i) Pool

Bullhead City (MCWA Subcontract)	Subcontract No. 95-102 to 5-07-30-W0320	1995	Domestic	7,000.00	/	164,652	=	4.251%

[16] Historically Arizona P4(i) entitlements have been quantified on a diversion basis. More recently, the Bureau of Land Management's and Town of Queen Creek's Arizona P4(i) entitlements have specified consumptive use volumes (consumptive use = diversions minus return flows). These entitlements are shown in **Table C-5** as their diversion equivalents (consumptive use + historical or current return flows = diversion equivalent) for modeling purposes because distribution during shortage within the Arizona P4(i) pool is assumed to be administered in proportion to all users' diversion volumes, not in proportion to consumptive use volumes, for uniformity and consistency. The diversion equivalency volumes listed in **Table C-9** are necessary to analyze the distribution of the Arizona P4(i) entitlements with a uniform metric, do not modify the entitlements, and are consistent with applicable contracts and agency decision documents.

P4(i) Entitlement Holders	Contract Number(s)	Contract Date	Type of Use	Diversion Entitlement in afy	Divided By	Sum of Entitlements in afy (Div. or Equiv.)	Equals	Proportionate Share of P4(i) Pool
Bureau of Land Management (diversion equivalent)	8-07-30-W0373	2000	Domestic	6,169.00	/	164,652	=	3.747%

Notes:
The Town of Queen Creek's "mainstream diversion equivalent" is calculated using GSC Farm, LLC's historical CU/Diversion ratio of 0.715; available water on a mainstream diversion equivalent basis would be converted back to CU for conveyance through the Central Arizona Project as provided in the related contracts, but this table does not make the calculation of water available for diversion. Bureau of Land Management's diversion equivalent is calculated with historical Decree Accounting data used to estimate average CU/Diversion ratios as part of development of the CRSS hydrologic modeling dataset for this EIS.
With the exception of Bureau of Land Management and Town of Queen Creek, water is contracted in this pool on a diversion basis, but CU shortage impacts are calculated for the purpose of analysis.
See Arizona Third Priority for Desert Lawn Memorial Park Association, Inc., Contract No. 14-06-300-2587.

For simplicity and transparency in avoiding repeated conversions between diversion and consumptive use, the Priority Shortage Allocation Model calculates each entitlement's shortage by multiplying its proportionate share of the pool on a diversionary basis by the P4(i) shortage in terms of consumptive use.

C.4.3.5.4 CAP Framework and Assumptions

In the Priority Shortage Allocation Model, Arizona priority three Colorado River water entitlements delivered through the CAP are assumed to be satisfied consistent with their Colorado River third priority, and Arizona P4(i) water transported through the CAP is assumed to be satisfied according to its priority.

The CAP Master Repayment Contract (Contract No. 14-06-W-245, Amendment No. 2, dated November 30, 2007) defines the Available CAP Supply as all fourth priority water available for delivery through the CAP, water available from CAP dams and reservoirs other than Modified

Roosevelt Dam, and return flows captured by the Secretary for CAP use. Available CAP Supply is used in contractual determinations related to a CAP Time of Shortage and the distribution of water among CAP contractors and subcontractors. For the purpose of the Priority Shortage Allocation Model, fourth priority water available to CAP for diversion from the mainstream, calculated as described above in **Section C.4.3.5.2**, is converted to Available CAP Supply through the addition of 7,143 afy of water estimated to be available from the CAP dam and reservoir (New Waddell Dam and Lake Pleasant) and the subtraction of 71.4 kafy representing estimated CAP system loss associated with the conveyance of P4(ii) water; CAP return flows are not currently captured.

Terms and conditions for priority in case of shortage to the Available CAP Supply relate only to CAP fourth priority water (P4(ii)) and the other two supplies listed in the previous paragraph. Certain third priority water transported through the CAP (described in **Section C.4.3.5.1** as being diverted on behalf of the Ak-Chin Indian Community and the Arizona cities of Chandler, Gilbert, Glendale, Mesa, Phoenix, Scottsdale, and Tempe),[17] and any other non-Project water diverted by the CAP from the Colorado River, has separate shortage protocols established by statute and contract. The Priority Shortage Allocation Model attempts to reflect the legislative and contractual terms and conditions applicable to a CAP Time of Shortage, which shortage would impact the distribution of water to CAP contractors and subcontractors. The CAP long-term contractors and subcontractors that receive Available CAP Supply are classified in one of three CAP priority pools: Indian Priority, Municipal and Industrial (M&I) Priority, and Non-Indian Agricultural (NIA) Priority. Modeling assumptions for these CAP priorities integrate the shortage-related provisions of a body of contracts and Secretarial determinations dating from the 1980s through the present, as codified by Congress including through Indian water rights settlement legislation. However, levels of shortage to date have not required the implementation of shortage provisions in all CAP contracts and subcontracts, and their modeling should be understood as theoretical.

Available CAP Supply is first made available to Indian Priority and M&I Priority long-term contracts and subcontracts; at or above an Available CAP Supply of 981,902 af, all Indian Priority allocations (343,079 af total) and M&I Priority allocations (638,823 af total) can be satisfied. Any Available CAP Supply in excess of 981,902 af becomes available to NIA Priority long-term contracts and subcontracts. After all long-term CAP contracts and subcontracts are fulfilled[18], the remaining available water could be ordered under one-year excess contracts; however, under the assumptions of the model regarding full use by Arizona Priorities 1 through 3, there is no remaining water available for excess contracts.

An Available CAP Supply less than 981,902 af is a contractually defined Time of Shortage for the CAP, affecting the Indian Priority and M&I Priority pools. Under that condition, the Available CAP Supply is distributed to the Indian Priority pool as set forth by Article 8.11(c) of the CAP Master

[17] See, e.g., Ak-Chin Water Rights Settlement Act of 1978 (Public Law 95-328), as amended; Salt River Pima-Maricopa Indian Community Water Rights Settlement Act of 1988 (Public Law 100-512), as may be amended.

[18] Under Article 3.(b) of the 1985 Contract Between the U.S. and the Ak-Chin Indian Community to Provide Permanent Water and Settle Interim Water Rights, in any year in which sufficient surface water is available, the Secretary shall deliver certain additional water to the Ak-Chin Indian Community. Such water is assumed to be available if there is unused CAP water after CAP orders under long-term contracts and subcontracts are fulfilled; however, that does not occur under the assumptions of the Shortage Allocation Models or Alternative Distribution Models.

Repayment Contract, with the M&I Priority pool receiving the remainder.[19] Then, those volumes must be used to satisfy the contractors and subcontractors in the priority pool. The Indian Priority supply must be used to satisfy all of the Indian Priority contracts, and is assumed to be controlled by and calculated in accordance with the CAP Master Repayment Contract. Likewise for the M&I Priority supply.

A range of Available CAP Supply from zero to 1,255,317 af, in rounded 10 kaf increments except at pivotal quantities, is presented in **Table C-11** below, showing the distribution of Indian Priority supply, M&I Priority supply, and NIA Priority supply for discrete levels of Available CAP Supply contained within the Priority Shortage Allocation Model.

Table C-11
Discrete Levels and Distribution of Available CAP Supply Modeled in the Shortage Allocation Model

Available CAP Supply (af)	Indian Priority Share	Indian Priority Supply (af)	M&I Priority Supply (af)	NIA Priority Supply (af)

Through term-limited or temporary arrangements, to the extent that such arrangements may be allowed under specific long-term CAP contracts or other legal authority, CAP contractors and subcontractors may make their water available for end use by others. The Shortage Allocation Model does not replicate those arrangements, and it only provides approximate estimates at the contract or subcontract allocation level that interested parties could then consider in planning for administering their respective arrangements during Shortage Conditions. The CAP contractor, subcontractor, and/or parties to those arrangements would have specific decisions to make during Shortage Conditions to administer those arrangements that Reclamation cannot predict with sufficient certainty to analyze in this EIS.

Unallocated water or water not yet placed under contract (including the Secretary's retention of CAP NIA Priority water consistent with the Arizona Water Settlements Act of 2004, section 104(a)) is not reflected in the distribution of available water and is not shown as bearing shortage. These modeling assumptions reflect only that it cannot be speculated when or whether such water or volumes may be allocated or placed under contract but are not intended to preclude allocations or the entry of contracts consistent with applicable law and authority.

CAP Indian Priority Assumptions

The overall deliverable quantity of Indian Priority supply is calculated as authorized in the 2004 Arizona Water Settlements Act (AWSA) (Public Law 108-451) section 104(d), as reflected in the CAP Master Repayment Contract and described in the previous section. The available Indian Priority supply is then distributed as described in applicable law, contracts, and subcontracts and as noted below.

Shortage to the Ak-Chin Indian Community's Indian Priority irrigation allocation is shown at the allocation level, and it does not reflect the conditional entitlement to a portion of that allocation that is held by the San Carlos Apache Tribe. In addition, the shortages attributed to Indian Priority allocations, pursuant to the internal priority system of the Indian Priority pool, do not account for the existence of external arrangements and commitments that would affect the ultimate impacts of shortage. For example, the ultimate impact of shortage may fall in whole or in part on a lessor who has leased a portion of a contractor's Indian Priority water, but the terms and duration of such leasing arrangements are varied, and the arrangement does not change the underlying allocation-

holder. Shortages attributed to Indian Priority allocations form the basis for operational determinations on a case-by-case basis as necessary to administer shortage consistent with applicable contracts and subcontracts.

Further, the Shortage Allocation Model does not analyze any applicable Secretarial obligations to deliver certain contractors or subcontractors other sources of water in any given year, which might have the effect of offsetting or negating the numerical impacts shown to specific Indian Priority pool allocations and could appear to understate the regional effect of a Colorado River shortage unless the other source(s) of water can be definitively identified and the shortage volume attributed to them. Reclamation declines to speculate about the acquisition of alternative sources of water in this Appendix. This EIS presents the worst-case impacts of a regional loss of supply relative to the quantified volumes of Colorado River water the Secretary has allocated and contracted for and actively administers, rather than attempting to analyze and monetize the loss relative to all sources of water supply any given water user may have available.

For the purpose of calculating water available to individual Indian Priority allocations, the Indian Priority supply is distributed under a set of assumptions consistent with the contracts and relevant Secretarial Decisions, including as published in the Federal Register on March 24, 1983 (1983 ROD), as codified by AWSA section 104(d), yielding the approach described in Exhibit 5.3.4.1 to the Tohono O'odham Settlement Agreement[20], *Secretary's Approach for Determining the Amount of Water Available to the Nation During a Time of Shortage Under 1980 Contract*.

In these calculations, CAP Indian Priority contractors are grouped by "Post-AWSA Contracts" and "Pre-AWSA Contracts" (see **Table C-12** on the following pages), each group with its own calculation of the Indian Priority supply for the purpose of calculating water supply available to individual contractors, reflecting that some shortage-related provisions incorporated into Post-AWSA Contracts do not yet apply to all Indian Priority contracts. The AWSA and related actions provided for a framework that enables consistent administration of both groups of contracts, as described below.

Post-AWSA Contracts are modeled to recognize a shared first priority between all homeland and remaining Indian irrigation allocations in accordance with the 1983 ROD.[21] Pre-AWSA Contracts are modeled to recognize the increase in Gila River Indian Community's irrigation reductions from 10 percent to 25 percent as reflected in the 1983 ROD and later contracts/settlements, and the 1993 Fort McDowell Yavapai Nation settlement's authorized increase in the total Indian Priority allocations from 309,828 af to 343,079 af. All Indian Priority entitlements are assumed to have been fully used on Indian lands, as necessary, during the most recent calendar year which was not a Time of Shortage.

Three stages of implementation of CAP Time of Shortage result from these assumptions, with pivot points at 981,902 af, 853,079 af, and 801,574 af of Available CAP Supply. Formulas for the distribution of available Indian Priority supply to individual allocations over each of these stages are

[20] **Attachment C-1** to this **Appendix C**

[21] The terms "homeland" and "irrigation" are historic labels relating to the administration of shortage within the Indian Priority pool and do not represent type of use restrictions where Federal law provides otherwise.

contained within the Excel workbooks of the Priority Shortage Allocation Model. These formulas yield the distribution of available Indian Priority water shown in **Table C-12** below for a range of discrete Available CAP Supplies.

Table C-12
Distribution of CAP Indian Priority Supply

CAP M&I Priority Assumptions

The M&I Priority supply is calculated as the remainder of Available CAP Supply (up to 981,902 af) after the Indian Priority supply is calculated. When Available CAP Supply equals or exceeds 981,902 af, the Indian and M&I Priorities both receive a full supply.

The available M&I Priority supply is distributed to each allocation proportionally, relative to all allocations of M&I Priority water. [22] (The proportions are shown below in **Table C-13**).

Table C-13
Distribution of CAP M&I Priority Water in Proportion to Allocations

M&I Contractor or Subcontractor	Allocation (af)	Percentage of M&I Allocations
San Carlos Apache Tribe	18,145	2.84%
ASARCO	21,000	3.29%
Avondale	5,416	0.85%

Green Valley CWC	2,858	0.45%
Green Valley DWID	1,900	0.30%
Marana	2,336	0.37%

[22] As a result of a joint consultation undertaken by Reclamation and the Central Arizona Water Conservation District with M&I Priority water users in 2022, documented by Letter Agreement No. 22-XX-30-W0743LA between Reclamation and Central Arizona Water Conservation District, dated May 15, 2023, the operational method of distributing M&I Priority water is a pro rata distribution on the basis of water scheduled for delivery. The results are currently consistent for most water users, and are expected to become more consistent over the long term.

M&I Contractor or Subcontractor	Allocation (af)	Percentage of M&I Allocations
Maricopa Cty P&R	665	0.10%
Mesa	43,503	6.81%

TOTAL	**638,823**	**100.00%**

CAP NIA Priority Assumptions

Only when Available CAP Supply is calculated to be greater than 981,902 af, the NIA Priority supply is calculated as the difference between Available CAP Supply and the sum of the Indian and M&I Priority entitlements. NIA Priority supply is assumed not to be available when Available CAP Supply is less than 981,902 af.

The Shortage Allocation Model does not contain data for CAP water use in the most recent year that a full NIA Priority supply (inclusive of NIA-A and NIA-B) was available. However, in this modeling, available water is distributed first to NIA Priority contractors and subcontractors assumed to have used CAP NIA Priority Water in the last year in which the Available CAP Supply was sufficient to fill all orders for CAP NIA Priority Water (NIA-A) (**Table C-14**), before available water is distributed to the other NIA Priority contracts and subcontracts (NIA-B) (**Table C-15**).[23] Within each sub-priority, available water is modeled as being distributed to each allocation proportionally, relative to total allocations for the sub-priority.

[23] The CAP NIA Priority Water is distributed in accordance with the CAP NIA Priority Water subcontracts, in particular paragraph 4.7(b)-(c) of such subcontracts, and the settlement agreements with the Gila River Indian Community and the Tohono O'odham Nation. The Hualapai Tribe's CAP NIA Priority water will be distributed in accordance with its settlement agreement (pending enforceability) and the Hualapai Tribe Water Rights Settlement Act of 2022, in particular section 13. In continuing to model the existence of separate NIA-A and NIA-B priority pools, no opinion is expressed or implied by the U.S. about the likelihood of a future year in which Available CAP Supply will be sufficient to fill all orders for CAP NIA Priority Water.

Table C-14
Distribution of CAP NIA-A Priority Water in Proportion to Allocations

NIA A Priority Contractor or Subcontractor	Allocation (af)	Percentage of NIA-A Allocations
Gila River Indian Community	120,600	58.80%
Tohono O'odham - Schuk Toak & San Xavier	28,200	13.75%
Hualapai Tribe	4,000	1.95%
Phoenix (HIDD, NIA-2043)	36,144	17.62%

C.4.4 Priority Shortage Allocation Model Results

The tables in this section present the results of the Priority Shortage Allocation Model over a range of total shortages to the Lower Basin including Mexico.

Table C-16, the Regional Summary, summarizes the shortage attributed to each priority within the Lower Division States and reflects shortage attributed to Mexico.

Table C-17, the Tribal Summary, presents the shortage impacts on tribes.

Table C-18, the Irrigation Summary, presents the shortage impacts on irrigators.

Table C-19, the Domestic Summary, presents the shortage impacts on domestic users.

Table C-16

[1]Agricultural and Other CAP Excess contracts do not confer a Colorado River water entitlement and cannot be exercised under any of the scenarios modeled here.

[2]These estimated shortages to priorities within the CAP reflect the effect of CAP system loss, and do not total to CAP shortage at the point of diversion

Disclaimer: These modeling results for the Priority Shortage Allocation Model should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and they are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and it cannot replicate the precision required for that process.

Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.

Note: Orange highlights indicate the level at which available water for a priority is reduced to zero.

.

[1]Denotes full or substantial use in tribal agricultural operations, which may or may not be impacted according to the terms of related agreements.
[2]Likely to include domestic, irrigation, and Tribal elements (including an unquantified entitlement for the Cocopah Reservation's 1985 lands)

Disclaimer: These modeling results for the Priority Shortage Allocation Model should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and cannot replicate the precision required of that process.

Note: This analysis attributes shortage to the base allocation or entitlement according to its priority, representing an opportunity cost. The ultimate impacts, both financial and in terms of the lost productive value of water, are diverse according to their varied uses and compensation structures under a large body of exchanges, leases, and other Federal and non-Federal arrangements and commitments. The modeled distribution of shortage to the base allocation reflects how shortage affects the ability for allocations to be exercised, and water users will face decisions in administering agreements during a Shortage Condition; actual water orders received each year will affect shortage impacts.
Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.
Note: Orange highlights indicate the level at which available water for a priority is reduced to zero.

[1]Combined irrigation and domestic entitlement where domestic use is contractually subordinated to irrigation.
[2]Combined irrigation and domestic entitlement where priority of domestic and irrigation uses may be subject to an annual determination that varies based on the water supply conditions.
[3]This user also holds a PPR entitlement, which is not affected at these levels of shortages, and it was not included here.
Note: PPR entitlements are not affected at these levels of shortage.
Note: Orange highlights indicate the level at which available water for a user under this priority is reduced to zero.
Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.

Disclaimer: These modeling results from the Shortage Allocation Model should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this Final EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and they are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and it cannot replicate the precision required for that process.

Table C-19

[1]This user also holds a PPR entitlement.

Note: Orange highlights indicate the level at which available water for a priority is reduced. Lighter orange indicates smaller reductions, while the darkest orange indicates a priority is reduced to zero.

Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.

Disclaimer: These modeling results from the Shortage Allocation Model should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and it cannot replicate the precision required for that process.

C.5 Continuing Current Strategies Shortage Allocation Model Assumptions

The Continuing Current Strategies Shortage Allocation Model describes the continued implementation of existing agreements that control operations of Glen Canyon and Hoover Dams. These include the 2007 Interim Guidelines and the 2019 DCP. The Continuing Current Strategies Shortage Allocation Model simulates shortages and distributes available water first among the Lower Division States based on the 2007 ROD and 2019 DCP and then among the entitlement holders within each state based on priority or as otherwise provided by the 2019 DCP.

The discrete volumes of total shortage to the Lower Division States considered in the Shortage Allocation Model comprise the 2007 Interim Guidelines shortage reductions and 2019 DCP water savings contributions, based on Lake Mead elevations.

This model exists as a comparative baseline, reflecting recent operations that water users in the Lower Basin are familiar with. The Excel workbook contains formulas to extend Continuing Current Strategies to deeper shortage levels as a modeling exercise relating to potential capacity constraints on Lake Mead releases, and as a basis for comparison with other distributions of shortage. This deeper shortage level modeling does not represent an effect of the Federal action(s) described in this EIS, and this modeling is for informational purposes only.

For each level of modeled shortage that exceeds the shortages and contributions prescribed by the 2007 ROD and 2019 DCP, the Continuing Current Strategies Shortage Allocation Model calculates a percentage reduction to the Lower Division States and applies the same percentage reduction to Mexico's 1,500,000 acre-feet per year allotment.

C.5.1 Present Perfected Rights Assumptions for the Continuing Current Strategies Shortage Allocation Model

See **Section C.4.1** for a discussion on the PPR assumptions in the Priority Shortage Allocation Model. The Continuing Current Strategies Shortage Allocation Model has no unique assumptions with respect to PPRs.

C.5.2 Distribution Among States for the Continuing Current Strategies Shortage Allocation Model

The Continuing Current Strategies Shortage Allocation Model distributes shortages among states based on state reductions specified in the 2007 Interim Guidelines. This Shortage Allocation Model also simulates water savings contributions that were distributed among states as agreed to in the 2019 DCP. For the purpose of analyzing the impacts of alternatives considered in this EIS, DCP contributions are assumed to represent reductions in deliveries, although parties retain flexibility in how to meet those contribution commitments.

Table C-20 on the following page shows a distribution of shortage among the Lower Division States (which includes both 2007 Interim Guidelines shortages and 2019 DCP water savings contributions) and corresponding volumes of water available to each Lower Division State. Total shortage volumes include an assumed component for Mexico, as described in the sections that follow, and will not sum across rows.

Table C-20
Summary of Shortage Volumes and Available Water by Lower Division State Under the Continuing Current Strategies Shortage Allocation Model (af)

Total Lower Basin Shortage Volumes	Arizona Shortage Volume	Arizona Available Water	California Shortage Volume	California Available Water	Nevada Shortage Volume	Nevada Available Water

(7,500,000)	(2,383,742)	416,258	(3,574,655)	825,345	(291,602)	8,398
(9,000,000)	(2,800,000)	0	(4,400,000)	0	(300,000)	0

The maximum shortage volume applied from the 2007 Interim Guidelines and 2019 DCP volumes to the Lower Division States is 1.1 maf, or 1.375 maf including Mexico.

C.5.2.1 Stage 1, 2, and 3 Shortage Assumptions

As in the Priority Shortage Allocation Model, the initial shortages to the Lower Division States are characterized by stages. In the Continuing Current Strategies Shortage Allocation Model, Stage 1 represented shortage volumes from the 2007 Interim Guidelines and the 2019 DCP. In the modeled Stage 2, additional shortages beyond Stage 1 are imposed only upon Arizona and Nevada and continue until the deliveries to the post-1968 water entitlement holders in Arizona (including the CAP) are reduced to zero. After deliveries to the fourth priority entitlements within Arizona are expected to be reduced to zero, any additional shortages are applied to Arizona, California, and Nevada in Stage 3. As with the Priority Shortage Allocation Model, the Continuing Current Strategies Shortage Allocation Model distributes shortage among the Lower Division States in a way that ensures PPRs can be satisfied (or reduced) in the prescribed order as a Basin-wide senior priority group. Instead of setting the entire volume of each state's apportionment as coequal to the others, only state apportionments in excess of PPRs are treated as coequal (but maintaining the assumption that Arizona bears California's share of shortage until the Arizona fourth priority is exhausted). In developing the Stage 2 and Stage 3 percentages for the sharing of shortage among the Lower Division States, the consumptive use (or equivalent) of PPR entitlements are removed from the apportionment volumes in each ratio, as detailed below.

The Stage 1 shortage volumes for the Continuing Current Strategies Shortage Allocation Model are fixed volumes and are shown above in **Table C-20**.

The Stage 2 shortage sharing percentages for the Continuing Current Strategies Shortage Allocation Model are computed as follows[24]:

- Nevada bears a reduction of about 9 percent of the total Lower Division States shortage volume, computed as a ratio of Nevada's apportionment less PPR consumptive use (or equivalent) entitlements within Nevada less the amount of shortage applied to Nevada under Stage 1, over the sum of the apportionments of the Lower Division States less all PPR consumptive use (or equivalent) entitlements less the total amount shorted to users under Stage 1
    - (300.0 kaf – NV PPRs – 30.0 kaf) / 7.5 maf – total PPRs – 1.1 maf) = 8.73 percent, or
        - (300.0 kaf – 8,698 af – 30.0 kaf) / (7.5 maf – 3,408,035 af – 1.1 maf) = 8.73 percent
- Arizona bears the remainder of the total Lower Division States shortage volume (approximately 91 percent), computed as a ratio of Arizona's and California's apportionments less PPR consumptive use (or equivalent) in both states less the amount of shortage applied to both states under Stage 1, over the sum of the apportionments of the Lower Division States less all PPR consumptive use (or equivalent) entitlements less the total amount shorted to users under Stage 1
    - (2.8 maf – AZ PPRs – 720 kaf + 4.4 maf – CA PPRs – 350 kaf) / (7.5 maf – total PPRs – 1.1 maf) = 91.27 percent, or
        - (2.8 maf – 597,811 af – 720 kaf + 4.4 maf – 2,801,326 af – 350 kaf) / (7.5 maf – 3,408,035 af – 1.1 maf) = 91.27 percent

As in the Priority Shortage Allocation Model, after deliveries to the fourth priority entitlements within Arizona are expected to be reduced to zero, any additional shortages are applied to Arizona, California, and Nevada. This Stage 3 shortage is the amount of additional shortage above the Stage 1 and Stage 2 shortage volumes, and the additional shortage is distributed according to the Stage 3 ratios.

The Stage 3 shortage sharing percentages are computed as follows, with the PPR volumes the same as in the Stage 2 ratios.

- Nevada bears about 9 percent of the Stage 3 shortage in addition to its Stage 1 and Stage 2 shortage, computed as a ratio of Nevada's apportionment less PPRs less the amount of

[24] Note that these ratios distribute shortage volumes, and the available water is calculated as a remainder.

shortage applied to Nevada under Stage 1 and 2, over the sum of the apportionments of the Lower Division States less PPRs less the total amount shorted to users under Stage 1 and 2

- (300,000 – NV PPRs – Nevada Stage 1 and 2 shortage) / (7.5 maf – total PPRs – total Stage 1 and 2 shortage) = 8.73 percent, or
    - (300 kaf – 8,698 af – 95,461 af) / (7.5 maf – 3,407,835 af – 1,849,591 af) = 8.73 percent

- Arizona bears about 35.6 percent of the Stage 3 shortage in addition to its Stage 1 and 2 shortage, computed as a ratio of Arizona's apportionment less PPRs less the amount of shortage applied to Arizona under Stage 1 and 2, over the sum of the apportionments of the Lower Division States less PPRs less the total amount shorted to users under Stage 1 and 2
    - (2.8 maf – AZ PPRs – Arizona Stage 1 and 2 shortage) / (7.5 maf – total PPRs – total Stage 1 and 2 shortage) = 35.59 percent, or
        - (2.8 maf – 597,811 af – 1,404,130 af) / (7.5 maf – 3,407,835 af – 1,849,591 af) = 35.59 percent

- California bears about 55.7 percent of the Stage 3 shortage, computed as a ratio of California's apportionment less PPRs less the amount of shortage applied to California under Stage 1, over the sum of the apportionments of the Lower Division States less PPRs less the total amount shorted to users under Stage 1 and 2
    - (4.4 maf – CA PPRs – California Stage 1 shortage) / (7.5 maf – total PPRs – total Stage 1 and 2 shortage) = 55.68 percent, or
        - (4.4 maf – 2,801,326 af – 350 kaf) / (7.5 maf – 3,407,835 af – 1,849,591 af) = 55.68 percent

This method represents one possible way to distribute deep shortages among the Lower Division States in a way that does not reduce PPR water deliveries in one state while fulfilling non-PPR water deliveries in another state.

C.5.3 Distribution Within States for the Continuing Current Strategies Shortage Allocation Model

C.5.3.1 Introduction

To estimate the impacts of given levels of shortage, assumptions were made with regard to how shortages might be shared. These assumptions are made to facilitate analysis of the potential impacts and they are not intended to represent current or future policy with respect to shortage allocation. The Continuing Current Strategies Shortage Allocation Model is not designed to replicate some of the annual processes that must be undertaken in determining the quantity of water that can be approved for diversion by specific users.

Modeling assumptions are consistent with the Priority Shortage Allocation Model unless described otherwise in the sections that follow.

C.5.3.2 General State Assumptions

For the purpose of analyzing the impacts of alternatives considered in this EIS, DCP contributions are assumed to represent reductions in deliveries, although parties retain flexibility in how to meet those contribution commitments.

C.5.3.3 Nevada Assumptions

The first 10 kaf shorted to Nevada is considered a DCP contribution. The Continuing Current Strategies Shortage Allocation Model does not treat Shortages and DCP contributions differently for the purpose of this EIS.

C.5.3.4 California Assumptions

The Shortage Allocation Model described in this Appendix E attributes 7 percent of California's DCP contributions to CVWD pursuant to the May 20, 2019, Drought Contingency Plan Implementation Agreement Between MWD and CVWD.

The first 325.5 kaf shorted to MWD is considered a DCP contribution, as is the first 24.5 kaf shorted to CVWD. The Continuing Current Strategies Shortage Allocation Model does not treat Shortages and DCP contributions differently for the purpose of this EIS.

C.5.3.5 Arizona Assumptions

The first 240 kaf shorted to Arizona is considered a DCP contribution. The Continuing Current Strategies Shortage Allocation Model does not treat Shortages and DCP contributions differently for the purpose of this EIS.

C.5.4 Continuing Current Strategies Shortage Allocation Model Results

The tables in this section present the results of the Continuing Current Strategies Shortage Allocation Model over a range of total shortages to the Lower Basin including Mexico.

Table C-21, the Regional Summary, summarizes the shortage attributed to each priority within the Lower Division States and reflects shortage attributed to Mexico.

Table C-22, the Tribal Summary, presents the shortage impacts on tribes.

Table C-23, the Irrigation Summary, presents the shortage impacts on irrigators.

Table C-24, the Domestic Summary, presents the shortage impacts on domestic users.

Table C-21

Disclaimer: These modeling results for the Continued Current Strategies Comparative Baseline should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled and cannot replicate the precision required of that process.

Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.
Note: Orange highlights indicate the level at which available water for a priority is reduced. Lighter orange indicates smaller reductions, while the darkest orange indicates a priority is reduced to zero.
[1]Agricultural and Other CAP Excess contracts do not confer a Colorado River water entitlement and cannot be exercised under any of the scenarios modeled here
[2]These estimated shortages to priorities within the CAP reflect the effect of CAP system loss, and do not total to CAP shortage at the point of diversion.

Disclaimer: These modeling results for the Continued Current Strategies Comparative Baseline should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and cannot replicate the precision required of that process.

Note: Orange highlights indicate the level at which available water for a priority is reduced. Lighter orange indicates smaller reductions, while the darkest orange indicates a priority is reduced to zero.
Note: This analysis attributes shortage to the base allocation or entitlement according to its priority, representing an opportunity cost. The ultimate impacts, both financial and in terms of the lost productive value of water, are diverse according to their varied uses and compensation structures under a large body of exchanges, leases, and other Federal and non-Federal arrangements and commitments. The modeled distribution of shortage to the base allocation reflects how shortage affects the ability for allocations to be exercised, and water users will face decisions in administering agreements during a Shortage Condition; actual water orders received each year will affect shortage impacts.
Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.
[1]Denotes full or substantial use in tribal agricultural operations, which may or may not be impacted according to the terms of related agreements.
[2]Likely to include domestic, irrigation, and tribal elements (including an unquantified entitlement for the Cocopah Reservation's 1985 lands)

Disclaimer: These modeling results for the Continued Current Strategies Comparative Baseline should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and cannot replicate the precision required of that process.

Note: Orange highlights indicate the level at which available water for a priority is reduced. Lighter orange indicates smaller reductions, while the darkest orange indicates a priority is reduced to zero.
Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.
[1]This user also holds a PPR entitlement.

C.6 Lower Basin Priority Shortage Allocation Model

The Lower Basin Priority Shortage Allocation Model represents the shortage distribution specified in the Lower Division States proposal submitted on March 6, 2024. It simulates shortages and distributes available water first among the Lower Division States based on the proposed distribution, and then among the entitlement holders within each state based on priority. The Excel workbook contains formulas to extend the proposed distribution to deeper shortage levels (based on priority) as a modeling exercise relating to potential capacity constraints on Lake Mead releases, and as a basis for comparison with other distributions of shortage. This deeper shortage level modeling does not represent an effect of the Federal action(s) described in this EIS, and this modeling is for informational purposes only.

C.6.1 Present Perfected Rights Assumptions for the Lower Basin Priority Shortage Allocation Model

(See **Section C.3.1** for a discussion on the PPR assumptions in the Priority Shortage Allocation Model.) That discussion is largely applicable to PPR assumptions in the Lower Basin Priority Shortage Allocation Model, but would only be relevant at volumes of shortage that are deeper than proposed by the Lower Division States.

C.6.2 Distribution Among States for the Lower Basin Priority Shortage Allocation Model

The Lower Basin Priority Shortage Allocation Model distributes shortages up to 1.5 maf among states based on state reductions specified in the Lower Division States proposal submitted on March 6, 2024. This includes an Initial Reduction Zone and a Static Reduction Zone, with a Basin-wide Reduction Zone modeled for shortages exceeding 1.5 maf.

C.6.2.1 Shortage Reduction Zone Assumptions

The Initial Reduction zone distributes shortages to the States based on the ratios in the Lower Division States proposal. In the First Initial Reduction Zone of the Lower Basin Priority Shortage Allocation Model, up to 300 kaf of shortages were distributed proportionally between Arizona (80 percent), Nevada (3.33 percent), and Mexico (16.67 percent). In the Second Initial Reduction Zone of the Lower Basin Priority Shortage Allocation Model, total shortages between 300 kaf and 1.5 maf were distributed proportionally between Arizona (43.33 percent), California (36.67 percent), Nevada (3.33 percent), and Mexico (16.67 percent).

The Initial Reduction Zone ramps up to 1.5 maf of shortages, which is distributed in a Static Reduction Zone. In the Static Reduction Zone of 1.5 maf of total shortage, 760 kaf of shortage is distributed to Arizona, 440 kaf of shortage is distributed to California, 50 kaf of shortage is distributed to Nevada, and 250 kaf is distributed to Mexico.

Shortages above 1.5 maf are distributed in the Lower Basin in a Basin-wide[25] Reduction Zone. This zone was split into an Initial Basin-wide Reduction Zone and a Secondary Basin-wide Reduction Zone. In the Initial Basin-wide Reduction Zone, additional shortages beyond the Static Zone are imposed only upon Arizona and Nevada and continue until the deliveries to the post-1968 water entitlement holders in Arizona (including the CAP) are reduced to zero. After deliveries to the fourth priority entitlements within Arizona are expected to be reduced to zero, any additional shortages are applied to Arizona, California, and Nevada in the Secondary Basin-wide Reduction Zone. As with the Priority and Continuing Current Strategies Shortage Allocation Models, the Lower Basin Priority Shortage Allocation Model distributes shortages in excess of 1.5 maf among the Lower Division States in a way that ensures PPRs can be satisfied (or reduced) in the prescribed order as a Basin-wide senior priority group. Instead of setting the entire volume of each state's apportionment as coequal to the others in the Basin-wide reduction zone, only state apportionments in excess of PPRs are treated as coequal (but maintaining the assumption that Arizona bears California's share of shortage until the Arizona fourth priority is exhausted). In developing the Basin-wide Reduction Zone, percentages for the sharing of shortage among the Lower Division States, the consumptive use (or equivalent) of PPR entitlements are removed from the apportionment volumes in each ratio, as detailed below.

The Initial Basin-wide Reduction Zone shortage sharing percentages for the Lower Basin Priority Shortage Allocation Model are computed as follows[26]:

- Nevada bears a reduction of about 8.5 percent of the total Lower Division States shortage volume in the Initial Basin-wide Reduction Zone, computed as a ratio of Nevada's apportionment less PPR consumptive use (or equivalent) entitlements within Nevada less the amount of shortage applied to Nevada under the Static Reduction Zone, over the sum of the apportionments of the Lower Division States less all PPR consumptive use (or equivalent) entitlements less the total amount shorted to the Lower Division States under the Static Reduction Zone
    - (300 kaf – NV PPRs – NV Static Reduction) / (7.5 maf – total PPRs – Lower Division States Static Reduction) = 8.49 percent, or
        - (300 kaf – 8,698 af – 50 kaf) / (7.5 maf – 3,407,835 af – 1.25 maf) = 8.49 percent
- Arizona bears the remainder of the total Lower Division States shortage volume (91.51 percent)

[25] The terminology used for this model is based on the March 6, 2024 proposal, but that proposal did not specify a distribution of the Lower Basin shortage in this zone. Additionally, Reclamation makes no assumption about Upper Basin reductions, and none are included, in the Shortage Allocation Models or Alternative Distribution Models.
[26] Note that these ratios distribute shortage volumes, and the available water is calculated as a remainder.

The Secondary Basin-wide Reduction Zone shortage sharing percentages are computed as follows, with the PPR volumes the same as in the Stage 2 ratios.

- Nevada bears about 8.5 percent of the Secondary Basin-wide Reduction Zone shortage volume in addition to its Static and Initial Basin-wide Reduction Zone shortage, computed as a ratio of Nevada's apportionment less PPR consumptive use (or equivalent) entitlements within Nevada less the amount of shortage applied to Nevada under the Static and Initial Basin-wide Reduction Zone, over the sum of the apportionments of the Lower Division States less all PPR consumptive use (or equivalent) entitlements less the total amount shorted to the Lower Division States under the Static and Initial Basin-wide Reduction Zones
    - (300 kaf – NV PPRs – NV Static Reduction - NV Initial Basin-wide Reduction) / (7.5 maf – total PPRs – Lower Division States Static and Initial Basin-wide Reductions)
        - (300 kaf – 8,698 af – 50 kaf – 59.76 kaf) / (7.5 maf – 3,407,835 af – 1.95 maf) = 8.49 percent
- Arizona bears about 37.3 percent of the Secondary Basin-wide Reduction Zone shortage in addition to its Static and Initial Basin-wide Reduction Zone shortage, computed as a ratio of Arizona's apportionment less PPRs less the amount of shortage applied to Arizona under the Static and Initial Basin-wide Reduction Zone, over the sum of the apportionments of the Lower Division States less PPRs less the total amount shorted to the Lower Division States under the Static and Initial Basin-wide Reduction Zones
    - (2.8 maf – AZ PPRs – AZ Static Reduction - AZ Initial Basin-wide Reduction) / (7.5 maf – total PPRs – Lower Division States Static and Initial Basin-wide Reductions)
        - (2.8 maf - 597,811 af - 760 kaf - 644,130 af) / (7.5 maf - 3,407,835 af - 1,953,891 af) = 37.32 percent
- California bears about 54.2 percent of the Secondary Basin-wide Reduction Zone shortage, computed as a ratio of California's apportionment less PPRs less the amount of shortage applied to California under the Static Reduction Zone, over the sum of the apportionments of the Lower Division States less PPRs less the total amount shorted to the Lower Division States under the Static and Initial Basin-wide Reduction Zones
    - (4.4 maf – CA PPRs – CA Static Reduction) / (7.5 maf – total PPRs – Lower Division States Static and Initial Basin-wide Reductions)
        - (4.4 maf - 2,801,326 af - 440 kaf) / (7.5 maf - 3,407,835 af - 1,953,891 af) = 54.19 percent

For each level of modeled shortage that exceeds the reductions specified in the Lower Division States proposal, the Lower Basin Priority Shortage Allocation Model calculates a percentage

reduction to the Lower Division States and applies the same percentage reduction to Mexico's 1,500,000 acre-feet per year allotment.

Table C-25 below shows a distribution of shortage among the Lower Division States and corresponding volumes of water available to each Lower Division State under the Lower Basin Priority Shortage Allocation Model. Total shortage volumes include an assumed component for Mexico, as described in the sections that follow, and will not sum across rows.

Table C-25
Summary of Shortage Volumes and Available Water by Lower Division State Under the Lower Basin Priority Shortage Allocation Model (af)

Total Lower Basin Shortage Volumes	Arizona Shortage Volume	Arizona Available Water	California Shortage Volume	California Available Water	Nevada Shortage Volume	Nevada Available Water
0	0	2,800,000	0	4,400,000	0	300,000

C.6.3 Distribution Within States for the Lower Basin Priority Shortage Allocation Model

To estimate the impacts of given levels of shortage, assumptions were made with regard to how shortages might be shared. These assumptions are made to facilitate analysis of the potential impacts and they are not intended to represent current or future policy with respect to shortage allocation. The Lower Basin Priority Shortage Allocation Model is not designed to replicate some of the annual processes that must be undertaken in determining the quantity of water that can be approved for diversion by specific users.

Other than the state-level distribution of shortage as described above, modeling assumptions match the Priority Shortage Allocation Model.

C.6.4 Lower Basin Priority Shortage Allocation Model Results

The tables in this section present the results of the Lower Basin Priority Shortage Allocation Model over a range of total shortages to the Lower Basin including Mexico.

Table C-26, the Regional Summary, summarizes the shortage attributed to each priority within the Lower Division States and reflects shortage attributed to Mexico.

Table C-27, the Tribal Summary, presents the shortage impacts on tribes.

Table C-28, the Irrigation Summary, presents the shortage impacts on irrigators.

Table C-29, the Domestic Summary, presents the shortage impacts on domestic users.

Table C-26

Disclaimer: These modeling results for the Lower Basin Priority should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and cannot replicate the precision required of that process.

Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.
Note: Volumes of total shortage include a portion modeled as attributed to Mexico, but that portion is not itemized in summary sheets.
Note: Orange highlights indicate the level at which available water for a priority is reduced. Lighter orange indicates smaller reductions, while the darkest orange indicates a priority is reduced to zero.
[1]Agricultural and Other CAP Excess contracts do not confer a Colorado River water entitlement and cannot be exercised under any of the scenarios modeled here
[2]These estimated shortages to priorities within the CAP reflect the effect of CAP system loss, and do not total to CAP shortage at the point of diversion.

Disclaimer: These modeling results for the Lower Basin Priority should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and cannot replicate the precision required of that process.

Note: Orange highlights indicate the level at which available water for a priority is reduced. Lighter orange indicates smaller reductions, while the darkest orange indicates a priority is reduced to zero.
Note: This analysis attributes shortage to the base allocation or entitlement according to its priority, representing an opportunity cost. The ultimate impacts, both financial and in terms of the lost productive value of water, are diverse according to their varied uses and compensation structures under a large body of exchanges, leases, and other Federal and non-Federal arrangements and commitments. The modeled distribution of shortage to the base allocation reflects how shortage affects the ability for allocations to be exercised, and water users will face decisions in administering agreements during a Shortage Condition; actual water orders received each year will affect shortage impacts.
Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.
[1]Denotes full or substantial use in tribal agricultural operations, which may or may not be impacted according to the terms of related agreements.
[2]Likely to include domestic, irrigation, and tribal elements (including an unquantified entitlement for the Cocopah Reservation's 1985 lands)

Disclaimer: These modeling results for the Lower Basin Priority should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and cannot replicate the precision required of that process.

Note: Orange highlights indicate the level at which available water for a priority is reduced. Lighter orange indicates smaller reductions, while the darkest orange indicates a priority is reduced to zero.
Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.
[1]Combined irrigation and domestic entitlement where domestic use is contractually subordinated to irrigation.
[2]Combined irrigation and domestic entitlement where priority of domestic and irrigation uses may be subject to an annual determination that varies based on the water supply conditions.
[3]This user also holds a PPR entitlement.

Table C-29

Disclaimer: These modeling results for the Lower Basin Priority should only be used to compare the relative magnitude of effects reasonably expected to occur under the alternatives evaluated in this EIS. Modeling assumptions should not be taken as agency position with respect to contract or statutory interpretation, and are not intended to limit Secretarial discretion with respect to current or future policy. This model is not a substitute for the annual process of reviewing water orders and determining which can be filled, and cannot replicate the precision required of that process.

Note: Orange highlights indicate the level at which available water for a priority is reduced. Lighter orange indicates smaller reductions, while the darkest orange indicates a priority is reduced to zero.
Note: This analysis does not reflect an operational estimate of when water may cease to be physically available to certain users.
[1]This user also holds a PPR entitlement.

C.7 Priority Without Tribal Shortage Alternative Distribution Model
